In a number of other instances the *pericardium* contained serum either alone or admixed with lymph or pus. The quantity varied from two ounces to a teacupful or even more. Cases 113, 137, 162, 172, 282, 288, 347, 348, 558, 694 and 776 may be cited as examples; and it may be remarked that those in which the existence of pericarditis is clearly indicated, as by the admixture of pus or lymph, were all associated with pneumonia, pleurisy, or both.

Fibrinous *heart clots*, with or without an admixture of ordinary coagula, were observed in a considerable number of instances, as in cases 118, 144, 147, 150, 153, 155, 158, 159, 162, 172, 179, 202, 212, 330, 337, 347, 348, 352, 353, 360, 364, 376, 377, 385, 386, 399, 412, 525, 603, 642, 749 and 776. The clots are spoken of as in the left cavities only in three cases; in the right cavities in nine; in the cavities of both sides in seventeen. In three cases it is not stated whether the clots were on one side or both. The presence of heart clots is also recorded in both sides of the heart in cases 177, 445 and 605, and in the right side only in case 644, without any indication of the character of the clot being recorded.

The *liver* did not usually present any very conspicuous lesion. It is sometimes spoken of as congested, or full of blood, as in cases 113, 202, 282, 328, 347, 377, 385, 415, 419, 503, 599, 644, 672 and 776; sometimes as enlarged, or large, as in cases 165, 175, 241, 280, 303, 353, 399, 525 and 716; sometimes as more or less fatty, as in cases 170, 179, 287, 692, 749, 760 and 763; or as presenting the nutmeg appearance, as in cases 230, 337, 348 and 360. In cases 131 and 153 it is described by Dr. Leidy as "rat liver." In case 345, the liver is said to have contained tubercles; in case 151, several white, firm, fibro-plastic tumors the size of shell-barks. In case 171 there were two multilocular abscesses of the liver, a large one in the right lobe, a smaller one in the left; there is no record that this patient had diarrhœa, the diagnosis in the hospital register being intermittent fever, but evidences of intestinal catarrh were observed in both ileum and colon by Dr. Leidy.

In the majority of the autopsies no mention is made of the contents of the *gall-bladder*, and in about half the cases in which this point is alluded to the record refers merely to the quantity of bile. Thus the gall-bladder is spoken of sometimes as full, or distended, as in cases 121, 151, 154, 157, 158, 280, 287, 466, 603, 639, 668 and 880; or a smaller quantity is indicated, from "very little" to an ounce and a half, as in cases 360, 366, 386, 446, 460 and 785. The appearance of the bile is indicated in a few cases: Thus, it is spoken of as resembling tar, in cases 171, 635 and 845; dark and tenacious, in case 359; very dark, in cases 364 and 445; dark-green, in cases 347 and 377; yellowish-green, in case 776; yellowish, in case 202; straw-colored, in case 353; ochre-colored, in case 361; brownish and flocculent, in case 376; mucous and viscid, in case 146; light-colored and watery, in cases 337 and 345. In case 348 the gall-bladder was empty. These descriptions are not very definite, but they will serve to show the absence of any constant peculiarity of the biliary secretion in these cases.

The *spleen* was apparently normal in the majority of the cases. In a number of instances, however, it was preternaturally small, and in about an equal number enlarged. Thus, it is spoken of as small in cases 155, 156, 157, 158, 171, 177, 282, 324, 517, 525 and 785, and an abnormally small weight is specified in several other cases, as four ounces and three-quarters in case 377, four ounces in case 348, three ounces and a quarter in case 345, three ounces in cases 359 and 749, two ounces and three-quarters in case 347, and ten

drachms and a half in case 551. On the other hand it is spoken of as enlarged in cases 113, 151, 222, 241, 465 and 466; about twice its natural size in cases 474 and 716. Sometimes the dimensions given show the degree of enlargement, as six inches by four, in case 361; seven inches by five and a quarter by three and a half, in case 385; seven inches and a half by five by three, in case 165. Sometimes the enlargement is indicated by the weight, which, in case 805, was ten ounces; in case 376, ten and a half; in cases 288 and 809, eleven; in case 386, twelve; in case 761, fourteen; in case 353, fifteen, and in case 763, eighteen ounces.

The *mesenteric glands* are spoken of in a number of cases as enlarged. In some of these instances tubercles existed in the lungs, and the mesenteric glands are described as tubercular or cheesy; cases 212, 331, 537, 605 and 644 are examples. In others, in which also the lungs were tubercular, the mesenteric glands are simply said to have been enlarged, as in cases 151, 525, 534, 538 and 642. There were, however, a number of instances in which the mesenteric glands were more or less enlarged although the lungs were free from tubercles, as cases 121, 126, 131, 157, 159, 328, 479, 498, 635, 639, 716, 749, 760, 763 and 845. Doubtless a certain amount of enlargement would have been more frequently observed in these glands had their condition been invariably ascertained and recorded; but in most of the autopsies they are not alluded to.

The *kidneys*, in the majority of the cases, presented no recognizable abnormity. In a few instances they are described as fatty, as in cases 150, 175, 212 and 397. In the latter case the right kidney weighed seven ounces and a half, the left eight and a half. The weight of the kidneys is given in a number of instances, and in cases 202, 288, 352, 359, 360, 581, 760 and 761 one or both kidneys weighed from eight to nine ounces. It is very probable that some at least of these large kidneys were fatty, and the same probability exists with regard to such cases as 157 and 280, in which the kidneys are spoken of as large and pale. In cases 525, 547 and 701 the kidneys are spoken of as granular, but the term appears to have been loosely used. In case 668 the kidneys are spoken of as inflamed.

PATHOLOGICAL HISTOLOGY OF THE INFLAMED INTESTINES.—The interpretation of the minute changes observable in the inflamed intestines presupposes, of course, an acquaintance with the histology of the normal intestine. For the details of this subject the reader must be referred to the treatises on histology;* yet there are certain points to which it appears desirable to allude in this place.

---

*Among which I may indicate A. KÖLLIKER—*Mikroskopische Anatomie*, Bd. II, *Specielle Gewebelehre*, Leipzig, 1850–54; also *Manual of Human Microscopic Anatomy*, London, 1860; J. HENLE—*Handbuch der systematischen Anatomie des Menschen*, Bd. II, *Eingeweidelehre*, Braunschweig, 1866; S. STRICKER—*Handbuch der Lehre von den Geweben des Menschen und der Thiere*, Leipzig, 1868–72; H. FREY—*Handbuch der Histologie und Histochemie des Menschen*, 2te Aufl., Leipsig, 1867; also English transl. of 1st ed., London, 1864. See also the essay of HERBERT WATNEY—*The minute anatomy of the alimentary canal*, Philosophical Transactions, Vol. 166, Part 2, London, 1877, p. 451, with 5 plates containing 43 figures, and an excellent bibliography. Abstracts will be found in the London Med. Record, March 24, 1875, p. 177; Proc. Royal Soc., April, 1874; Centralblatt für die med. Wiss., 1874, No. 48; and Quarterly Journal of Microscopical Science, July, 1877, p. 213 and Plate XV. Copious references to the older literature of the anatomy of the stomach and intestinal canal are given by A. HALLER—*Elementa Physiologiæ Corporis Humani*, T. VI, Lausanne, 1777, Lib. XIX, Sect. I, p. 108; T. VII, 1778, Lib. XXIV, p. I *et seq.* As especially noteworthy in connection with our subject, I may single out, however, the essays of J. C. PEYER—*De glandulis intestinorum*, [1677:] I cite from the Bibl. Anat. of Mangetus, T. I, Geneva, 1685, p. 111 *et seq.*; J. C. BRUNNER—*Novarum glandularum intestinalium descriptio*, Ephemer. Med.-Phys. German., Dec. II, Ann. 5, 1686, Obs. 241, p. 464; also *De Glandulis in Duodeno Intestino Detectis*, Heidelberg, 1687: I have not obtained access to this work; J. N. LIEBERKÜHN—*Diss. de fabrica et actione villorum intestinorum tenuium hominis*, Leyden, 1745, with three copper plates. The glands which bear his name are described in § 10. Among the numerous special treatises, besides those to be mentioned hereafter, I have consulted the following with interest: J. DÖLLINGER—*De vasis sanguiferis quæ villis intestinorum tenuium hominis brutorumque insunt*, Munich, 1828; KARL A. RUDOLPHI—*Einige Beobachtungen über die Darmzotten*, Reil's Archiv f. die Physiologie, Bd. IV, [1800,] S. 63 and 339; L. BOEHM—*Diss. de glandularum intestinalium structura penitiori*, Berlin, 1835, (two plates:) J. HENLE—*Symbolæ ad anatomiam villorum intestinalium*, Berlin, 1837, (one plate:) C. KRAUSE—*Vermischte Beobachtungen und Bemerkungen*, Müller's Archiv, 1837, S. 7, on the intestinal glands. J. BERRES—*Anatomia Microscopica Corporis Humani*, Vienna, 1837, Tab. 20–22, (injected vessels;) JOHN GOODSIR—*On the structure of the intestinal villi in man and certain of the mammalia, &c.*, Edinburgh New Philosophical Journal, Vol. XXXIII, 1842, page 165, (one

Remarks on certain points in the histology of the normal intestines.—One of these is the structure of the peculiar tissue which forms the proper substance of the mucous membrane, uniting together the glands of Lieberkühn * (tubular glands) in both large and small intestine, and constituting also in the latter the parenchyma of the villi. This tissue, for which His† has proposed the name adenoid tissue, on account of its resemblance to the substance of the lymphatic glands, consists of a network or reticulum of stellate cells, the meshes of which are filled with round, delicately granular cells resembling those of the lymphatic glands or the white corpuscles of the blood. In thin sections the latter elements are usually so numerous as to obscure the reticulum, unless they are first pencilled away with a brush, when the meshes of the reticulum come into view. The bloodvessels and lymphatic sinuses of the villi, and the rich network of blood and lymph capillaries between the glands of Lieberkühn, lie in the substance of this adenoid tissue.

The mucous membrane is separated from the submucous connective tissue by a delicate muscular layer less than the thousandth‡ of an inch thick, which extends from the stomach throughout both small and large intestine. This layer, which is known as the muscle of the mucous membrane, or the muscle of Brücke,§ is composed of unstriped muscular fibre-cells, and, like the proper muscular coat of the intestine, consists of two laminæ—an internal, the fibre-cells of which are disposed circularly, and an external, composed of longitudinal fibres. These two laminæ are of nearly equal thickness. The inner, or circular one, gives off great numbers of delicate processes, which run between the glands of Lieberkühn, in both small and large intestine, towards the surface of the mucous membrane. In the small intestine similar but rather stronger muscular processes are given off, which enter the parenchyma of the villi and form in each a muscular sheath around the central lymph-sinus; and there is also a more superficial layer of muscular fibre-cells in the peripheral portion of the parenchyma of the larger villi of the duodenum and upper portion of the jejunum.‖

The submucous connective tissue occupies the space between the longitudinal layer of the muscle of Brücke and the circular layer of the proper muscular coat of the intestine. It consists of a delicate fibrillated matrix with branching, often stellate cells, the processes of which appear to anastomose, and contains also a considerable number of delicate elastic fibres. The branching cells form an irregular reticulum, the meshes of which are smaller in the immediate neighborhood of the muscle of Brücke than in any other part of the

HANDFIELD JONES—*Some observations on the intestinal mucous membrane*, London Medical Gazette, Vol. VII, [1848,] p. 835; A. NUHN—*Untersuch. und Beob. aus dem Gebiete der Anatomie, Physiologie und practischen Medicin*, Heft 1, Heidelberg, 1849, S. 8, Ueber die Anfänge der Saugadern in den Darmzotten, (Tab. VI, Fig. 1–15;) R. O. ZIEGLER—*Ueber die solitären und Peyer'schen Follikel*, Würzburg, 1850; C. J. M. LANGENBECK—*Mikroskopisch-Anatomische Abbildungen*, Göttingen, 1850, Lief. III and IV; F. ERNST—*Diss. über die Anordnung der Blutgefässe in den Darmhäuten*, Zurich, 1851; see also the account of the anatomy of the stomach and intestines, in the work of R. B. TODD and WM. BOWMAN—*The Physiological Anatomy and Physiology of Man*, London, 1856, Vol. II, pp. 190 and 216.

* GALEATI—*De cribriformi intestinorum tunica*, Comment Bonon., Vol. I, 1731. I have not seen this paper, and quote from MANDL, *op. cit.*—was probably the original discoverer of these tubular glands. According to LACAUCHIE, [*op. cit.*, p. 38,] he succeeded in observing them by imbibing the intestine with ink, and represented in a figure, which this author has reproduced, [Plate II, Fig. 4,] the peculiar manner in which they are arranged around the solitary glands of the large intestine.

† W. HIS—*Untersuchungen über den Bau der Peyer'schen Drüsen und der Darmschleimhaut*, Leipzig, 1862.

‡ According to HENLE, *op. cit.*, p. 163, the average thickness is .02 millimetres.

§ Consult BRÜCKE—*Ueber ein in der Schleimhaut aufgefundenes Muskelsystem*, Sitzungsberichte der K. Acad. der Wiss. in Wien, Bd. VI, (1851) S. 214; also A. KÖLLIKER—*Ueber das Vorkommen von glatten Muskelfasern in Schleimhaüten*, Zeitschrift für Wiss. Zoologie, Heft I, 1851, and *Histologische Studien angestellt an der Leiche einer Selbstmörderin*, Würzburger Verhandlungen, Bd. IV, 1854, S. 55. From the statement of E. VERSON in Stricker's Handbuch, (Bd. I, S. 407,) it appears that MIDDELDORPF—*De Glandulis Brunneriannis*, Diss. Vratisl., 1846—observed this muscle before Brücke. I have not obtained access to Middeldorpf's dissertation.

‖ LOUIS FASCE—*Obs. microscopiques sur la couche musculeuse sous-muqueuse de l'intestin des mammifères*, Jour. de l'Anat. et de la Physiologie, T. I, 1864, p. 623—has described these fibres, proceeding from the muscle of Brücke towards the surface of the mucous membrane, as a third layer.

submucosa. In this region, moreover, a considerable number of lymphoid elements, resembling those of the adenoid tissue of the mucous membrane, lie in the meshes of the reticulum. A small number of similar elements are found scattered in all parts of the submucous connective tissue; many of them are of irregular form, and are probably wandering white corpuscles. By the action of silver solutions it is shown that the fibrillated matrix of the submucous connective tissue is channelled by an intricate series of anastomosing lacunæ, the serous canals (saft canälchen) or lymph-spaces, which inosculate with the lymphatics.* The stellate cells of the connective tissue appear to lie on the margins of these canals, and the investigations of Ranvier and Boll into the structure of tendon† would seem to render it probable that the well-known figures which they present in sections result from their deformation by the methods of preparation usually employed, and that in fact these elements are irregular flattened plates which form a partial covering to the separate bundles of connective tissue fibrillæ, or an imperfect endothelium to the serous canals. The bloodvessels of the submucous connective tissue form a rich plexus just beneath the muscle of Brücke, from which the vessels of the mucosa are derived.

Another point to which it seems desirable to refer in this place is the structure of the closed follicles of the intestine and their relation to the lymphatics. Both in the case of the solitary follicles (solitary glands) and of the individual follicles which make up the patches of Peyer,‡ the glandular parenchyma is essentially similar in structure to the adenoid tissue of the mucous membrane, being composed of a reticulum of delicate stellate cells the meshes of which are filled with lymphoid elements. These follicles lie chiefly in the submucous connective tissue beneath the muscle of Brücke, but their apices penetrate through openings in this muscle into the mucous membrane proper, and extend between the glands of Lieberkühn almost or quite to the epithelial layer. That portion of their parenchyma which thus lies in the mucous membrane is not bounded by any distinct sheath, but is directly continuous with the adenoid tissue of the mucous membrane, while the portion which lies in the submucous connective tissue is invested by a sheath of some-

‡ PEYER [*op. cit. supra*] not only described the patches which bear his name, and which he spoke of as "corpusculorum glandulosorum agmina sive plexus," or simply "plexus glandulosi," and the isolated glands of the same character in the small intestine, but also the similar glands in the large intestine, which he himself called "glandulæ solitariæ" TODD and BOWMAN [*op. cit.*, Vol. II, p. 233] have claimed, with apparent justice, that prior to the publication of Peyer's work in 1677, these glands had been "discovered in several animals" by Dr. NEHEMIAH GREW, "who also delineated them with great accuracy, and described them in his lectures to the Royal Society, in the year 1676." There is in the library of the Surgeon General's office a copy of GREW'S *Catalogue of the Rarities belonging to the Royal Society and preserved at Gresham Colledge*, London, 1694, to which is subjoined "*The Comparative Anatomy of Stomachs and Guts begun. Being several Lectures read before the Royal Society. In the year*, 1676. London, Printed by W. Rawlins, for the Author, 1681." On the reverse of the title-page of this subjoined work is the following "*Advertisement to the Reader*, Whereas a Book Entitul'd, Exercitatio Anatomico-Medica de Glandulis Intestinorum, earumq; Usu et Affectibus. Cui subjungitur Anatome Ventriculi Gallinacei. Studio Joh. Conradi Peyeri Scafhusa-Helvetii, 1677. In which are found some of those Observations contained in the following Lectures. It was therefore thought fit, here to take Notice, That the said Book was not Published, till the Year after these Lectures were Read." The matter of these lectures has been rearranged into ten chapters, and evidently considerably modified to fit it for publication. As it was first printed five years after the appearance of Peyer's book, and as the advertisement shows that its author was acquainted with that work, it is impossible now to say how much modification was due to that circumstance. Nor can I ascertain the precise date of the execution of the plates, which might throw some light on the question. It appears from the dedicatory letter to the Catalogue that the plates were prepared for that work, which was not published till 1694. Be this as it may, I note that the second gut of the polecat is said to be "Glandulous and very thick." "The Glands extream small, no bigger than little *Pins heads*. Yet every Gland hath its *Orifice*, out of which a *Mucus* or *Pituita* may be visibly squeez'd." The third gut has two clusters of glands in it. "Each Gland in both these *Clusters*, is about the bigness of a *Mustard-Seed*. Each of these *Clusters*, may be called a little *PANCREAS INTESTINALE*. Their difference is, That This hath not one common *Ductus*," (p. 3.) Now absolutely nothing of all this appears in the plate representing "The Stom: and Guts of a Pole-Cat. Tab: 23." On the other hand, on the same plate the figure representing "The Stom: and Guts of a Fox" shows some fourteen groups of glands in the small intestine, and a number of solitary glands in the large intestine, together with a considerable number of similar glands in the pyloric half of the stomach, of all which only the "Clusters" in the small intestine are described in the text. These "Clusters" appear also in the plates in the figures of intestines of the mole, rat and rabbit, and in the text are also mentioned in the cat, bitch, etc., the description in the case of the last being rather the most satisfactory. When I compare these fragmentary observations with the beautiful and complete description given by PEYER of the glands of the human intestine, I do not feel that his credit ought to be diminished in the least by this subsequent publication. At the same time, I do not feel inclined to doubt, from the circumstances under which GREW'S publication was made, that he had actually noticed these glands in some of the lower animals before the appearance of PEYER'S work, or even that he may have called attention to them in his lectures before the Royal Society.

what condensed connective tissue, from which, however, it is to a great extent separated by large lymph-sinuses of irregular form, which appear in sections as one or more fissures between the parenchyma of each gland and its connective tissue-sheath. By the action of silver solutions these lymph-sinuses are shown to be lined with a single layer of flat endothelial cells. They communicate freely with the plexus of lymphatic capillaries in the mucous membrane and in the submucosa. This description substantially applies to the solitary follicles of both small and large intestine, as well as to the several follicles which make up the patches of Peyer; in the latter case the lymph-sinuses belonging to the individual follicles inosculate freely. The parenchyma of the closed follicles of the intestine is so similar in its structure to that of the lymphatic glands, and their relations to the intestinal lymphatics are so intimate, that of late they have very generally been regarded as minute lymphatic glands.

The lymphatics of the intestinal canal have been made the subject of much careful investigation, especially by Teichmann,* His,† Frey,‡ and Auerbach.§ In the mucous membrane of both small and large intestine there is a beautiful superficial network of lymphatic capillaries, the meshes of which surround the orifices of the glands of Lieberkühn. In the small intestine this network inosculates with the central lymphatic vessels of the villi; and in both small and large, it communicates freely with a second plexus in the submucosa; a third plexus exists between the circular and longitudinal layers of the muscular coat, and a fourth in the subperitoneal connective tissue. These several networks communicate freely with each other, and from them the lymphatic trunks of the mesentery and mesocolon take their rise.

The nerves of the intestine form two distinct networks, of which one, the plexus of Meissner,‖ lies in the submucosa, and gives off branches to the bloodvessels, muscle of Brücke, and mucous membrane; the other, the plexus of Auerbach,¶ lies between the circular and longitudinal layers of the muscular coat, and is distributed chiefly to their fibre-cells. Both these networks are composed of non-medullated nerve-fibres, and are provided with numerous ganglia composed of from two or three to thirty, forty or more nerve-cells. The precise facts with regard to the ultimate relations of the terminal nerves in the mucous membrane are not yet known, nor have fruitful investigations been made as yet into the pathological alterations of these nerves.

Lastly, a few words may be said with regard to the epithelium, which covers all parts of the mucous membrane, including the villi, and lines the glands of Lieberkühn. This consists of the well-known single layer of columnar cells, among which, at irregular intervals, are scattered the so-called goblet-cells, (Becherzellen.)** These are somewhat conical or goblet-formed elements, attached by their apices to the mucous membrane, while their open mouths present towards the lumen of the intestine. They appear to be about half filled from the point upwards by a granular protoplasm, with or without a nucleus, while the wider portion of each cell seems to be empty. They have been by some sup-

¶ L. AUERBACH—*Ueber einen Plexus myentericus*, Breslau, 1862. I have not seen this paper, and cite from STRICKER'S *Handb.*, (see p. 317, note.)

** In the essay of THEODOR EIMER—*Zur Geschichte der Becherzellen insbesondere derjenigen der Schleimhaut des Darmcanals*, Berlin, 1868—will be found an interesting account of these cells, with numerous references to the more important investigations made up to that date.

posed to be special organs for the absorption of fat and albuminoid bodies, others imagine them to secrete the intestinal mucus, and various other functions have been suggested, none of which can be regarded as demonstrated. On the other hand, it has been held that the goblet-cells are merely ordinary columnar cells transformed by the reagents employed, or by other post mortem influences, and this view is supported by the observations of Stricker and Kocslakoff,* who encountered, in experimentally produced acute inflammation of the mucous membrane of the stomach and intestines of the rabbit, tracts of considerable extent in which the columnar epithelium was entirely replaced by goblet-cells.

Debove† has recently described a layer of flat cells resembling endothelial cells in form, seen when the epithelium is pencilled off from the mucous membrane and the surface treated with a solution of silver, and supposed by him to constitute a limiting membrane between the epithelium and the proper tissue of the mucous membrane. It may, however, perhaps be questioned whether the forms displayed under these circumstances are not in fact simply the endothelial cells of the superficial blood and lymph capillaries which are brought into view by the same method.

Among the cells of the epithelium of recently killed mammals, (rabbit, guinea-pig, dog, cat,) Arnstein‡ has observed wandering white blood-corpuscles, which appear to find their way by this route from the bloodvessels of the mucous membrane into the lumen of the intestines, where they constitute the mucous corpuscles of the intestinal juices. Similar observations have been made by Eimer and Watney.§

The foregoing sketch has been confined chiefly to points with regard to which our knowledge has assumed its present shape during the last ten or fifteen years, to the exclusion of what may be found in the older text-books with which all medical readers may be assumed to be acquainted. It has been introduced chiefly for the benefit of those who have not been able to follow the progress of recent histological research, but with the hope that even those familiar with this branch of knowledge will find it of some service as indicating the anatomical stand-point whence the subsequent descriptions of the pathological histology of the intestines in diarrhœa, dysentery and fever are to be viewed.

Histological methods employed.—In studying the histology of the diseased intestine, the examination of portions taken as fresh as possible and immersed in serum or some nearly indifferent fluid, (as for example a .75 per cent. solution of chloride of sodium,) should not be neglected. Groups of a few villi, snipped off with curved scissors, portions of the mucous membrane or of the submucous connective tissue removed in the same manner, and fragments obtained by teasing with needles, may thus be examined with advantage, and permit the observation of details visible in no other way. The secretions adhering to the mucous membrane may also be advantageously examined either without reagents or diluted with some indifferent fluid. But for a complete study of the histology of the diseased intestines thin sections are indispensable. These may be obtained by fastening the pieces selected for study to a flat piece of cork with pins and permitting them to dry; thin

‡ C. ARNSTEIN—*Ueber Becherzellen und ihre Beziehung zur Fettresorption und Secretion*, Virchow's Archiv, Bd. XXXIX, (1867,) S. 537.

§ T. EIMER—*Zur Becherfrage*, Virchow's Archiv, Bd. XL, 1867, S. 283—injected aniline-blue into the lymph sac of the frog, and found cells loaded with the color both in the mucosa and in the goblet-cells of the epithelium. WATNEY—*op. cit.*, p. 317, *supra*—made observations similar to those of ARNSTEIN, but insists that the lymph-corpuscles are always between the epithelial cells, and do not enter their substance as ARNSTEIN thought they do. He cites observations which he regards as corroborative by EBERTH, RINDFLEISCH, FRIES, LIPSKY and VERSON. He also asserts that the reticulum of the mucosa extends between the epithelial cells, and regards it as the chief route of fat-absorption.

perpendicular sections can then be cut with a sharp knife, and after soaking out in water, or glycerine and water, may be stained with carmine or aniline and immersed in glycerine, or in acidulated water, for microscopical examination. This somewhat rude method is of course open to several objections. The pieces are apt to shrink irregularly in drying, and never fully regain their normal characteristics even when carefully soaked out: moreover, the dried tissue is apt to split or chip off before the knife, so that it is not easy to obtain large sections; nevertheless, many of the particulars of the morbid changes may be made out by the study of sections of diseased intestine prepared in this simple way. Far better results can be obtained by freezing the portion to be examined and cutting thin sections of the frozen tissue.* These may be examined without previous treatment, in serum or some indifferent fluid, or they may be stained with carmine or aniline, silver, gold, or osmic acid, and mounted in glycerine. It is to be regretted that this excellent method was not known at the Museum till some years after the war; it certainly gives satisfactory results with normal tissues, and appears full of promise for future pathological investigations.

During 1864–'65 and '66 especially, the following method was employed at the Museum in preparing thin sections of diseased intestines:† The pieces selected were first boiled in a porcelain capsule with dilute nitric acid, (two or three drops of commercial acid to the ounce of distilled water,) the boiling being continued from two to five minutes, according to the thickness of the pieces. These were then pinned out loosely on a flat cork and allowed to dry; afterwards they were macerated in ether for some time. The latter step, originally intended to remove the greasiness of the tissue, which otherwise appeared under the microscope in the form of numerous oil drops, was found, if somewhat prolonged, to confer a peculiar non-elastic consistency upon the preparations which facilitated the cutting of thin sections of considerable size. The maceration in ether was therefore usually continued some time longer than would have been necessary to remove the grease, for which a day or two was sufficient. The thin sections were then cut by a razor, with the help of one of the section cutters usually employed in cutting microscopical sections of wood, and the nuclei having been tinted with red, blue or yellow aniline, the cuts were immersed in glycerine for study.

It was thus found possible to prepare perpendicular sections through the whole thickness of the intestine from one-half to three-quarters of an inch in length, and sufficiently thin to be studied with a $\frac{1}{5}$ or $\frac{1}{10}$-inch objective, or even higher powers. The boiled preparations did not shrink in drying like fresh pieces, and boiling in acidulated water, by rendering the connective tissue matrix transparent, brought the cellular elements more distinctly into view. These sections appeared to be so satisfactory that various methods were tried to secure their permanent preservation in the Museum. Immersion in Canada balsam did not answer well, the proper steps not having been hit upon at that time; the resulting preparations showed the general form of certain lesions such as ulcers, enlargement of the closed glands, &c.; but the elements of the tissues were not satisfactorily displayed. On the other hand, a considerable number of preparations were mounted in dilute acetic acid and other aqueous solutions, in pure glycerine, in glycerine acidulated with acetic acid, in Deane's preservative mixture of glycerine and gelatine, and in Farrants' gum and

* This result may be attained by a great variety of devices, for one of the most satisfactory of which consult WILLIAM RUTHERFORD—*A new Freezing Microtome*, The Monthly Microscopical Journal, Vol. X, (1873,) p. 185.

† For the original account of this method see J. J. WOODWARD—*On the use of Aniline in Histological researches; with a method of investigating the histology of the human intestine, &c.*, The American Journal of the Medical Sciences, Jan., 1865, p. 106. Boiling in glycerine, with or without the addition of two or three drops of nitric acid to the ounce, was subsequently used. The results were not materially improved by this change.

glycerine medium.* All these methods answered well for a while, the preparations mounted in acid glycerine being perhaps the most beautiful; but after a few months they began to deteriorate, and ultimately the majority of them perished. Those preserved in aqueous media were earliest lost; some by molecular changes in the sections, others by the evaporation of the preservative liquid through cracks in the varnish. Those preserved in acid glycerine kept longer, but ultimately became so granular, from slow molecular changes, that their structure was no longer recognizable, although the best English glycerine (Price's) had been employed. Moreover, most of those stained with aniline, which had been preferred to carmine on account of its more rapid and uniform action, speedily began to fade, so that after a few years only those stained with yellow aniline and mounted in Deane's and Farrants' media, especially the latter, remained in a serviceable condition. These had a longer life; less beautiful originally than those mounted in glycerine, they have altered very slowly, and a number of them were still in a serviceable condition, permitting the recognition of many details at the date of printing this paragraph.†

The most satisfactory perpendicular sections of both normal and diseased intestine as yet obtained at the Museum, however, were made by gradually robbing the tissue of its water and hardening it by immersion, first in strong, afterwards in absolute alcohol; imbedding the hardened piece in parafine to hold it in position while thin sections are cut with a razor; subsequently staining the sections with carmine, and transferring them through absolute alcohol and benzole to a solution of dried Canada balsam in benzole, in which they are permanently preserved.‡ This method, which has been quite extensively used at the Museum in the preparation of sections of various diseased tissues, gives such excellent results that it is a matter of regret it was not adopted at an earlier period, and especially that it was not employed during the war in the examination of fresh specimens of diseased intestines. After this method had been perfected, it was therefore a source of great satisfaction to find that it was applicable to the alcoholic preparations which had been collected at the Museum during the war, and that the results obtained from the use of this rich material were often fully equal to the best that could have been attained with perfectly fresh specimens. During the year 1877 a considerable number of such sections were prepared, and the results attained have been freely used in supplementing former work.

It was often found, especially when the specimen had originally been quite fresh when first introduced into alcohol, that it was already very firm, and that it was sufficient to transfer it for a while to absolute alcohol to fit it for the preparation of excellent sections, which were then stained and mounted precisely as when fresh material is treated with alcohol and sections prepared as soon as it is hard. In other words, little or no change had occurred in the ten or fifteen years during which the specimen had been immersed in alcohol. This favorable result was most frequently obtained in specimens of the colon; sometimes also of the small intestine. Very often, however, in the case of the latter, and sometimes

* The formula employed was that given by BEALE—*How to work with the Microscope*, 3d edition, London, 1865, p. 62—four ounces each of gum Arabic and distilled water, glycerine two ounces, all by weight, which differs from Mr. Farrants' original formula—Quarterly Journal of Microscopical Science, Vol. VI, (1858,) p. 118—especially in the absence of arsenious acid.

† *July*, 1877, eleven to fourteen years after they were put up.

‡ For a detailed account of this method, which is very generally available for the permanent preservation of thin sections of morbid tissue, see J. J. WOODWARD—*Microscopical Memoranda for the use of practitioners of Medicine*, The Lens, Vol. I, (1872,) pp. 34, 93, 158 and 223. Since these papers were published, various slight modifications of the processes detailed have been employed at the Museum. Of these I may specially mention the substitution of a solution of dried Canada balsam in absolute alcohol for the solution in benzole, mentioned in the text. The dried balsam is not wholly soluble in absolute alcohol cold, but if it be cut into small pieces with a hot knife, thrown into absolute alcohol in a beaker and heated over a water-bath, the whole of the balsam will dissolve, and when it cools no precipitation occurs. This solution has been used at the Museum a good deal, in the same way as the solution in benzole; but after several years' trial I am not satisfied that it offers any material advantages.

of the former, on opening the preparation jars the intestine was found to be quite soft and flaccid; and then immersion in absolute alcohol often failed to make it hard enough for section cutting. This was especially apt to be the case in specimens from autopsies made so long after death that putrefactive changes were fairly under way; and the reason the small intestine was more frequently affected than the large is, because it undergoes post mortem changes more rapidly. Such soft preparations were soaked for twenty-four hours in a concentrated solution of gum Arabic, and then thrown into alcohol till the gum was hardened. Sections were then cut in the usual way, and the gum afterwards soaked out with a little water before staining. Such sections stained with difficulty, as is always the case with pieces of intestine which come into the hands of the histologist so long after death that putrefactive changes have commenced. I must think, also, that the length of time that these preparations had been in alcohol had something to do with their slowness of staining; for preparations which had been quite fresh when originally put up also stained more sluggishly than recent preparations of the kind generally do. In many instances the lilac staining fluid, habitually employed at the Museum, proved quite inefficient, while excellent results were obtained by the original carmine fluid of Thiersch;* but in some few cases all attempts at carmine staining failed. I believe these were specimens in which putrefactive changes had well advanced before they were immersed in alcohol. Such specimens, as is well known, also refuse to stain even when quite recent.

Besides the foregoing methods, fresh specimens may be hardened by the action of various other reagents as a preliminary to the preparation of thin sections; as, for example, by dilute solutions of chromic acid, solution of bichromate of potassa, Müller's fluid, &c., followed by subsequent treatment with alcohol. These methods, however, did not yield as good results at the Museum as those given above. Recently Kelsch has made use of picric acid in hardening dysenteric intestines previous to the preparation of thin sections, and, if his drawings are to be regarded as simple copies from nature rather than as diagrams representing his interpretation of the appearances observed, with such admirable results as to make his method well worthy of thorough trial.†

---

* The lilac staining fluid employed at the Museum was suggested by an observation made while using the "Lilafarbige Carmintinctur" recommended by THIERSCH—*Der Epithelialkrebs*, Leipzig, 1865, S. 92—for staining cartilage and bones decalcified by chromic acid. He prepared that fluid as follows: 4 parts, by weight, of borax and 1 of carmine, are dissolved in 56 parts of distilled water. One volume of this solution is mixed with two volumes of absolute alcohol and then filtered. The resulting tincture is said by THIERSCH to stain somewhat more slowly than his carmine solution, which certainly does not exaggerate the facts. Now, when these directions are strictly followed, it will be found that by far the greater part of the carmine, crystalizing in some as yet unstudied combination with the borax, remains on the filter. It is precisely with these crystals, thrown away when the directions of THIERSCH are followed, that the most generally available carmine staining fluid yet employed at the Museum is prepared. The crystals are simply dissolved in distilled water to any desired degree of concentration, and the solution used in the same way as any other staining fluid. Sections stained in this way are at first tinted of a dark lilac color; but on subsequent treatment with a solution of oxalic acid in alcohol, as recommended by THIERSCH, or a mixture of hydrochloric acid and alcohol (one part of commercial hydrochloric acid to from three to six parts of alcohol of 70 to 80 per cent.) as preferred at the Museum, the nuclei assume a brilliant carmine red, while all superfluous color is removed from the intervening matrix. It might be thought that a mere solution of carmine in saturated borax solution would answer the same purpose, and so in truth it does when first mixed. On standing, however, like a simple ammoniacal solution of carmine, this mixture soon decomposes. Precipitation by absolute alcohol effects some changes in the composition of the carmine, which secures its preservation unaltered for a considerable time. The original solution of THIERSCH (*loc. cit.*) recommended in the text for staining sections of tissues preserved for years in alcohol, is prepared as follows: (A.) Take one part, by weight, of carmine, one of caustic ammonia, and 3 of distilled water; rub them up thoroughly together and filter the solution. (B.) Take one part, by weight, of oxalic acid and 22 of distilled water. Mix one volume of solution A with 8 of solution B; add 12 volumes of absolute alcohol and filter. The filtrate can at pleasure be made to incline to an orange-red by the addition of a little more of the oxalic acid solution; or by the addition of a little more ammonia, made of a violet color. Either will answer to stain with; but it was found at the Museum that *the orange-red fluid, when freshly prepared*, stained old preparations, such as are mentioned in the text, most actively. If, on the addition of the solution of oxalic acid crystals (of oxalate of ammonia) form, they may be separated by filtration, or dissolved by the addition of a little water.

† KELSCH—*Contributions a l'Anatomie path. de la Dysenterie Chronique*, Archives de Physiologie, July and Sept., 1873, pp. 406 and 573, and *Contribution à l'anatomie path. de la dysenterie aigue*, same Journal, Nov., 1873, p. 687. The method referred to is as follows: Remove from the diseased parts some quite small fragments, which are to be placed, without washing them, in strong alcohol for twenty-four hours, and then for one or two days in a saturated solution of picric acid; afterward they are to be stretched by means of pins on a slice of cork and soaked in a solution of gum for twenty-four hours; then, finally, in ordinary alcohol, in which the pieces will acquire sufficient firmness to permit very thin sections to be made with the microtome; these are to be colored with picro-carminate—p. 581. See also a memoir on the same subject by KELSCH—Mém. de la Soc. de Biologie, Tom. V, 1873, p. 3, (with a colored plate.)

Histological changes in the inflamed intestines.—The following is a summary of the chief textural changes to be observed in the inflamed intestinal mucous membrane when death takes place before the inflammatory process has proceeded to the stage of ulceration.* It will usually be found that the capillaries and small veins of the inflamed intestine are preternaturally full of blood, and this will be particularly noted in the circlet of capillaries by which the closed follicles are surrounded. This character is of course especially to be sought in those portions of the intestine which appear more or less red to the naked eye. It is best observed in clippings or frozen sections of the perfectly fresh intestine, but can also be recognized with more or less distinctness in sections prepared from portions of intestine hardened by any of the methods indicated above. As already mentioned,† the redness of the inflamed intestine may also be due to actual hæmorrhage into the tissue of the mucous membrane and submucous connective tissue, or to the transudation of the coloring matter of the blood. The former of these conditions usually occurs in the form of little hæmorrhagic extravasations, which are often exceedingly numerous, but also occasionally in larger patches. The latter is no doubt very frequently, at least, a post mortem appearance the result of commencing decomposition, though its occasional occurrence in well-defined purpura-like spots or blotches would seem to indicate that the transudation sometimes takes place during life.

At a very early period of the inflammatory process an increased number of lymphoid elements will be found scattered through the submucous connective tissue. This will be noticed especially in the immediate vicinity of the muscle of Brücke, where these elements are most numerous in the normal condition, but it will also be observed in all portions of the submucous tissue. It will frequently be observed in sections that the lymphoid elements occur in swarms around the peripheries of the small veins. They also appear in rows, and in more or less irregular stellate groups corresponding in outline to the serous canals of the connective tissue. These latter appearances were the foundation of the opinion formerly prevalent, that the new elements were produced by cell-multiplication from the connective tissue corpuscles; an opinion which the discovery of Cohnheim‡ compels us to modify, so far as to regard the new elements as consisting in part at least of white blood-corpuscles which have migrated from the bloodvessels. Whether any cell-multiplication actually occurs is difficult to be seen in the intestine.

The discovery of such an increase in the number of lymphoid elements in sections of the submucous connective tissue may be regarded as conclusive evidence that actual inflammation has existed during life, while the abnormal fulness of the bloodvessels alone, may result from mechanical obstructions to the portal circulation, or may represent merely a condition of hyperæmia hardly amounting to inflammation. Besides the lymphoid swarm

* An excellent description of the histological processes about to be considered is given by E. RINDFLEISCH—*Lehrbuch der Pathologischen Gewebelehre*, 3te Aufl., Leipzig, 1873, S. 296 *et seq.*; or the New Sydenham Society's translation of the second edition of the same work, Vol. I, London, 1872, p. 403 *et seq.* Histological details will also be found in most of the works cited in the first note on page 266 and the second note on page 292. I must confess to surprise at the summary manner in which the whole subject of the histology of intestinal catarrh is dismissed by LEUBE—*Krankheiten des Darms*, in Ziemssen's Handbuch der Spec. Path. u. Ther., Bd. VII, Abth. 2, S. 246 *et seq.*—also American transl., Vol. VII, New York, 1876, p. 358—according to whom desquamation of the epithelium, enlargement of the cells, a granular metamorphosis of their protoplasm, and indistinctness of their nuclei are the most important microscopico-anatomical alterations. He admits that the separation of the epithelium occurs also as a mere post mortem change, concerning which see subsequent remarks. The indistinctness of the nuclei is probably also merely a post mortem appearance, and the same may be true of some kinds of granular metamorphosis. There remains, therefore, but little in his description which can be regarded as characteristic of the morbid process. One paragraph, however, I must quote with approval, having myself expressed the same opinion on page 294; (see also note †, on the same page.) viz: "It should be borne in mind that an intestinal catarrh, with all its symptoms, may be present during life without any injection of the mucous membrane after death, just as happens in the case of other mucous membranes where inflammation can be directly seen during life, and which nevertheless appears pale at the autopsy."

† *Supra*, p. 297.

‡ J. COHNHEIM—*Ueber Entzündung und Eiterung.* Virchow's Archiv, Bd. XL, 1867, S. 1.

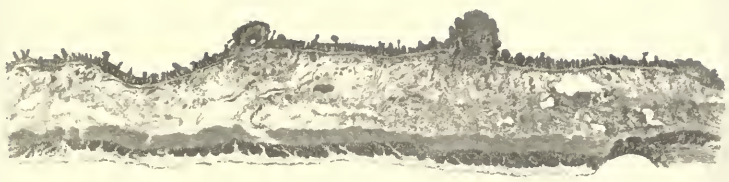
in the submucous connective tissue, this layer is generally infiltrated with an excess of plasma, by which the cohesion of the fibrillated matrix is loosened and the lymph-spaces increased in size. To this cause, together with the vascular congestion and the presence of the lymphoid swarm, is due the thickening of the submucous layer which is generally present. Sometimes also the large oval nucleated cells observed by Basch and Thierfelder* in sections of the colon from cases of diphtheritic dysentery are found lying loose in the lymph-spaces, or adherent to their parietes. They are probably swollen and loosened endothelial elements, and are especially noticeable in diphtheritic cases, or in chronic cases accompanied by follicular ulceration, in connection with which I shall again recur to them, and will then give a description of their appearance.

Simultaneously with the increase in the number of lymphoid elements in the submucous connective tissue, a similar increase takes place in the number of these elements in the adenoid tissue of the mucous membrane and of the closed follicles. Here the increased number is not to be recognized by simple inspection, as in the case of the submucous connective tissue, but must be inferred, because, while the closed follicles increase in dimensions, and while the adenoid tissue of the mucous membrane becomes more bulky, pushing the glands of Lieberkühn preternaturally apart,† the individual elements do not appear to be increased in size. The origin of these new elements also is a matter of inference rather than of observation; but, in the absence of direct evidence of the multiplication of the normal cells by division, the probability that the new elements chiefly accumulate by migration from the bloodvessels at once suggests itself as the most plausible view here as elsewhere. Of course, also, the possibility that the two processes may coexist should not be overlooked. In sections the margins of the swollen follicles are more or less obscured by a swarm of lymphoid elements in the adjoining submucosa. No reasonable explanation has been suggested for the fact already mentioned,‡ that the solitary follicles are more conspicuously enlarged than the agminated, the reverse of what usually occurs in typhoid fever.

The behavior of the columnar epithelium on the surface of the intestine while the foregoing changes are taking place remains involved in considerable obscurity. The intestinal epithelium separates from the mucous membrane, in consequence of cadaveric changes, at a very early period after death, even in the perfectly normal intestine. Perhaps this separation takes place at a still earlier period in inflamed intestines, as, indeed, all cadaveric changes appear to do. But the readiness with which even the normal intestinal epithelium separates after death, excites doubt as to the proper interpretation of those observations, which seem to indicate any very extensive desquamation of the intestinal epithelium during life as a result of the inflammatory process. Such observations, for example, as case 150,§ in which "desquamation of epithelium of ileo-colic valve, cæcum and ascending colon," is recorded in an autopsy made the day after death, in the month of September, can hardly be regarded as establishing even a probability that the epithelium separated during life. To warrant a belief that this has happened in any case, the exam-

* S. BASCH—*Anat. u. klin. Untersuchungen über Dysenterie*, Virchow's Archiv, Bd. 45, [1869,] S. 204. & Taf, 13. A. THIERFELDER—*Atlas der Path. Hist.*, Lief. 2, Leipzig, 1873, Taf. XII, Fig. 5. See also HEUBNER—in Ziemssen's Cycl., Am. edit., Vol. I, [New York, 1874,] p. 543.

† A similar increase of the adenoid tissue of the mucous membrane of the small intestine would appear to have been observed by BEALE—*Microscopical Researches on the Cholera*, No. V, The Medical Times and Gazette, Vol. II, for 1866, p. 388—in the intestines of subjects dead of Asiatic cholera. He describes it as combined with a "wasting and shrivelling" of the glands of Lieberkühn, "allied to that wasting which occurs in the gland structure of the liver in cases of cirrhosis, and of the kidney in chronic degeneration of this organ;" and his diagrams, Figs. 14 to 18, not merely represent the follicles as more or less pushed apart, but as diminishing in diameter in proportion as they are separated. This wasting of the glands of Lieberkühn was not observed at the Museum in any of the cases of intestinal inflammation examined. ‡ *Supra*, p. 298. § *Supra*, p. 114.



ination should be made much sooner after death than is usually practiced. Certainly the autopsies which furnished the material examined at the Museum, in connection with diarrhœa and dysentery, were generally made long enough after death to render it certain that the separation of the epithelium observed was merely a post mortem phenomenon.*

Rindfleisch† still maintains that an endogenous formation of pus corpuscles may take place in the epithelial cells of inflamed mucous membranes, though he does not look upon this as the exclusive mode of their formation. The observations on which this view is based, with the single exception of that brought forward by Eberth,‡ were not made on the intestinal mucous membrane; still, if it were certain that pus corpuscles originated in this manner on other mucous membranes, the occurrence of the same process in inflamma-

* It may be here remarked that the very general belief that an extensive desquamation of epithelium takes place in the intestinal catarrh of Asiatic cholera is probably also the result of a misinterpretation of post mortem changes. This view was put forth by LUDWIG BÖHM—*Die kranke Darmschleimhaut in der Asiatischen Cholera mikroskopisch untersucht*, Berlin, 1838, S. 7, u. 19; also Tab. 1—as the result of post mortem examinations of the intestinal mucous membrane and of the contents of the alimentary canal. It is supported among others by NIEMEYER—*Lehrbuch der spec. Pathologie und Therapie*, 7te Aufl., Bd. II, S. 725; and RINDFLEISCH, S. 304, *op. cit.*, p. 325, *supra*—and among the English observers, especially by BEALE—*Microscopical Researches on the Cholera*, Med. Times and Gazette, Vol. II, for 1866, p. 166. It may be remarked, however, that of the seven figures of detached epithelial cells given by the latter author in the paper cited, six are stated to have been taken from the jejunum; hence, of course, from the intestinal contents, and not from the rice-water stools; while the source of the cell represented in the seventh figure is not stated. The supposition that the appearances observed in the fluid contents of the alimentary canal after death may be predicated of the rice-water stools discharged during life, is an error often encountered in cholera literature. And yet a moment's reflection ought to show that if the epithelium were thrown off during life as actively as asserted, the intestines after death could hardly be expected to contain such immense quantities of detached epithelium as are actually found. It is astonishing to find so careful an observer as J. L. W. THUDICHUM—*Report on Cholera Chemically investigated*, Ninth report of the Medical Officer of the Privy Council, (1866.) London, 1867, Appendix No. 10, p. 453—heading a section of his paper "Chemical examination of intestinal contents and rice-water discharges," p. 482, which is devoted solely to an examination of the contents of the colon of a cholera patient, removed from the body after death. It is not, however, so astonishing to find practitioners unpracticed in histological investigations quoting his statement, based on this examination, that rice-water contains "cells from the surface of the intestine," as an authoritative description of the cholera stools. This has been done, especially by C. MACNAMARA—*A Treatise on Asiatic Cholera*, London, 1870, p. 351—and by my colleague, Surgeon E. MCCLELLAN, U. S. Army, in his report on *The Cholera Epidemic of 1873 in the United States*, Washington, Government Printing Office, 1875, p. 42. MACNAMARA goes further, and affirms that in the case of a little boy three years old suffering from cholera, he examined "the first stool" and found that "it contained a vast number of columnar epithelial cells." He has also described a "rapid molecular formation in the epithelial-cells of the intestinal canal," observed after death, by which the cells are ultimately completely destroyed, thus producing the "molecular masses which constitute the bulk of the flocculent substance noticed in the rice-water stools of cholera patients." MACNAMARA made his observations with a 1-70th of an inch objective by Messrs. Powell and Lealand, of which he naively says: "I confess I have learned but little through the aid afforded me by this marvellous piece of optical work," p. 336. MCCLELLAN, besides citing THUDICHUM and MACNAMARA, gives in detail (*op. cit.*, p. 37 *et seq.*) the results of a series of microscopical examinations made by Dr. I. N. DANFORTH, of Chicago, in 1873, of which I regret that I cannot speak with praise. DANFORTH received for microscopical examination "eleven bottles containing specimens of the dejections." He "observed occasional oblong patches of small round or polygonal cells, probably epithelial cells thrown off from the villi and floor of the intestinal canal; and, scattered here and there, an occasional full-grown epithelial cell, not yet carried out of the intestine, (*sic.*) but looking cloudy and nebulous, as though it had been for some time macerated in the intestinal contents." I should think this passage a misprint, but it is repeated textually in a *Note upon the results of microscopic examination of the choleraic discharges*, Public Health, Vol. I, (for 1873,) New York, 1875, p. 264. It will not surprise the reader that this gentleman found in the small intestine of a cholera patient that "the villi are nearly all torn away, and the remaining stumps present a rather ragged appearance." (*Sic.*) See MCCLELLAN, *op. cit.*, p. 41. On the other hand, almost all those who have made a special study of the rice-water discharges in cholera, have failed to find any noteworthy quantity of epithelial cells in them. Consult, among others, E. A. PARKES—*On the Intestinal discharges in Cholera*, London Journal of Medicine, Vol. I, (1849,) p. 151; W. LAUDER LINDSAY—*Histology of the Cholera evacuations in Man and the lower animals*, The Edinburgh Medical Journal, Feb. and March, 1856, pp. 728 and 810; M'CARTHY and DOVE—*Abstract of notes of the Cholera cases under the care of Dr. A. Clark, with remarks.* The London Hospital Clinical Lectures and Reports, Vol. III, 1866, Appendix, p. 451; MAX BRUBERGER—*Chemisch-mikroskopische Beobachtungen aus dem städtischen Cholera-Lazareth No. III in Berlin*, Virchow's Archiv, Bd. XXXVIII, (1867,) S. 301—who investigated this question in the stools of five hundred and forty cholera patients. HAYEM—*Bull. et Mém. de la Soc. Méd. des hôpitaux de Paris*, T. X, 1873, p. 265; also *L'Union Médicale*, T. XVI, 1873, p. 541, and T. R. LEWIS—*A report on the microscopical objects found in cholera evacuations, &c.*, Sixth Annual Report of the Sanitary Commissioner with the government of India, 1869, Calcutta, 1870, Appendix A, p. 151—who, after most ample opportunities for observation, writes: "It may perhaps be remarked that no drawing of columnar epithelium, said to be so universal in cholera dejecta, appears in this report. The reason is that its presence, to an appreciable extent, has not been observed in the contents of the intestine discharged during life." The weight of the evidence would certainly appear to warrant the conclusion of AITKEN—*Science and Practice of Medicine*, 3d Amer. from the 6th Lond. edit., Philadelphia, 1872, Vol. I, p. 654—that the separation of the epithelium alleged to take place in cholera is to be interpreted simply as a post mortem change.

† *Op. cit.*, S. 56, u. 303.

‡ C. J. EBERTH—*Zur Entstehung der Schleimkörper*, Virchow's Archiv, Bd. XXI, (1861,) S. 106—describes and figures what he interprets as the endogenous formation of mucous corpuscles in the columnar epithelial cells of the duodenum of a duck killed during digestion. Among the other observations which appear to support the same view, I may mention the following: BUHL—*Ueber die Bildung der Eiterkörperchen*, Virchow's Archiv, Bd. XVI, (1859,) S. 168—observed in a pneumonic lung certain forms, which he interpreted as epithelial cells, from the air vesicles, containing pus corpuscles of endogenous origin. REMAK—*Ueber endogene Entstehung von Eiter-und Schleimzellen*, Virchow's Archiv, Bd. XX, (1861,) S. 198—found similar forms in the urine, which he interpreted as examples of the endogenous formation of mucous or pus corpuscles in the epithelial cells of the bladder and ureter. It may be mentioned, however, that in the two cases referred to by this investigator one patient presented evidences of uræmic intoxication, and the other of albuminuria, so that the possibility is suggested that the figures in question may represent fragments of fibrinous casts with imbedded pus corpuscles from the kidneys. BUHL—*Ein Fall von ulcerativer Pylephlebitis. Bildung der Eiterkörper*, Virchow's Archiv, Bd. XXI. (1861,) S. 480—in a later paper describes and figures the endogenous formation of pus in the columnar cells of the biliary passages; and RINDFLEISCH—*Ueber die Entstehung des Eiters auf Schleimhäulen*, Virchow's Archiv, Bd. XXI, (1861,) S. 486—by the examination of the secretion in catarrhal inflammation of the air passages and of the inflamed bronchial mucous membrane, but especially by means of perpendicular sections of the nictitating membrane of the frog, in which he induced inflammation by means of glacial acetic acid, seemed to have placed the doctrine of the endogenous origin of pus corpuscles in epithelial cells on the basis of direct observation. It has since been called in question by VOLKMANN and STEUDENER—*Ueber die endogene Eiterzellenbildung*, Centralblatt für die med. Wiss. 1868, No. 17, S. 257, and again supported by L. OSER—*Ueber endogene Bildung von Eiterkörperchen an der Conjunctiva des Kaninchens*, Studien aus dem Institute für Exp. Pathologie in Wien, Wien, 1870, S. 74.

tion of the intestinal canal would certainly appear highly probable. On the other hand it must be remarked that the intestinal contents in cases of diarrhœa and dysentery, especially the mucus or muco-pus coating inflamed patches of mucous membrane, have been subjected many times to microscopical examination at the Museum; but that although columnar epithelial cells, both isolated and adhering together, were usually present in multitudes along with the more or less abundant pus corpuscles, no appearances were ever observed which seemed to support the view in question.

Yet another mode in which pus corpuscles may possibly arise from the epithelium of the inflamed intestines is indicated by the paper of Stricker and Kocslakoff, already referred to,* in which it is suggested that the goblet cells they observed to replace the columnar epithelium in the inflamed stomach of rabbits, were produced by a rupture of the latter cells and the escape of a portion of their protoplasm without or with the nucleus, and that in the latter case the nucleated masses of protoplasm thus set free would correspond in appearance to many of the elements found in the secretion with which the inflamed surface was coated. Further observations, however, are needed before this view can be regarded as more than a mere possibility. Finally, the observations of Arnstein, Eimer and Watney, already quoted,† suggest the probability that the pus corpuscles found in the secretions of the inflamed mucous membrane may in fact be migrated white blood corpuscles which have found their way into the lumen of the intestine through the epithelial layer.‡ In the present condition of pathological histology this view commends itself to the most favorable consideration, but more detailed observations are required before it can be accepted as fully established.

In addition to the alterations which have been sketched, certain changes are sometimes observed in simple acute inflammations of the intestine, which, however, are more frequently present among the turbulent disturbances of diphtheritic dysentery, or the extensive alterations of chronic follicular ulceration of the colon; I refer to a peculiar cyst-like transformation of the glands of Lieberkühn, in the course of which they sometimes invade the tissue of the closed follicles in the curious manner so well described and figured by Kelsch§ in his account of the lesions characteristic of chronic diarrhœa and dysentery. I have observed this process in several cases of simple intestinal catarrh of a few weeks' duration, but so much more frequently in chronic cases, or in diphtheritic dysentery, that its further discussion is postponed until these conditions come under consideration.

I have collected a number of photo-micrographs illustrative of the histology of the inflamed intestines, a few of which have been selected for reproduction. The plate facing page 326 is an etching on steel from a photo-micrograph of a portion of No. 417, Microscopical Section, Army Medical Museum, and the annexed diagrammatic figure (Fig. 3) is intended to aid in its interpretation.

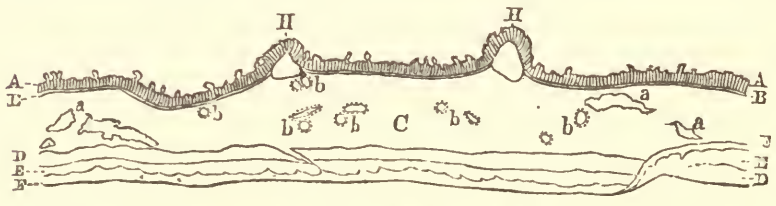


Fig. 3. Diagram explanatory of the plate facing page 326. A. Mucous membrane, with glands of Lieberkühn and villi. B. Muscle of Brücke. C. Subperitoneal connective tissue.

* *Supra*, p. 321. † *Supra*, p. 321.

‡ ARNSTEIN not merely stated that the white corpuscles migrating between the epithelial cells may enter their substance, as mentioned in the note on page 321, *supra*, but asserted that he has seen red blood corpuscles also imbedded in the substance of the epithelial cells, in the hæmorrhagic condition of the mucous membrane produced by injecting oil into a loop of intestine in a living rabbit. These statements, if correct, explain away the observations on which the doctrine of the endogenous formations of pus in epithelial cells is based § *Loc. cit.*, p. 324, *supra*.

PERPENDICULAR SECTION OF ILEUM.

SHOWING AN ENLARGED SOLITARY GLAND. MAGNIFIED 63 DIAMETERS.

PHOTO-MICROGRAPH BY ASSISTANT SURGEON J. J. WOODWARD, U. S. A.

From No. 417. MICROSCOPICAL SECTION.

LIBRARY
UNIVERSITY OF
CALIFORNIA.

The plate represents a perpendicular section of an inflamed ileum with two enlarged and protruding solitary glands, as seen with a power of twelve diameters. The preparation is one of a series of seven perpendicular sections cut transversely to the axis of the ileum through two enlarged glands, various planes of which are thus displayed. They are numbered in the Catalogue of the Microscopical Section 416 to 422 inclusive,* and are from the same subject as Nos. 459 and 460 of the Medical Section of the Museum. The patient, Private John Rice, company F, 10th Vermont, died, October 14, 1864, at the Annapolis Junction hospital, of diarrhœa following typhoid fever. On autopsy several well-marked cicatrices of former ulcers of Peyer's patches were found in the ileum, together with inflammation of the mucous membrane and enlargement of the solitary glands. The colon was thickened and ulcerated. This case will be given in full hereafter, together with a plate representing several of the cicatrices referred to.

The plate facing page 328 is a reproduction of a photo-micrograph of a portion of the same preparation as seen with a higher power. It is magnified 63 diameters, by a Beck's two-thirds of an inch objective. Fig. 4 is a diagram intended to aid in the interpretation of this plate.

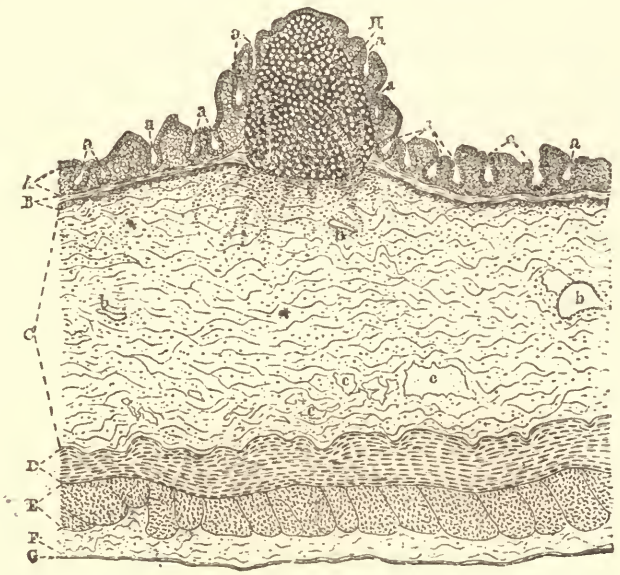

Fig. 4. Diagram explanatory of the plate facing page 328. A. Mucous membrane, showing the follicles of Lieberkühn *a*, *a*, *a*, *a*, pushed apart by the abnormal growth of adenoid tissue. B. Muscle of Brücke. C. Submucous connective tissue, showing sections of bloodvessels, as at *b*, *b*, *b*, and some accidental rents, as at *c*, *c*, *c*. D. Circular layer of the muscular coat of the intestine. E. Longitudinal layer. F. Subperitoneal connective tissue. G. Peritonæum. H. Enlarged solitary gland. The cells of the epithelium, adenoid tissue and solitary gland in this diagram are much exaggerated in size, and, of course, correspondingly few in number.

The portion of the specimen represented displays at the middle of its upper edge an enlarged solitary gland, about one-sixtieth of an inch in its large diameter, projecting from the surface and situated almost entirely above the level of the muscle of Brücke, so as to form a minute tumor which bears upon its periphery the villi and glands of Lieberkühn displaced by its growth. The intestine is somewhat thickened, the thickening chiefly affecting the submucous connective tissue. In the mucous membrane the glands of Lieberkühn are pushed considerably apart by the increased quantity of adenoid tissue. The villi have been damaged by the razor in making the section, and are not well shown. The thickened submucous connective tissue displays a swarm of lymphoid elements, which are most numerous in the vicinity of the enlarged solitary gland and just below the muscle of Brücke. These appear in the plate as round or irregular black dots, which are so numerous immediately below the solitary gland as to obscure its inferior outline. In preparing the specimen some accidental violence, probably undue pressure of the thin glass cover, has produced a certain amount of laceration of the connective tissue just above the circular muscle, giving rise to a number of gaps of various sizes. Indications of the course of the enlarged bloodvessels cut transversely, or at various degrees of obliquity, can also be observed in the submucosa and even in the solitary glands. For the most part these vessels are stuffed

* *Catalogue of the Microscopical Section of the U. S. Army Medical Museum*, Washington, 1867, p. 56. In the description there given it is stated that there is "active cell-multiplication" in the submucous connective tissue in these preparations; a statement based on the number of cellular elements present, and which, on the re-examination of the preparations in the light of our present knowledge, it seems necessary to modify.

with bloodclots, and hence appear black and opaque; a few of the larger vessels, however, are empty. The muscular coat of the intestine and the peritonæum present no marked abnormity; in the subperitoneal connective tissue, however, an unusual number of lymphoid elements are present. The series of preparations to which the one here represented belongs were prepared by the method described on page 322, stained with yellow aniline, and preserved in Farrant's gum and glycerine mixture; they are still, at the time of printing this paragraph,* in a serviceable condition, and can advantageously be studied with much higher powers ($\frac{1}{5}$ to $\frac{1}{10}$) than that used for preparing the photo-micrograph here reproduced. At one extremity of most of them the section passes through a portion of a slightly thickened Peyer's patch, the several somewhat enlarged follicles of which are surrounded by a swarm of lymphoid elements in the submucosa, similar to those shown in the plate beneath the solitary glands. In portions of most of the sections, also, a few of the villi have escaped destruction by the razor. They are all, of course, denuded of epithelium. There are in the Museum quite a number of microscopical preparations, which exhibit various stages of similar lesions of the ileum, some from subjects in which mere inflammation of the colon coexisted, while in others it was coated with pseudomembrane or more or less ulcerated.†

A representation of the conditions to be observed in the case of a slight degree of enlargement of the solitary glands of the colon will be found in the plate facing this page, which is a reproduction of a photo-micrograph of a portion of No. 650, Microscopical Section, magnified 63 diameters by a Beck's two-thirds of an inch objective. The specimen is one of a series of perpendicular sections, Nos. 642 to 650, Microscopical Section, which were cut transversely to the axis of the colon, and prepared for permanent keeping in the same way as the specimens of small intestine just described. This series is from the same colon as No. 547, Medical Section. The patient was Private J. Zinke, the history of whose case was presented on page 308, in connection with a chromo-plate representing the appearances of the colon when recent. It was there stated that this man died of aneurism of the aorta a short time after recovering from a diarrhœa of some months' duration. The colon was in a condition of resolution, but had not yet attained perfect restoration to the normal state, the solitary glands were still somewhat enlarged, and were the seat of pigment deposit.

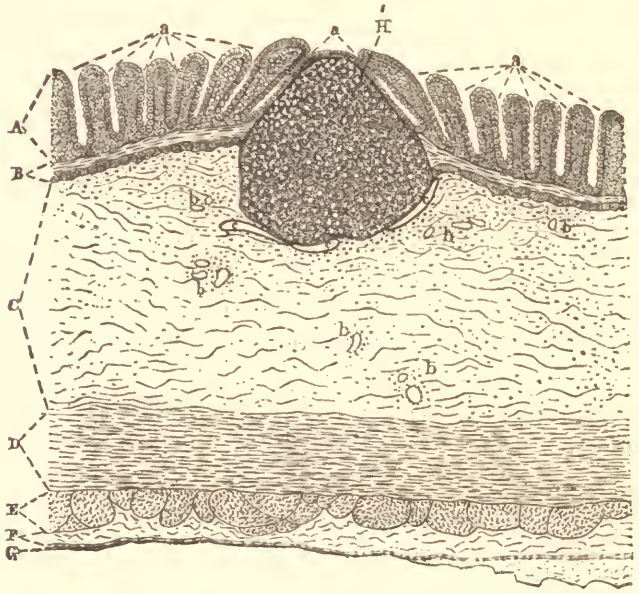

FIG. 5.—Diagram explanatory of the plate facing this page. A. Mucous membrane, showing the follicles of Lieberkühn, *a*, *a*, *a*, pushed apart by a somewhat increased quantity of adenoid tissue. B. The muscle of Brücke. C. The submucous connective tissue, showing sections of bloodvessels, as at *b*, *b*, *b*, and of the lymph sinus *c*, *c*, adjoining the enlarged solitary glands. D. Circular layer of the muscular coat of the intestine. E. Longitudinal layer. F. Subperitoneal connective tissue. G. Peritonæum. H. Enlarged solitary follicle. The cells of the epithelium, adenoid tissue, and solitary gland in this diagram are much exaggerated in size and of course correspondingly few in number.

* September, 1877.

† I am not acquainted with any satisfactory pictorial representation of the microscopical appearances under consideration. ALBERT THIERFELDER—*Atlas der pathologischen Histologie*, Lief. 2, Leipzig, 1873, Taf. XI, Fig. 3—gives a drawing of "follicular catarrh of the ileum," as seen with a low power, which, however, represents a section through a Peyer's patch, and gives of course no notion of the peculiar protrusion of the enlarged solitary glands in such cases.

The portion of the section represented in the plate, an explanatory diagram of which is presented in Fig. 5, exhibits at the middle of its upper surface a somewhat enlarged solitary follicle, about $\frac{1}{10}$ of an inch in diameter, which, it will be observed, does not project above the general surface of the mucous membrane in the way enlarged follicles so often do in the small intestine, but nevertheless appears to have produced some protrusion of the mucous membrane around it, so that the surface slopes upwards on each side from the edges of the picture to the apex of the follicle. The total thickness of the portion of intestine represented is about $\frac{1}{16}$ of an inch, of which nearly one-half belongs to the thickened submucous connective tissue, where the number of scattered lymphoid elements is somewhat more numerous than normal, especially in the vicinity of the enlarged solitary gland. Just below this gland there are two fissures which represent sections of the lymph sinus which surrounds its base. The adenoid tissue of the mucous membrane is somewhat increased in quantity. On microscopical examination of the section from which the photograph here reproduced was taken, the pigment ring which has been described as surrounding the solitary follicles and the diffuse streaks of pigmentation on the general surface of the mucous membrane were found to consist of brown granules deposited for the most part in the lymphoid cells of the adenoid tissue between the glands of Lieberkühn, while the dots of pigment in the solitary follicles consisted of similar granules deposited in the lymphoid cells of the parenchyma of these glands. In the first two situations, the pigment was most abundant about midway between the epithelium and the muscle of Brücke. This was not shown in the photograph, because the brown pigment and the yellow aniline were very nearly equally non-actinic; it can still, however, be pretty well made out in the microscopical preparation.

Besides the above series, there are a number of other preparations in the Microscopical Section of the Museum which exhibit enlargement of the solitary glands in the inflamed colon, and the same lesion is displayed in portions of a number of the preparations in the same collection which illustrate ulceration of the colon. These preparations differ in the degree of enlargement of the solitary glands, in the abundance of the lymphoid elements in the submucous connective tissue, in the extent to which the glands of Lieberkühn are pushed apart by the accumulation of new elements in the adenoid tissue of the mucous membrane, and in the degree to which the coats of the colon, especially the submucous connective tissue, are thickened. They differ from each other, however, rather in degree than in any essential feature; and the plate just described will serve to give a good general notion of them all.

The description given above of the pigment deposit in the series No. 642 to 650, Microscopical Section, may be taken as generally true for the pigment deposits found in chronic cases in both the small and large intestine, in so far that the pigment granules are most abundantly found in the lymphoid elements of the closed glands and of the adenoid tissue of the mucous membrane. In the small intestine the extremities of the villi are a common seat of the pigmentation, as has already been mentioned.* In this case also the pigment granules are most abundant in the lymphoid elements of the villi.† Sometimes, however, both here, and in the other situations mentioned, the pigment appears in masses of larger size, and apparently between the lymphoid elements instead of in their substance.

* *Supra*, p. 305. † See, for a figure representing this condition, the Atlas of *Thierfelder*, (*op. cit.*) Lief. 2, Taf. XI. Fig. 5.

The next two plates are intended to illustrate certain points in the arrangement of the swarm of lymphoid elements in the mucosa and submucous connective tissue as seen in sections of the intestine in both acute and chronic cases. The plates are reproductions of four photo-micrographs taken from different portions of the same preparation, No. 668, Microscopical Section, which is a perpendicular cut of the colon made parallel to the axis of the intestine, from a boiled piece stained with yellow aniline. The intestine selected was affected with subacute inflammation of two or three months' duration, and was not only thickened, but ulceration had already commenced in the vicinity of some of the solitary follicles; these were surrounded by circles of ulceration in the centres of which the swollen follicles still maintained their integrity. The submucous connective tissue was moderately swollen, ($\frac{1}{30}$ to $\frac{1}{20}$ of an inch in thickness.) The specimen was cut through the margin of a patch of more intense inflammation, whence the lymphoid elements are more numerous at one of its extremities than at the other, and this rendered it possible to select views showing different stages of the process.

The plate facing this page is a reproduction of two photo-micrographs taken from the left half of the cut, where the submucosa is least thickened and has fewest new elements. They are magnified 280 diameters by a one-fifth immersion objective made by R. B. Tolles, of Boston. Each represents adjoining portions of the mucous membrane and of the submucous connective tissue. In the mucous membrane of both the glands of Lieberkühn are pushed apart in consequence of the accumulation of lymphoid cells in its adenoid tissue. In the submucous connective tissue of both a few lymphoid cells are scattered among the proper elements of the tissue; but the most conspicuous appearance in each view is presented by a small vein just below the muscle of Brücke, which is surrounded concentrically by a dense lymphoid swarm, while a small artery in the immediate vicinity (on the left of the vein in the upper view, on the right of the vein in the lower view) has comparatively few lymphoid elements around it. All the processes are more advanced in the lower view, and especially the lymphoid swarm around the vein occupies in it a greater area, and is composed of a much larger number of lymphoid cells. The light line that crosses the lower view obliquely from above downward is the optical expression of a crack in the thin cover of the preparation.

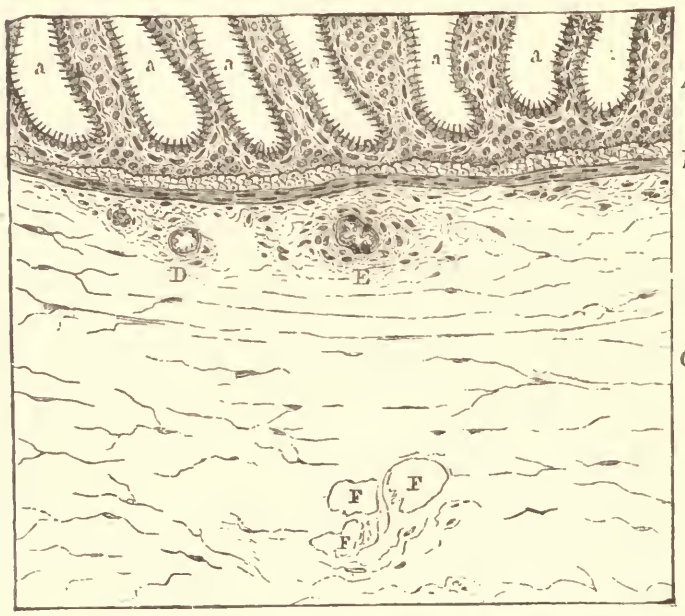

FIG. 6.—Diagram explanatory of the plate facing this page. A. Mucous membrane; *a*, *a*, *a*, *a*, follicles of Lieberkühn pushed apart by the swarm of new elements in the adenoid tissue. B. Muscle of Brücke. C. Submucous connective tissue. D. A small artery. E. A small vein surrounded by the lymphoid swarm. F, F. Accidental rents in the section. This diagram is drawn from the preparation represented in the upper figure of the plate facing this page, but will serve also to interpret the lower figure, and also the two figures in the plate facing page 334.

The plate facing page 334 reproduces two other photo-micrographs, taken with the same objective and magnifying power, from the right half of the same preparation [No.

PERPENDICULAR SECTION OF COLON.

SHOWING AN ENLARGED SOLITARY GLAND. Magnified 63 Diameters.

PHOTO-MICROGRAPH BY ASSISTANT SURGEON J. J WOODWARD, U S. A.

From No. 650. MICROSCOPICAL SECTION.

668, Microscopical Section] in which, as mentioned, the thickening was greater and the lymphoid elements were more numerous. The upper portion of the plate represents a view very similar to that in the lower portion of the last plate, and, like it, shows an artery and vein—the latter uppermost—a short distance below the muscle of Brücke. The lymphoid swarm which densely infiltrates the submucosa is still arranged for the most part concentrically around the vein, although a considerable number of the elements are to be seen also in the vicinity of the artery. The lower portion of the plate represents another artery and vein—the artery uppermost—found still further to the right in the same piece, and a little further below the muscle of Brücke, which accordingly does not appear in the photograph. It exhibits conditions very similar to those shown in the upper portion of the plate. Certainly such conditions as are exhibited in these plates, which are constantly to be encountered in perpendicular sections of the inflamed submucous connective tissue, would appear to be best explained by supposing, in accordance with Cohnheim's doctrine, that the lymphoid brood has migrated from the small veins.

In concluding this sketch of the histology of the inflamed intestines it remains to be mentioned that in the more chronic cases of intestinal catarrh without ulceration, as well as in the ulcerative cases, I have occasionally observed the so-called amyloid* degeneration in the intestinal arterioles and capillaries, especially in the villi of the small intestine, and in the submucosa both of the small intestine and of the large. Usually the process had only moderately advanced, the intima of the small arteries alone having undergone the characteristic glassy swelling, while the muscular coat was not yet involved or at least but slightly implicated. I regret that I did not during the war feel the importance of instituting systematic examinations, of all the fresh specimens at my disposal, with iodine to determine the frequency and extent of this complication, especially in view of the statement of Aitken† that he has repeatedly seen soldiers dead of diarrhœa in the hospital at Netley whose whole alimentary canal presented this lesion to a marked degree.

Amyloid degeneration of the alimentary canal was first minutely described by Virchow, though Meckel‡ had previously observed the characteristic iodine reaction in both small and large intestine. Virchow detected the change in question in the œsophagus and

* I employ the designation amyloid degeneration, introduced by Virchow, because it is that most generally in use, although it was based upon a misconception. The disease had previously been very generally called lardaceous degeneration (Speckige Entartung) in Germany, and waxy degeneration in England, on account of the physical appearance of the liver and other organs when affected by it. H. MECKEL—*Die Speck-oder Cholestrinkrankheit*, Annalen des Charité-Krankenhauses, Jahrg. IV, Heft 2 [Berlin, 1853,] S. 264—advanced the view that it was a form of fatty degeneration, the abnormal substance consisting probably of various mixtures of cholesterin and other fatty bodies. Among these he distinguished at least four substances: "Speck-roth, Speck-violet, Cholesterin and Speck-kalk;" the first two so named from their reaction with iodine. VIRCHOW—*Archiv*, Bd. VI, [1854,] S. 135, 268 and 416—relied chiefly on the reaction with iodine, with or without sulphuric acid, and his view, that the substance in question is really allied to starch in chemical composition, was for a time very generally accepted. FRIEDREICH and KEKULÉ—*Virchow's Archiv*, Bd. 16, [1859,] S. 61—however, found by actual chemical analysis of so-called amyloid masses, obtained from the spleen, that it was a nitrogenous body whose ultimate chemical composition closely resembled that of albumen; and C. SCHMIDT—*Ueber das sogenannte thierische Amyloid*—Annalen der Chemie u. Pharmacie, Bd. 109, [1859,] S. 250—by independent analyses arrived at similar results. Subsequently these results were confirmed by KÜHNE and RUDNEFF—*Zur Chemie der amyloiden Gewebsentartung*, Virchow's Archiv, Bd. 33, [1865,] S. 63—who brought forward improved methods of isolating the amyloid substance from large organs, such as the liver and spleen, thus diseased. In view of the composition thus established, the old designation "colloid," preferred by I. M. SCHRANT—*Over de goed-en kwaadaaige gezwellen*, Amsterdam, 1851, [I cite from VIRCHOW'S review in *Canstatt's Jahresbericht*, Bd. IV, [1852,] S. 315. See also, in the same publication, Bd. II, [1852,] S. 21, VIRCHOW'S review of SCHRANT'S essay *Over den oorsprong van het Colloid*, and, in Bd. II, [1851,] S. 34, his review of SCHRANT'S essay on the syphilitic liver] would seem a more appropriate designation than amyloid, were it not that there are other pathological products known as colloid which do not give the same reaction with iodine. WM. H. DICKINSON—*On the nature of the waxy, lardaceous, or amyloid deposit*, Med. Chir. Trans., 2d Series, Vol. 32, [1867.] p. 39; also by the same—*Pathology and Treatment of Albuminuria*, Amer. Ed., New York, 1868, p. 166 *et seq.*—argues that the deposit is allied in its nature to *fibrin*, from which it differs chiefly by being deficient in the fixed alkali with which the fibrin of the blood is generally associated. He states that if fibrin (or albumen) is dissolved in dilute hydrochloric acid (0.6 in 1,000) and evaporated to dryness at a low temperature, the substance obtained will react with iodine exactly like the so-called amyloid material. Albumen treated the same way gives similar results. DICKINSON proposed sulphate of indigo as an additional test for the so-called amyloid degeneration, for which he suggests the designation "depurative infiltration" on account of the conditions under which it arises.

† WM. AITKEN—*The Science and Practice of Medicine*, 3d Amer. Ed., Philadelphia, 1872, Vol. II, p. 632, Article, *Lardaceous disease of the intestines.*

‡ MECKEL, *loc. cit.*, observed the characteristic iodine reaction [his Speck-roth] in the intestinal canal in several cases. (cases 2, 3, 5 and 10 of the paper cited,) in all of which chronic disease of the bones also existed. In case 10 the change affected the minute arteries of the whole intestine.

stomach, as well as in all parts of the intestinal canal, and especially in the small intestine.* He regarded it as almost exclusively limited to the minute arterioles, especially those in the villi and the superficial layers of the submucosa, but stated that it could be followed for a short distance also along the capillaries given off from these vessels. Little alteration of the affected parts could be detected with the naked eye; the mucous membrane was merely very pale, somewhat thickened and preternaturally translucent. On the application of iodine to a portion of small intestine thus diseased, the general surface of the mucous membrane becomes yellow, while numerous reddish or brownish points make their appearance. These are the intestinal villi whose vessels have undergone the amyloid change. In like manner the affected vessels assume the characteristic color with iodine in the submucosa of both small and large intestine. Virchow states that he has seen cases in which the whole digestive tract from the mouth to the anus possessed no single arteriole which was not thus diseased.

Since attention was first directed to this subject additional observations have been published by various authors, especially by Friedreich, Beckmann, Neumann, Lambl, Frerichs, Hayem and Stewart.† Lambl has shown that the process is not limited to the bloodvessels of the intestine, but that all the muscular tissues of the intestine, as well as the epithelium of the mucous surface‡ of the villi, of the follicles of Lieberkühn, and even the peritoneal epithelium, are also involved. Hayem mentions the occurrence also of "amyloid concretions" in the closed follicles. In all these cases the amyloid disease of the intestines was associated with amyloid disease of other parts of the body, especially of the liver, spleen and kidneys. According to Hayem the disease in these organs is usually more advanced than in the intestine, whence he infers that the latter is a secondary affection. The cases of Meckel and the earlier cases of Virchow all occurred in subjects who had suffered from chronic disease of the bones, especially caries and necrosis. This was trüe also of one of the cases of Frerichs and of all the cases of Hayem. Virchow at first too exclusively emphasized this connection. Subsequently he himself reported a case in which it did not exist.§ Secondary syphilis without bone disease, (Friedreich, Frerichs, Stewart,)

* R. VIRCHOW—*Ueber den Gang der amyloiden Degeneration*, Virchow's Archiv, Bd. VIII, [1855,] S. 364. VIRCHOW states in this paper that Dr. JOCHMANN was the first to observe the iodine reaction on the mucous membrane of the stomach, and that he himself, pursuing the investigation, arrived at the results stated in the text. I do not know that JOCHMANN'S investigations were ever published, nor have I found any mention of amyloid degeneration of the intestinal canal in VIRCHOW'S earlier papers on that form of disease. A summary statement of Virchow's views on this subject will be found in *Die Cellularpathologie*, Berlin, 1858, S. 340. In the 4th edition of this work [Berlin, 1871, S. 445] he recommends the use of acetic acid after the iodine solution to ensure the success of the reaction. See also an additional case observed by VIRCHOW, in which there was no bone affection—*Neue Beobachtungen über amyloide Degeneration*, Virchow's Archiv, Bd. XI, [1857,] S. 188.

† N. FRIEDREICH—*Einige Fälle von ausgedehnter amyloider Erkrankung*, Virchow's Archiv, Bd. XI, [1857,] S. 387; also an additional case, *op. cit.*, Bd. XIII, [1858,] S. 498. In these cases there was either general tuberculosis or secondary syphilis; bone disease in none. In two of the cases extensive amyloid degeneration of the intestinal vessels was observed. O. BECKMANN—*Ein Fall von amyloider Degeneration*, Virchow's Archiv, Bd. XIII, [1858,] S. 94; E. NEUMANN—*Neue Beobachtungen über amyloide Degeneration*, Deutsche Klinik, Bd. XII, [1860,] S. 337, 353 and 373—relates eight cases of more or less extensive amyloid disease in all of which the intestinal tract was involved. In five of these cases tubercular disease of the lungs, &c., coexisted. One case (No. 6) was a sailor who had contracted dysentery in Java, since which for three-quarters of a year he had suffered from chronic flux. Numerous follicular ulcers of the colon were found during the autopsy, together with amyloid degeneration of the small arteries of the liver and both small and large intestines; also commencing amyloid degeneration of the cells of the splenic pulp. LAMBL—*Beob. u. Studien.* [aus dem Prager Kinder-Spitale,] Prag, 1860, S. 319, *Ueber amyloide und colloide Degeneration im Allgemeinen und die des Darms insbesondere*—has described this lesion with great detail as observed by him in the intestines of children dead of intestinal catarrh and other wasting diseases. He observed the amyloid change not merely in the bloodvessels, but in the muscular coat of the intestines, the muscular fibre-cells of the villi, the epithelium of the villi, of the follicles of Lieberkühn, and of the peritonæum. The appearances are figured in a colored lithographic plate, Taf. 16. FRERICHS—*Diseases of the Liver*, Transl. of New Syd. Soc., London, 1861, Vol. II, p. 180 *et seq.*, especially Obs. 27 and 28, both syphilitic cases; in the first, syphilitic ulceration of the left parietal bone existed. M. G. HAYEM—*Note sur la dégénérescence amyloïde du tube digestif*, Compte Rendu des Séances de la Soc. de Biologie, Nov., 1865, 4me Série, T. II, Année, 1865, p. 191; also Gaz. Méd. de Paris, T. 21, [1866,] p. 90; and Biennial Retrospect of New Syd. Soc. for 1865–6, p. 176. This author found amyloid disease of the intestines in five out of forty scrofulous children, all having chronic suppuration of the bones with or without tuberculosis. The observations were made in the Hôpital des enfans malades at Paris. T. GRAINGER STEWART—*On hæmorrhage from waxy or amyloid degeneration*, British and Foreign Med. Chir. Rev., Vol. 41, [1868,] p. 201. This paper contains the details of three cases in which amyloid disease of the intestines was found on post mortem examination. All syphilitic—no bone disease.

‡ This observation is also corroborated by RUDNEFF—*Amyloidentartung der Bauchorgane*, Virchow's Archiv, Bd. 33, [1865,] S. 76.

§ The last case cited in the previous note. See also an interesting discussion of the relations of amyloid degeneration to syphilis by the same author—*Ueber die Natur der constitutionell-syphilitischen Affectionen*, Virchow's Archiv, Bd. 15, [1858,] S. 217.

general tuberculosis, (Friedreich, Neumann,) and other wasting diseases, (Virchow, Neumann, Lambl,) may induce the general amyloid disease of which the intestinal lesion is only a part.

It is reasonable to believe with Virchow* that this lesion must produce serious disturbance of the functions of the intestinal canal. Its relations to the inflammatory conditions of the intestinal mucous membrane, with which it is so often associated, are less obvious. According to Hayem these inflammatory conditions are the consequence of the amyloid disease. He describes accordingly a "*psorentérie amyloïde*"† which terminates in amyloid erosions and ulcerations. It is not clear, however, that the intestinal inflammation is not the antecedent condition which determines the invasion of the intestinal vessels in some cases of general amyloid disease, while they escape in others. So also, according to Colberg,‡ amyloid disease of the intestinal mucous membrane precedes and determines the formation of the intestinal ulcers which so often occur, quite independently of any tubercular disease of the intestine, in cases of chronic ulcerative pneumonia; but in these cases, as Colberg himself does not omit to state, the ulceration is always associated with intestinal catarrh, and it may well be questioned whether this is not the true cause both of the ulceration and the coexisting amyloid disease. Stewart § has given prominence to the occurrence of hæmorrhage in amyloid disease which had previously been observed by Hayem and Wilson Fox.‖ According to him, next after the spleen the most common seat of such hæmorrhages is the intestinal tract, where it occurs independently of any visible ulcerative process, and probably depends upon rupture of the diseased capillaries. He does not, however, regard hæmorrhage from this cause as necessarily a dangerous accident, remarking that sometimes it comes and goes for years without markedly depressing the vital powers.

Diarrhœa is another symptom attributed to amyloid disease of the intestines by Virchow, Hayem and others. It is not clear, however, that it occurs unconnected with more or less pronounced intestinal catarrh, which so generally coexists to a marked degree. Further observations on this point, and also with regard to the frequency of the disease, are much to be desired;¶ meanwhile, in the present imperfect condition of our knowledge of the nature of the amyloid change, it appears premature to introduce into our nomenclature a new species of diarrhœa based upon the existence in the intestinal coats of this ill-understood anatomical lesion.

---

* *Die Cellularpathologie*, loc. cit., *supra*.

† *i. e.* An intestinal catarrh with enlargement of the solitary follicles. HAYEM'S account of this process has been largely drawn upon by AITKEN (*loc. cit., supra*) in his description of lardaceous disease of the intestines. I am unable to see that either the first or second stage of the process described differs from what may be observed in ordinary intestinal catarrh except in the presence, in addition to the other lesions, of the amyloid disease of the intestinal bloodvessels.

‡ COLBERG—*Beitrage zur normalen und path. Anat. der Lungen*, Deutsches Archiv für klin. Med., Bd. II, 1867, S. 478—observed the amyloid change in the capillaries of the villi and of the mucosa in the margins of the intestinal ulcers referred to in the text. He explains the mode in which such ulcers commence by supposing the villi to become stiff and brittle in consequence of the amyloid condition of their capillaries, and thus prone to break down before the mechanical violence of the passage of the intestinal contents, ("den mechanischen Insulten der Ingesta.") If the intestinal contents are mingled with the products of urea-decomposition, as often occurs when amyloid kidney disease coexists, the chemical action of the ammoniacal compounds is superadded.

§ *Loc. cit., supra.* STEWART concludes: "1. That hæmorrhage is not a very infrequent consequence of waxy or amyloid degeneration of vessels," which AITKEN, *loc. cit.*, p. 684, by some mistake renders: "1. That it is not a frequent occurrence."

‖ HAYEM—*loc. cit., supra.* WILSON FOX—*Case of fatal purpura associated with waxy degeneration of the striated muscles, and also of the vessels in the affected parts*, British and Foreign Med.-Chir. Rev., Vol. 36, [1865,] p. 481.

¶ E. WAGNER—*Beiträge zur Kenntniss der Speckkrankheit, insbesondre der Speckleber*, Archiv der Heilkunde, Jahrgang II, [1861,] S. 481—states that in 1,200 autopsies made by him between September 30, 1856, and May 24, 1861, he found one or more organs affected by this condition in 48 cases. Of these, 16 were consecutive to suppuration of the bones; 27 to chronic lung tuberculosis; 3 to ulcerative cancer, and 3 to syphilis—in one case complicated with cancer. The paper concludes with a bibliography of the subject. On the subject of the affections which precede the development of amyloid or lardaceous disease generally the reader may advantageously consult S. WILKS—*Cases of lardaceous disease and some allied affections*, Guy's Hospital Reports, 3d Series, Vol. II, [1856,] p. 103; T. GRAINGER STEWART—*On the waxy or amyloid form of Bright's disease*—Edinb. Med. Journ., Vol. VI, 2, [1861,] p. 710; *Further observations* on the same, same Journ., Vol. X, 1, [1864,] p. 97; and *On the diagnosis of the forms of Bright's disease*, British and Foreign Med.-Chir. Rev., Vol. 38, [1866,] p. 196; DICKINSON, *op. cit., supra*, p. 333; and E. KYBER—*Studien über die amyloide Degeneration*. Dorpat, 1871. The account given in the last treatise of the use of reagents, especially of iodine and sulphuric acid, in the diagnosis of the amyloid lesion, deserves attention. The work of A. PAGENSTECHER—*Ueber amyloide Degeneration*, Würzburg, 1858—I have been unable to see.

2. Acute Dysentery.

Acute dysentery,* because of its frequency, painfulness and fatality, has occupied a large share of the attention of medical writers since the time of Hippocrates, who described, under the designation *Δυσεντερία*, essentially the same disease which has been known ever since by that name.† With the revolutions of medical knowledge the precise limitations assigned to the use of the term have been considerably modified, and accordingly the various definitions of dysentery, with which medical literature abounds, are by no means strictly accordant. They vary in part because of the various degrees of extension given to the use of the name, and in part because certain writers have predicated of the disease in general symptoms peculiar to the particular group of cases which fell under their own observation. Without discussing these various definitions, some of the more important of which are given below in a foot-note,‡ and without venturing to offer any new definition,

* Synonyms: Δυσεντερία, [Hippocrates, Galen and other Greek writers;] Ῥεῦμα γαστρός, [Galen—*I Com. in Prog. Hip.*, § 8, Ed. Kühn, Tom. XVIII, B, p. 33;] Tormina, [Celsus;] Rheumatismus intestinorum cum ulceratione; [Cælius Aurelianus;] Difficultas intestinorum; Fluxus dysentericus, [Lamonière—*Obs. Flux. dysent.*, Lyons, 1626;] Flumen dysentericum; Fluxus cruentus cum tenesmo; Tormentum intestinorum; Alvi fluxus torminosus; Febris dysenterica; Catarrhus intestinorum spasmodicus; Colo-typhus, [Eisenmann—*Die Krank. Familie Typhus*, Erlangen, 1835, S. 362;] Colonia, [Craigie—*Pract. of Phys.*, Edinb., 1837, Vol. I, p. 902;] Dysenterie, Flux de sang, [French writers;] Colite, [Broussais;] Dysentery, Bloody flux. [English writers;] The griping of the guts, [Willis—*Pharm. Rat.*, Sect. III, Cap. 3;] Ruhr., [German;] Disenteria. [Italian.] Sauvages—*Nos. Meth.*, Amsterdam, 1763, Tom. II, p. 324—enumerates among the synonyms the morbus dissolutus of Paracelsus, but it is clear that Paracelsus—*Lib. XIV Paragraphorum*, Lib. I, De Morbo dissoluto, and, *In Lib. XIV Par. Commentaria*, Opera omnia, Geneva, 1658, Tom. I, pp. 491 and 539—rather intended to indicate by morbus dissolutus a genus of which dysentery, lientery, diarrhœa, vomiting, and even certain disorders of the urine were species. He says (Cap. I, Par. I,) "Omne quod perfectum et per stomachum indigestum abit, morbus dissolutus est: et illud quod à perfecto ad imperfectum descendit, dissoluti materia cruda et non præparata est, et cruda à præparatis. Centrum stomachus est, exitus per anum, per vomitum et vesicam." Whichever road the flux might take, there were three species, (Cap. I, Par. III,) "Tres sunt morbi ex dissolutione, vel dissolutis primæ speciei, rubeus, albus et laxus."

† See, for example, the account given by Hippocrates of the dysentery of the island of Thasus—*Epidemics*, Lib. I, Sect. 2, [Ed. Littré, Tom. II, p. 617 *et seq.*,] and Lib. III, Sect. 3, [Ed. Littré, III, pp. 87–89.] Compare also the treatise on *Airs, Waters and Places*, § 7 and 10, [Ed. Littré, II, pp. 27 and 43;] *Aphorisms*, Sect. III, 22, and Sect. IV, 24 and 26, [Ed. Littré, IV, pp. 497 and 511,] and many other places, to some of which allusion will be made in subsequent notes. I have preferred, in quoting Hippocrates in these notes, to give references as a rule to the Greek-French edition of É. Littré *Œuvres Complètes d'Hippocrate*, Paris, 1839–1861, (ten vols. 8vo.,) which is not only easily accessible, but has many advantages from the critical acumen of the editor, whose admirable French translation is also a great convenience to most modern readers. The English translation of Dr. Francis Adams, [Printed for the Sydenham Society, London, 1849,] which I have used with great pleasure on many occasions, has the disadvantage that it contains but a portion of the Hippocratic writings. Among the older Greek-Latin editions of Hippocrates contained in the Surgeon General's library, I have frequently consulted with advantage the original edition of Anutius Foes [Francofurti, apud Andreæ Wecheli heredes, 1595,] and the Geneva reprint, [S. Chouët, 1657,] which, on account of its more convenient paging and various additions in the way of annotations, is perhaps to be preferred. That the word dysenteria was used familiarly in the same sense as at present, at the time of Hippocrates or even earlier, is shown by the passage in the history of Herodotus, [Lib. VIII, Cap. 115,] which describes a pestilence and dysentery [λοιμὸς καὶ δυσεντερίη] that decimated the army of Xerxes while retreating through Thessaly.

‡ The following definitions from Hippocratic writings of doubtful origin, harmonize well with the descriptions and allusions scattered through the genuine books. In *Regimen*, (*De victus rat.*,) Lib. III, [Ed. Littré, VI, p. 617,] after stating that diarrhœa is one of the consequences of habitually taking too much food in proportion to the amount of exercise used, we are told that so long as putrescent alimentary matters only are passed from the bowels the disease is called diarrhœa; "But when, the body being heated, acrid matters are discharged, the intestine is excoriated, ulcerated, and the stools are bloody; this is dysentery, a grave and dangerous disease." So also in the treatise on *Affections*, [Ed. Littré, VI, p. 235,] "When there is dysentery, pain occupies the whole abdomen; bile, phlegm and heated blood are discharged." Celsus—*Medicinæ Libri Octo*, Lib. IV, Cap. 15, [Leyden Edit. of 1785, p. 179]—gives a short description which may be taken as a definition: "The next disease of the intestines is usually called tormina: in the Greek language it is termed dysenteria. The intestines are ulcerated internally: grumous evacuations come from them; sometimes the excretions are mixed with fæcal matter always liquid, at other times the discharges are slimy; sometimes particles like flesh pass with them: there is a frequent desire of going to stool, and pain in the anus: with this pain a small portion is voided; and even by this the pain is augmented; that is relieved after some time; and then there is a short repose: the sleep is interrupted; slight fever ensues, and in the progress of time, that disease either destroys the patient, when it has become inveterate, or even although it may be terminated, exerts a baneful influence for a long time." [Lee's Translation, London, 1831.] Aretæus briefly affirmed that the different forms of intestinal ulcers constitute dysentery—*De Causis et Signis Morborum Diuturnorum*, Lib. II, Cap. IX, [Boerhaave's edition of Aretæus, Leyden, 1731, p. 59.—See also the English translation of T. F. Reynolds—American reprint, Philadelphia, 1841, p. 72]—and a similar definition, with the addition that the ulcer is produced by external causes, was given by Archigenes, if indeed he has been correctly reported by Ætius.—*Contractæ ex veteribus medicinæ tetrabilos.* Translation of J. Cornarius, Basel, 1542, Tetrab. III, Serm. I, Cap. 43. [I cite the Lyons edit. of 1549, p. 599.] The definition given by Galen in the treatise *De Locis Affectis*, Lib. I, Cap. 2, [Ed. Kühn, VIII. p. 381,] is conceived in the same spirit. "In the present work we should understand the name dysentery properly, that the appellation signifies an ulceration of the intestine;" and, further on—"At first there is an excretion of very biting (*i. e.* corrosive) bile; then shreds of the intestines follow; afterwards a little blood is discharged along with the shreds, and now the affection is dysentery." Compare the Galenical treatise on *Definitions*, which, however, Kühn [Tom. I, p. CLIX] does not regard as genuine. "Dysentery is an ulceration of the intestines, with an excretion of phlegm and bloody material, or of shreds resembling lees, and accompanied by griping and pain in the abdomen and bowels."—[Ed. Kühn, XIX, p. 421.] In these and subsequent citations from Galen, I quote from Kühn's Greek-Latin edition, [Leipsic, 1821–33, 20 vols. 8vo.] Among the other editions in the library of the Surgeon General's office, I have also sometimes used with advantage the 3d edition apud Juntas, Venice, 1556, chiefly on account of the unrivalled index of Brasavolus, and the Greek-Latin edition of Hippocrates and Galen, by R. Charterius, [Paris, 1679.] The French translation of Ch. Daremberg [Paris, 1856] has also been of use to me, and I regret that it represents so few of the Galenical books. The Hippocratic conception of dysentery differed somewhat from our modern notions, since a part of the cases which would now be included under the head of dysentery were then spoken of as tenesmus. Compare the account of tenesmus in the treatise on *Affections* [Ed. Littré, VI, p. 239] with such passages as that in *Diseases*, Lib. I, [Ed. Littré, VI, p. 147,] where it is said that a tenesmus may

it seems most convenient for the purposes of this work to embrace under the designation acute dysentery all the various forms of acute alvine flux, whether mild or severe, in which tenesmus is a prominent symptom. Tenesmus arises whenever the inflammation of the mucous membrane upon which the flux depends affects the descending colon and rectum with sufficient intensity to make the expulsive efforts painful. Mere intensity in the inflammatory process does not determine dysentery rather than diarrhœa, unless the descending colon and rectum are affected, and on the other hand comparatively slight inflammation of the mucous membrane of this region may give rise to dysenteric symptoms; but it is worthy of note that the more severe forms of acute inflammation of the intestinal mucous membrane are exceedingly prone to involve this portion of the canal also, and thus produce dysentery much more frequently than diarrhœa.

---

change into a dysentery, or that in *Epidemics*, Lib. II. Sect. 2, [Ed. Littré, V, p. 91,] in which it is asserted that those who already suffer from tenesmus are especially liable to dysentery. This distinction, which was doubtless much older than HIPPOCRATES, is satisfactorily accounted for by GALEN, who tells us, in his second commentary on the Hippocratic treatise just cited—*Hippocrates Epidem. II, et Galeni in illum Commentarius* II, § 17 [Ed. Kühn, XVII, A, 347]—that the ancient physicians named some diseases from the parts affected, as ophthalmia, dysentery, &c., and others from the symptoms, as ileus, tenesmus, &c. CELSUS also, describes tenesmus as a separate affection—*Medicina*, Lib. IV, Cap. 18, [Leyden Edit. of 1785, p. 183,]—and GALEN does the same, as in *De Locis Affectis*, Lib. VI, Cap. 2, [Ed. Kühn, VIII, p. 383] and other places; but ARETÆUS merely describes it as a symptom of dysentery. [Boerhaave's Edit., p. 60.] GALEN also more sharply separated the hepatic flux from dysentery than his predecessors had done. Consult, for example, the passages just cited in *De Locis Affectis*, and *Com. II in Hippoc. Epidem. II.* He describes at length four varieti s of bloody stools: 1, those proceeding from plethora, as in the case of those who have lost limbs, or in whom habitual hæmorrhages are suppressed; 2, those due to hepatic trouble, (the hepatic flux,) in which the stools resemble the washings of flesh; 3, those due to black bile, (ex melancholia,) and, 4, those due to ulceration of the intestine, which alone is properly to be called dysentery. Compare *De Sympt. Causis*, Lib. III, Cap. 7, [Ed. Kühn, VII, p. 246,] with the passage cited above in *Com. II, in Hippoc. Epidem. II.* GALEN tells us that all the physicians of his own time, and most of the ancient ones, limited the use of the term dysentery to cases in which the intestines are ulcerated—*De Locis Affectis*, Lib. II, Cap 5, [Ed. Kühn, VIII, p. 85;] but elsewhere—*Com. IV, in Hip. de Articulis liber*, § 38, [Ed. Kühn, XVIII, A, 724,]—he shows that Hippocrates included all kinds of bloody discharges from the bowels under the designation dysentery. GALEN's four varieties of bloody stools long figured in medical literature. Compare, for example, P. FORESTUS—*Obs. et Cur. Med.*, Lib. XXII, Leyden, 1596, Obs. 31, Scholia, p. 344; HOLLERIUS—*De Morb. Intern.*, (1565,) Lib. I, Cap. 43, (ejusdem Hollerii Scholia,) in Opera, Paris, 1664, p. 341; G. FAB. HILDANUS—*De Dysent.*, (1602,) Cap. I, [in Opera, Frankfort, 1646, p. 667;] L. RIVERIUS—*Prax. Med.*, (1640,) Lib. X, Cap. 6, [in Opera, Lyons, 1679, p. 300;] and ROLFINCIUS—*Epit. Meth. Cognoscend. et Cur.*, &c., Jena, 1655, Lib. III, Cap. 17, p. 291—a list which might readily be greatly extended. CÆLIUS AURELIANUS defined dysentery as rheumatism of the intestines with ulceration—*De Morb. Chron.*, Lib. IV, Cap. 6, [J. C. Amman's edit., Amsterdam, 1709, p. 524.]—He did not treat of tenesmus as a separate affection, but preferred to embrace it under the head of dysentery. According to PAULUS ÆGINETA, dysentery is an ulceration of the intestines, sometimes arising from tenesmus or some f rm of bowel complaint, sometimes being itself the primary disease—Lib. III, Cap. 42, [*Totius Rei Medicæ, Libri VII*, Latin version of J. Cornarius, Basel, 1556, p. 111, or English translation of Francis Adams, Sydenham Society, London, 1844, Vol. I, p. 525.]—Tenesmus he treats as a separate affection– Lib. III, Cap. 41—and describes hepatic dysentery quite after the Galenical view. Compare Cap. 46. GORDONIUS—*Lilium Medicinae*, Venice, 1496, Part. V, Cap. XIV, Fol. 161—"Dissinteria est fluxus sanguineus cum excoriatione et ulceratione intestinorum." FERNELIUS defined dysentery as bloody stools, with pain and griping of the bowels—"Cruenta alvi dejectio cum dolore et ventris torsione"—*Medicina, Pathologia*, Lib. VI, Cap. 10, [Paris edit. of 1554, p. 187.] LOMMIUS—*Obs. Med.*, Antwerp. 1560, Lib. II, fol. 62—as "Cruenta alvi dejectio, cum ulcere intestinorum, cum dolore et torsione." FABRICIUS HILDANUS, as a bloody flux of the bowels, "De Dysenteria, hoc est, Cruento Alvi Fluore," and thought it was best to include all kinds of bloody stools under the name, "Omne cruentum alvi profluvium ex quacunque causa." He describes the four varieties of GALEN, and follows him in regarding the last as dysentery proper—*De Dysenteria*, Liber Unus, in Opera, Frankfort, 1646, p. 666. DANIEL SENNERTUS remarks: "Dysentery consists of frequent and bloody dejections from the bowels, with pain in the abdomen and ulceration of the intestines; or it is an ulceration of the intestines with frequent bloody and purulent dejections, with pain in the abdomen and griping, arising from an acrid matter peculiarly adverse to the intestines and eroding them."—*De Dysenteria Tractatus*, Wittenberg. 1626, p. 2; also *Pract. Med.*, Lib. III, Pars II, Sect. II, Cap. 7, [in Opera Omnia, Paris, 1641, Tom. III, p. 123.] SYDENHAM says: "I discovered that it was a fever—a fever, indeed, of a kind of its own—turned inwardly upon the bowels."—*Obs. Med. circa Morb. Acut. Hist. et Curat.*, Sect. IV, Cap 3, [Opera Medica, Geneva, 1736, Tom. I, p. 111. Latham's Eng. transl., Sydenham Society, London, 1848, Vol. I, p. 169.] FRID. HOFFMANN classed dysentery among the spasmodic and convulsive affections, and defined it thus: "It is, in truth, nothing else than the peristaltic motion of the intestines augmented to a convulsive degree, in consequence of a caustic, ulcerating humor adhering to their coats, and producing a frequent desire of going to stool, these dejections being frequent, consisting of a foul muco-bilious matter, stained with more or less blood or sanies, and accompanied by violent gripings and by febrile disturbance."—*Med. Rat. Syst.*, Tom. IV, Pars III, Sect. II, Cap. 7, [Opera, Geneva, 1740, Tom. III, p. 151.] The definition of SAUVAGES was: "Frequent griping, muco-bloody dejections from the bowels—(Frequens torminosa mucoso-cruenta alvi dejectio.")—*Nos. Meth.*, Amsterdam, 1768, Vol. II, p. 324. He treated of Hepatirrhœa, (the hepatic flux,) Melæna and Tenesmus under separate headings. J. C. NYANDER defined dysentery as a scabies of the intestines, and his thesis, *Exanthema Viva*, having been published by LINNÆUS—*Amœn., Acad.*, Tom. V. (1760,) p. 92—and the imaginary acarus having been described by the great naturalist in the 12th edition of the *Syst. Nat.* [Stockholm, 1767, Tom. I, Pars II, p. 1024] under the designation Acarus Dysenteriæ, NYANDER's definition has been very generally attributed to him In his *Genera Morborum*, (Upsal, 1763,) Linnæus himself defined dysentery as "Diarrhœa cruenta cum Colica, Tenesmo."—I quote from the *Synopsis Nos. Meth.* of CULLEN, Amsterdam, 1775, p. 68. According to CULLEN, dysentery is "a contagious fever; with frequent mucous or bloody stools, the fæces being generally retained; tormina and tenesmus"—(Pyrexia contagiosa; dejectiones frequentes, mucosæ, vel sanguinolentæ, retentis plerumque fœcibus alvinis; tormina; tenesmus)—*Synopsis Nos. Method.*, Amsterdam, 1775, p. 192.—CULLEN classed dysentery among the fevers—*loc. cit.*—See also *First Lines*, Book V, Chap. 2, [Thomson's Ed. of the Works of Cullen, Edinb., 1827, Vol. II, p. 319,] while he placed diarrhœa among the spasmodic affections, [Thomson's Ed., Vol. II, p. 479.] MAXIMILIAN STOLL, like CÆLIUS AURELIANUS, described dysentery as a "rheumatism of the intestines."—*Ratio Medendi*, Pars III, Sect. 4, *De Natura et Indole Dysenteriæ Commentatio*, Vienna, 1780, p. 251 *et seq.* FOURNIER et VAIDY, "On entend par dysenterie une affection qui se reconnait aux caractères suivans: tranchées, ardeur dans le gros intestin, épreintes, ténesme, besoin fréquent, irrésistible et parfois continuel d'aller à la selle, accompagné de violens efforts; évacuation, en très petite quantité, d'une matière muqueuse ou puriforme, souvent mêlée de sang; d'autres fois, purement sanguinolente. Odeur spécifique, extrêmement fétide et nauséabonde des déjections. Fièvre dans la plupart des cas."—*Dict. des Scien. Méd.*, Paris, 1814, T. 10, p. 316. P. VIGNES, "On entend par dysenterie, cette maladie qui consiste dans une phlegmasie, ou inflammation des gros intestins, et qui offre, pour caractères particuliers des tranchées plus ou moins fortes et fréquentes, ayant en général leur siége dans le trajet du côlon transverse; et au bas du rectum, des épreintes ou ténesme, avec des envies fréquentes d'aller à la garde-robe, et des efforts quelquefois inutiles."—*Traité Complet de la Dys. et de la Diarrh.*, Paris, 1825, p. 190. BROUSSAIS defined dysentery as the highest degree of colite, saying, in his account of that inflammation: "Dans son plus haut degré, qui est décrit par tous les

Tenesmus, then, may be conveniently regarded as the pathognomonic symptom in making the distinction between diarrhœa and dysentery, both of which, after all, depend upon different degrees of the same morbid processes;* but even the ancients avoided the error of supposing tenesmus to be a symptom of dysentery alone,† and the systematic writers of the sixteenth and seventeenth centuries, such as Nicholas Piso, Fabricius Hildanus, Felix Plater and Daniel Sennert, correctly enumerated various local causes, such as hemorrhoids, ascarides, ulcers of the rectum, fissure of the anus, stone in the bladder, tumors of adjacent parts, as of the uterus, &c.,‡ by which tenesmus may be produced independently of dysentery. Of course the presence of any of these local conditions must be taken into consideration in making a diagnosis.

The morbid conditions observed in the intestinal mucous membrane after death from acute dysentery suggest a division of the cases into two groups. In the first, the mucous membrane is in a state of ordinary acute inflammation, differing in no essential particular from that which occurs in diarrhœa, except that the inflammatory process is more pronounced in the lower colon and rectum than it is in diarrhœa; in the second, the mucous membrane is affected by a peculiar form of inflammation which may be described as pseudomembranous or diphtheritic. The lesions belonging to the first class exist, as a rule, in the milder, those of the second in the severer, forms of dysentery; the cases belonging to the first group yield readily to medication, indeed, would probably, in the majority of instances, recover without medication; those belonging to the second are exceedingly intractable, and very often prove fatal in spite of the best efforts of the medical attendant. The division of acute dysentery into two varieties, (*a*) simple inflammatory, or catarrhal dysentery, and (*b*) diphtheritic dysentery, which is suggested by anatomical considerations, is therefore warranted by clinical experience. It is true that it is not always possible during life to distinguish between these two forms of dysentery, and that both clinical and anatomical considerations make it highly probable that cases of the simple inflammatory variety often pass into the diphtheritic form in their later stages, yet

auteurs sous le nom de dysenterie, le malade est tout-à-coup saisi de tranchées violentes, suivies de selles, d'abord stercorales, ensuite muqueuses, bilieuses, sanguinolentes, et en même temps d'efforts tres douloureux qu'on appelle ténesmes."—*Hist. des Phlegmasies*, 3ème Édit., Paris, 1822, Tome III, p. 49. CHOMEL et BLACHE, "On donne généralement le nom de dysenterie à une des formes de l'entérite, dont les symptômes particuliers sont le besoin répété ou même presque continuel d'aller à la selle, des douleurs cuisantes et une chaleur vive au dessus de l'anus, qui augmentent, dans les efforts, l'excrétion fréquente, laborieuse de mucus sanguinolent, quelquefois vitré, de sérosité rougeâtre, rendus presque toujours en petite quantité à la fois."—*Dict. de Méd.*, Tome 10, Paris, 1835, p. 544. J. BROWN, "Frequent mucous or muco-sanguinolent stools, pain in the abdomen, griping and tenesmus, generally accompanied with pyrexia."—*Cycl. of Prac. Med.*, Vol, I, Amer. Ed., Philadelphia, 1845, p. 720. COPLAND, "Tormina, followed by straining and scanty mucous and bloody stools, containing little or no fæcal matters; and attended by febrile disturbance."—*Dict. of Pract. Med.*, Vol. I, London, 1858, p. 693. J. DELIOUX DE SAVIGNAC, "La dysentérie est une maladie douloureuse et grave, caractérisée symptomatiquement par des coliques, des épreintes, du ténesme, avec production d'une matière spécifique muco-sanglante au début et flux séro-bilieux plus ou moins considérable ultérieurement; elle a pour caractère anatomique une phlogose du gros intestin, qui, frappant d'abord la muqueuse, peut ensuite en attaquer toutes les tuniques, et tend à l'ulceration, à la suppuration, ou à la gangrène."—*Traité de la Dysentérie*, Paris, 1863, p. 5. A. BARRALLIER, "La dysenterie est une maladie spécifique de nature infectieuse, ayant pour principaux symptômes: une douleur abdominale plus ou moins intense avec envies incessantes d'aller à la selle, accompagnée d'un sentiment très-pénible de tension et de cuisson à la région recto-anale (ténesme);—des évacuations peu abondantes de matières liquides non fécales, le plus souvent mêlées à une quantité plus ou moins considérable de sang;—un mouvement fébrile très-variable dans son intensité et sa continuité;—un amaigrissement rapide et très prononcé;—une grande tendance aux récidives et à la chronicité, surtout pour les dysenteries endémiques;—et caractérisée anatomiquement par des lésions ayant leur siége principal dans le gros intestin."—*Nouv. Dict. de Méd. et de Chir. Prat.*, T. XI, Paris, 1869, p. 714. S. JACCOUD, "La dysentérie est une COLITE ULCÉRO-MEMBRANEUSE TRANSMISSIBLE, caractérisée par du ténesme, des épreintes, l'excrétion répétée de mucosités sanguinolentes, et un état général plus ou moins grave."—*Traité de Path. Interne*, 2me Édit., Paris, 1872, T, II, p. 326. G. B. WOOD, "Dysentery is inflammation of the mucous membrane of the colon and rectum, characterized by small mucous or bloody evacuations, griping pains in the abdomen, straining at stool, and tenesmus. Inflammation in the colon, without these phenomena, would rank under enteritis."—*Prac. of Med.*, 6th Ed., Philadelphia, 1866, Vol. I, p. 712. AITKEN, "An infectious febrile disease, accompanied by tormina, followed by straining, and scanty mucous or bloody stools, which contain little or no fecal matter. The minute lenticular and tubular glands of the mucous membrane of the large intestines, with the intertubular connective tissue, are the chief seats of the local lesion, which sometimes extends into the small intestine beyond the ileo-colic valve; as in cases in which scorbutus is a predisposing cause."—*Science and Pract. of Med.*, 3d Amer. Ed., from 6th Lond. Edit., Philadelphia, 1872, Vol. II, p. 634.

* This relationship did not escape the author of the Hippocratic treatise *On Affections:* "These diseases, dysentery, lientery and diarrhœa, are similar."—*De Affect. Liber* [Ed. Littré VI, p. 237.] Compare the quotations from Bouillaud in the second note to p. 266, *supra*.

† See, for example, the descriptions of tenesmus in the passages cited in note ‡ to p. 336, *supra*, from the Hippocratic writings, and those of CELSUS, GALEN, &c.

From No. 668. MICROSCOPICAL SECTION.

important differences exist, which, if carefully observed during the progress of the disease, are sufficient to serve as the basis of diagnosis in the majority of cases.

Specimens collected at the Army Medical Museum, and autopsies recorded in Section III, show that the majority of the cases of acute dysentery which proved fatal during the late war belonged to the diphtheritic form. They also show that patients in the last stages of acute diphtheritic dysentery, emaciated and moribund, were often received from the field into the general hospitals, where, in the absence of any previous history except the imperfect and sometimes contradictory statements of the dying men, the diagnosis "chronic diarrhœa" or "chronic dysentery" was entered on the hospital register. These facts must be considered in interpreting the statistics of acute dysentery published in the First Medical Volume of this work. According to these statistics, as has been shown in the first section of this chapter,* the mortality of acute dysentery during the war was one death to every fifty-seven cases among the white troops, one to every seventeen among the colored troops; but these figures no doubt altogether understate the mortality of the disease, owing to the frequency with which the fatal cases were reported under the head of chronic diarrhœa or dysentery, in the manner just mentioned. This consideration must serve to correct the impression, which would otherwise be given by the statistics, that the acute dysentery of our armies during the late war was, especially among the white troops, a comparatively mild affection.† At the same time there is testimony from various sources that mild cases of dysentery were common enough, particularly during the early part of the war. Without going into details in this place, the reports for May and June, 1861, which give 994 cases of acute dysentery and but 3 deaths,‡ may be referred to, and attention may be directed to the fact that, although the source of error just pointed out can hardly have had a greater influence during the first year of the war than subsequently, the reports for the year ending June 30, 1862, represent but one death to every ninety-five cases of acute dysentery.§ The majority of these milder cases belonged, doubtless, to the simple inflammatory or catarrhal form, and it is on account of this circumstance that the lesions characteristic of this form of dysentery were observed in the autopsies made during the war so much less frequently than the diphtheritic lesions. The severer diphtheritic cases not merely constituted an exceedingly frequent and fatal variety of the camp dysentery of the civil war, but since the close of the war cases of this form of disease have occasionally been observed, during the course of local epidemics in the garrisons of the military posts, of which the epidemic that occurred in the detachment of troops stationed at Columbia, South Carolina, during the fall of 1868, and is described by Assistant Surgeon Elliott Coues, U. S. A., in the second section of this chapter,‖ affords an excellent example.

The division into two groups here employed is substantially the same as that into catarrhal and diphtheritic dysentery adopted by the best modern German writers on

* Page 5.

† In my "*Outlines of the Chief Camp Diseases of the United States Armies as observed during the present war*," Philadelphia, 1863, p. 223, I fell into this error, remarking: "Simple cases of ordinary acute dysentery have been common enough in the army. They have, however, as a general rule, been very mild. Of 32,237 cases reported prior to June 30, 1862, but 347 died. The malignant dysentery of European armies has not yet made its appearance among our troops." I am now satisfied that the diphtheritic form of acute dysentery, which will be described in this section, and which is essentially the same as the form which has at times decimated European armies, had made its appearance before I wrote, and that indeed a portion of the 638 deaths from chronic diarrhœa and dysentery reported during the same period were really due to this form of disease, which, however, certainly became still more frequent subsequently, and always produced a greater mortality among our troops than would be suspected from the sick reports alone. [The figures in the quotation from my book, which are the same as those subsequently given in *Circular* No. 6, p. 103, are slightly inaccurate; including the months of May and June, 1861, they should read 33,214 cases and 341 deaths. See Medical History, Vol. I. p. 636.]

the disease, such as Virchow, Griesinger, Bamberger, Niemeyer and Heubner.* The credit of having first made this distinction has been assigned by Heubner to Virchow, but while acknowledging that great observer to have done good service, by the publication of two remarkable essays, towards bringing about the modern general acceptance of this view, his own contribution to it was merely the substitution of the term diphtheritic, as applied to the dysenteric inflammation, for such terms as "inflammation with the effusion of coagulable lymph," "pseudomembranous inflammation," and "croupous inflammation," which had previously been employed to describe the lesions of the intestinal mucous membrane observed after death from the graver form of dysentery. Indeed, Alexander of Tralles,† as early as the sixth century, under the title of *Dysenteria Rheumatica*, discriminated that form of dysentery in which various humors merely are discharged by stool, from the graver variety due to ulceration of the bowels, in which shreds of the intestine (pseudomembrane) are mixed with the discharges, and pointed out that the first variety, if protracted, might pass into the second. His descriptions are far from complete, especially from the anatomical point of view; yet the candid reader will not fail to be struck by their correspondence with the modern descriptions of catarrhal and diphtheritic dysentery. That this sagacious discrimination of the two chief forms of dysentery, which appears to have been based almost exclusively upon clinical considerations, and especially upon a study of the dejecta, did not attract the attention it deserved, is not surprising, when we consider that the study of pathological anatomy was not sufficiently advanced to furnish a sound anatomical basis for the distinction until the commencement of the present century.

The adjective rheumatic was not used by Alexander of Tralles in its modern sense, but as the equivalent of the term catarrhal, a use which is warranted by the derivation and history of the word. Cælius Aurelianus and Theodore Priscian‡ had previously spoken of dysentery as rheumatism of the intestines with ulceration, and still earlier Philumenus§ had called diarrhœa rheumatism of the bowels in the very same sense. By the Greek physicians the word *Rheuma* was used to signify a flux, and the derivatives *Rheumatikos* and *Rheumatismos* were employed, the first as an adjective, the second as a noun, to indi-

* R. VIRCHOW—*Zur Lehre der Unterleibsaffectionen*, V. Archiv, Bd. V, (1853,) S. 348; Idem, *Kriegstyphus und Ruhr*, Bd. LII, (1871,) S. 21. W. GRIESINGER—*Die Krankheiten von Egypten*, Abs. X, Cap. 2, Dysenterie. Archiv für Phys. Heilkunde, 1854, p. 529. H. BAMBERGER—S. 384, *op. cit.*, p. 266, *supra*. F. v. NIEMEYER—*Lehrbuch der Spec. Path. und Ther.*, 7te Aufl., Berlin, 1868, Bd. I, S. 621; Bd. II, S. 747 *et seq.* HEUBNER—*Dysenterie*, in Ziemssen's Handbuch der Spec. Path. und Ther., Bd. II, Theil I, Leipsic, 1874, S. 518. American Transl., New York, 1874, Vol. I, p. 537.

† ALEXANDER of TRALLES—*Libri duodecim*, Greek text with Latin transl. of J. Guinterius, Basel, 1556, Lib. VIII, Cap. 7, in edit. cited, pp. 423–431—treats of diarrhœa under the title of rheumatism of the intestines, (Περὶ ῥευματισμοῦ τῆς γαστρός.) The account professes to be borrowed from PHILUMENUS, and it is from this writer doubtless that the term used is derived. In Cap. 8 [pp. 432–454] he treats of rheumatic dysentery, (Περὶ δυσεντερίας ῥευματικῆς.) which he explains is excited by diarrhœa, (rheumatism of the intestines.) In Cap. 9 [pp. 454–472] he treats of the dysentery of the ancients, or that which arises from ulceration of the intestines. In rheumatic dysentery various acrid humors are discharged from the bowels, and, if the affection lasts long, it may result in ulceration of the bowels, which is true dysentery: "Quòd si hic affectus diutius perseveraverit, ad ulcerationem intestinorum perveniet, quæ propriè dysenteria dicitur," [p. 432.] This seems to be essentially the same idea which VIRCHOW has expressed in the words, "Dass eine katarrhalische Ruhr sich durch besondere Einwirkungen zur diphtheritischen Ruhr steigern könne."—*Kriegstyphus und Ruhr*, Virchow's Archiv, Bd. LII, S. 21. See also a similar passage in Archiv, Bd. V, S. 348. In the dysentery of the ancients the intestines are ulcerated, and the stools contain blood and scrapings of the intestines, (Ξύσματα;) the latter were undoubtedly our modern pseudomembranes and sloughs. Besides these two varieties of dysentery, our author in another place—Lib. VIII, Cap. 3 and 4, [pp. 400–413,]—describes hepatic dysentery, in which the stools resemble the washings of flesh, very much after the Galenical view. He has also a separate chapter on tenesmus, Cap. 6, [pp. 420–22,] and one on the cœliac flux, borrowed from PHILUMENUS, Cap. 5, [pp. 413–420.]

‡ THEODORE PRISCIAN—*Ad Timotheum*, Lib. II, Pars 2, Cap. 18, [in the Aldine *Med. Antiq.*, Venice, 1547, fol 306.] This author, who wrote in the 4th century, says: "Est nanque dysenteria intestinorum vulneratio, cum rheumatismo." CÆLIUS AURELIANUS, two centuries before, had written: "Est autem intestinorum rheumatismus cum ulceratione." [*Loc. cit.*, *supra*, p. 337]

§ PHILUMENUS, according to MANGETUS—*Bibl. Script. Med.*, Geneva, 1731, Vol. II, Part 1, p. 502—lived about the year 352 A. D., a date in regard to which some doubt may be entertained. None of his works are extant, but extracts from them are to be found in ALEXANDER of TRALLES, as for example those referred to above in note † *supra*, and a still larger number in the writings of ÆTIUS. Among the latter, note especially the chapter on diarrhœa—Tetrab. III, Serm. 1, Cap. 35, [*op. cit.*, *supra*, p. 335.]—headed: "Quomodo alvum fluxione laborantem curare oporteat; ex libris Philumeni," which appears to be translated from the same source as Cap. 7, Lib. VIII of ALEXANDER of TRALLES. The Greek text of the last eight discourses of ÆTIUS has not been printed, and I have not obtained access to any Greek manuscript; but the chapter of ALEXANDER of TRALLES, just referred to, seems to leave no doubt that PHILUMENUS spoke of diarrhœa as rheumatism of the bowels. GALEN himself, who ordinarily used the word diarrhœa in the sense in which it is now employed, substituted for it the expression ῥεῦμα γαστρός in his *First Commentary on the Prognostics of Hippocrates*, § 8, [Ed. Kühn, XVIII, B, p. 33.] Note the remarks on the passage in question by GORRÆUS in his *Def. Med.*—Opera, Paris, 1622, p. 550.

cate the morbid condition from which the flux results.* The word Catarrh was substituted whenever the flux was believed to take place from the upper part of the body to the lower. The disease which we now know as rheumatism was described by them along with gout, under the designation Arthritis,† and is first spoken of as rheumatism in the seventeenth century, when we find the modern conception of that affection taking shape in the writings of Ballonius, C. Piso, Riverius, Chesneau and Sydenham,‡ who bestowed the term rheumatism upon it on account of its supposed fluxionary character. Since the general adoption of this

* The Greek words used were ῥεῦμα and its equivalent ῥόος, or some inflection or compound of the verb ῥέω, to flow. For the doctrine of fluxes as taught in the Hippocratic writings,—see the treatise *De Locis in Homine*, [Ed. Littré, VI, p. 291.]—The morbid humor (*e. g.* phlegm) is formed in the head, and thence may be transported to any one of seven places, making seven fluxions, viz: to the nose, ears, eyes, chest, spinal marrow, vertebræ and flesh (producing dropsy) and the hip. In connection with the fifth variety, fluxes to the belly producing loose alvine discharges, are ascribed to the humor finding its way to the intestines through the œsophagus; the word here used to express such a flux is ῥεῦμα, § 20, p. 312. In the treatise on *Affections*, [Ed. Littré, VI, p. 237,] it is explained that the flux producing diarrhœa, lientery or dysentery, comes from the head or chest; the word here used is catarrhus, (κατάῤῥοος.) Compare also the treatise *De Flatibus*, [Ed. Littré, VI, p. 105,] in which the doctrine of fluxions is discussed at length, and flatus in the veins of the head declared to be the cause of the formation of the morbid humor; and the treatise on *Glands*, [Ed. Littré, VIII, p. 565,] in which the origin of the morbid humor in the brain, here compared to a gland, the doctrine of the seven fluxes and the flux to the abdomen are explained very much as in *De Locis in Homine*, cited above. The accord between the above passages, which occur in Hippocratic treatises of doubtful origin, derived probably from several distinct sources, would seem to indicate that the doctrine in question was widely accepted among the older Greek physicians. In all its essential points this doctrine was taught also by GALEN, but with him it formed only a portion of the general doctrine of fluxes which lies at the foundation of his pathology, and which, mainly on his authority, was generally accepted for more than fourteen centuries. According to GALEN, every part of the body is endowed by nature with four faculties: 1, the faculty of attracting its proper aliment; 2, of detaining this within it; 3, of altering and assimilating it; 4, of expelling the superfluous or excrementitious matter which results from the nutritive process.—*De Diff. Feb.*, Lib. II, Cap. 14, [Ed. Kühn, VII, p. 381;] *De Cur. Rat. per Venæ Sectionem*, Cap. 8, [Ed. Kühn, XI, p. 275.] These four faculties, which play a great part in the Galenical physiology, are discussed at length in the treatise *De Nat. Facult.*, [Ed. Kühn, II, pp. 1–214.] If now, in any morbid condition, the quantity of nutriment supplied to a part is greater than it is able to assimilate, the surplus may undergo various unhealthy changes, and the phlegm, or other excrementitious humor which results, and which would produce morbid alterations in the part itself if it remained in it, is very often driven from it by the expelling faculty, and finds its way to other parts through the bloodvessels or any of the pores and passages of the body. In this transfer of the morbid humor it finds its way usually from the upper parts of the body to the lower, or, in a more general way, from the stronger parts to the weaker, even without regard to position.—*De Diff. Feb.*, Lib. II, Cap. 14. Moreover, a flux may be called to a part by an abnormal increase of the attractive faculty of the part itself.—*De Diff. Feb.*, Lib. II, Cap. 15, [Ed. Kühn, VII, p. 384.] The formation of a morbid humor in the head and its descent thence to the nose, eyes, mouth, fauces, throat, or even to still lower parts, as the thorax, abdominal viscera, &c., is only one illustration of this morbid process, or one kind of flux, but a very important and frequent kind. Compare the account of this kind of flux in *De Sanitat. Tuenda*, [Ed. Kühn, VI, pp. 420–5.] In the Commentary on Aphorism III, 12, [Ed. Kühn, XVII, B, p. 586,] GALEN explicitly teaches that dysentery may be produced by the flux of phlegm from the head to the intestines, and the same doctrine is taught more or less clearly in various other places. But the flux may also take place from the liver, spleen or other parts, to adjacent or even to distant organs—*De Diff. Feb.*, (loc. cit.,)—or even from the interior parts of the body to the exterior, producing inflammations.—*Ad Glauconem de Medendi Methodo*, Lib. II, Cap. 2, [Ed. Kühn, XI, p. 78.] The morbid condition of debility or cachexia, which favors the development of such fluxes, is the rheumatic diathesis, [Ῥευματικὴ διάθεσις.]—*De Curandi Rat. per Venæ Sectionem*, Cap. 8, [Ed. Kühn, XI, p. 275.] See also the passage last cited above. The morbid humor, whose movement constitutes the flux, may consist either of phlegm or morbid bilious matter, (black or yellow bile,) in accordance with the causes by which it is produced. See, for example, *Com. IV, in Hippoc. de Acut. Morb. Victu*, § 27, [Ed. Kühn, XV, p. 790.] If the flux takes place from an upper part to a lower, it is called a catarrh, [κατάῤῥοος.] This term is especially applied to the flux which descends from the head to the mouth and air-passages,—*De Sympt. Causis*, Lib. III, Cap. 11, [Ed. Kühn, VII, p. 262,]—but it may also be bestowed upon the flux if it descends to the abdominal viscera.—*Com. in Hipp. Aph. III*, 12, cited above; also *Meth. Medendi*, Lib. VII, Cap. 11, [Ed. Kühn, X, p. 513.] For a concise abstract of the Galenical doctrine of catarrh and flux the reader may consult GORRÆUS, *Def. Med.*, Articles Ῥεῦμα, Ῥευματικὴ διάθεσις and Κατάῤῥοος.

† See, for example, the Hippocratic account of arthritis in *De Affect. Liber*, [Ed. Littré, VI, p. 213.] Acute rheumatism appears to be referred to as a variety of fever (ἄλλος τῦφος) in the treatise *De Intern. Affect.*, [Ed. Littré, VII, p. 267.] See also ARETÆUS—*De Causis et Signis Diut. Morb.*, Lib. II, Cap. 12, [Boerhaave's Ed., p. 65.]

‡ BALLONIUS, in his *Definitiones Medicæ*—[in Opera, Geneva, 1762, Tom. I, p. 265]—published after his death, (1616,) expounded, under the head of "Rheumatic diathesis," the humoral doctrine of flux as taught by HIPPOCRATES and GALEN, and referred at the end of the article to his own views as explained in his *Liber de Rheumatismo et Pleuritide Dorsali*, [op. cit., Tom. IV, p. 314 *et seq.*] In the part of the latter work which treats of rheumatism, he tells us that this affection has not been sufficiently explained by the ancients, and gives a very fair description of rheumatism in the modern sense, with pains in the muscles and tendinous parts as well as in the joints. See also the thesis appended to this treatise, entitled "An Rheumatismus et Arthritis Congeneres?" [*op. cit.*, Tom. IV, p. 331;] a question which he decides in the affirmative, giving the differential diagnosis in a manner which shows that he had under consideration the same diseases which we now call rheumatism and gout. Compare also his *Liber de Arthritide*, [op. cit., Tom. IV, p. 205.] CAR. PISO—*Morbi Externi Habitus à Diluvie Serosa, Obs. et Consil.* [Ed. Princeps, 1618; I quote from the Leyden Ed. of 1714]—treats of Arthritis in Sect. V, Cap. 1 and 2, and in Cap. 3 treats separately of pains affecting not only the joints, but also the muscles, periosteum, &c.; he does not, however, employ the term rheumatism. LAZARUS RIVERIUS—in *Prax. Med.*, Lib. XVI, Cap. 3, *De Rheumatismo*, [Opera, Lyons, 1679, p. 418,]—also distinguished rheumatism from gout (arthritis) by the circumstance that in rheumatism the muscles, periosteum, &c., are affected as well as the joints, while in gout the joints alone are involved. He remarks: "This is no new disease, yet it is not sufficiently described by the ancients," and "most physicians, who are ignorant of the nature of rheumatism, are wont to call it universal gout," (eum arthritidem universalem nominare solent.) His description applies to chronic rheumatism rather than to acute, for he says: "Experience shows that in rheumatism, for the most part, there is no swelling, inflammation or change of color in the parts pained." Yet the acute form would seem to be indicated when he says: "If rheumatism begins with fever it is usually shorter, but torments the patient with more direful and cruel pains, and then gets well, or, at least, is much improved in from twenty to forty days." [*Op. cit.*, p. 420.] He relates in detail two cases of rheumatism—*Obs. Med. et Cur. Insig.*, Cent. III, Obs. 41, [*op. cit.*, p. 525,] and Cent. IV, Obs. 42, [*op. cit.*, p. 543.] NICOLAS CHESNEAU—*Observationum*, Libri V, Paris, 1672—has a chapter on rheumatism [Lib. IV, Cap. 12, p. 446] in which that disease is similarly explained. SYDENHAM, in his chapter on rheumatism—*Obs. Med.*, Sect. VI, Cap. 5, [Princeps Ed. 1676; I quote Opera, Geneva, 1736, Tom. I, p. 170. See also Translation of Sydenham Society, Vol. I, p. 254,]—gives the first complete description of acute rheumatism as now understood. A summary account of these changes in the use of the word rheumatism will be found in the article *Rheumatismus* in the *Medicinal Dictionary* of R. JAMES, London, 1745, Vol. III. See also the historical introduction to the curious work of EISENMANN—*Die Krankheits-Familie Rheuma*, Erlangen, 1841, Bd. I, S. 1–11—which is particularly valuable on account of its excellent bibliography, both on the subject of rheumatism in general and of the various disorders supposed to be of rheumatic origin, under which head EISENMANN includes, apparently with the utmost confidence, everything that any of his predecessors ever suspected to be of rheumatic nature.

use of the term, the old broader conception of its meaning has gradually become entirely obsolete, and at the present time the semi-obsolete word *rheum*, applied to thin discharges from the air-passages, or from certain skin diseases, appears to be its only survivor.

In the latter half of the last century, when the views of Alexander of Tralles with regard to this subject had long fallen into undeserved neglect, several writers,* among whom the most notable was Maximilian Stoll,† brought up anew the doctrine of the catarrhal nature of dysentery. Stoll brought again into use the old term rheumatism of the intestines, which he employed, as he himself explains, as the equivalent of "coryza ventris," and "intestinorum catarrhus;" but he had also adopted the new use of the word rheumatism proposed by Ballonius;‡ and this led him to assert a close relationship between the intestinal flux and the flux to the joints, which modern pathology cannot admit. Moreover, he fell into an error that Cœlius Aurelianus and Alexander of Tralles had escaped. He asserted, led to this erroneous belief by the results of his own dissections, that ulceration of the intestine is an extremely rare complication in dysentery.§ The doctrine of Stoll found numerous partisans‖ at the time, and if of late it has seemed ridiculous to certain writers, this is only because the old signification of the word rheumatism has been forgotten.

* Among those who, before STOLL, insisted upon the catarrhal nature of dysentery, I may mention ANDREW WILSON—*An Essay on the Autumnal Dysentery*, London, 1761—who, though he did not use the epithet catarrhal, rejected all the popularly accepted causes of dysentery, such as the abuse of fruits or "venomous or infectious effluvia in the air," and attributed it to a suppression of the cutaneous perspiration due to exposure to cold: "The two surfaces of the lungs and intestines being to the surface of the skin, in a manner like two seconds to a principal, assisting and relieving it, in accommodating its perspiration to the seasons; whenever any sudden change gives a damp to the perspiration," the lungs or intestines suffer; the former for the most part in the spring, the latter in the autumn. MARK AKENSIDE—*De Dysenteria Commentarius*, London, 1764—known to the literary reader as the author of "The Pleasures of the Imagination,"—insisted upon the strict affinity of dysentery with rheumatism: "ejus est arctissima cum rheumatismo affinitas," (p. 21.) He explains that he gives the name of rheumatism "to those pains with which the joints, and the muscular and membranous parts of the body are affected, whether there is fever or not," and insists upon the fact that such pains sometimes occur during convalescence from dysentery, and sometimes during the progress of the disease, very much as STOLL subsequently did. With these views, he insisted on the use of diaphoretics, and especially of ipecacuanha, in the treatment, (p. 40.) BENJ. MOSELEY—*Obs. on the Dysentery of the West Indies*, London, 1781—in a tract dated Kingston, in Jamaica, July 15, 1780, (of which the copy cited is a reprint from the second Jamaica edition,) says: "That a flux is a *certain fever* of the intestines, and that this fever is caused by the *obstructed perspiration* being thrown there," (p. 5,) and therefore recommends sudorifics; "*a careful, continued course of them, to keep up a* SWEAT, *in extent proportioned to the violence of the disease*," (p. 10.) The same ideas were subsequently still further elaborated in *A Treatise on Tropical Diseases*, &c., 3d Ed., London, 1792, pp. 215 and 225.

† MAXIMILIAN STOLL—*De Natura et Indole Dysenteriæ Commentatio*, [Rat. Med., Pars III, Vienna, 1780, p. 245 *et seq.*]—asserted the cause of dysentery to be exposure to cold while in a state of perspiration. This cause produces in the winter inflammations of the upper parts of the body; of the middle parts in spring, and of the abdomen in summer and autumn. Of this reflux of the perspirable matters upon the intestines he says: "Hinc materies, quæ alio anni tempore aut odontalgias fecerat, aut coryzas, anginas, catarrhos, &c., morbos videlicet serosos: nunc ad intestinorum membranas projecta *ventris coryzam*, aut *intestinorum catarrhum*, aut *eorundem rheumatismum* fecit." [*Op. cit.*, p. 251.] In chaps. 2 and 3 he divides dysentery into—1, simple rheumatic; 2, rheumatico-bilious, or simply dysentery associated with excessive secretion of bile, allied to which are dysenteric bilious fever and dysenteric putrid fever, (synochus putris dysenterica,) and 3, inflammatory dysentery, *i. e.*, associated with inflammatory fever. This last variety he subdivides into benignant and malignant. In chap. 4 he offers a new subdivision of dysentery, drawn from its supposed relationship with the varieties of rheumatism. So strongly does this relationship impress him that he exclaims: "Hinc dysenteria non ob remotam quamdam analogiam, et per metaphoram, sed *verè* ac *genuinè rheumatismus intestinorum* dicetur, suntque hi duo morbi ἀδελφέα παθήματα, atque ejusdem matris," (p. 275.) The proposed subdivision is—1, simple benign, easily-curable dysentery; 2, chronic dysentery, comparable to chronic rheumatism of the limbs; 3, a grave and mortal variety, due to an inflammation of the intestines, which he compares to erysipelas, and 4, bilious dysentery. In this chapter he plainly shows that he uses the word rheumatism, in part at least, in the new sense, pointing out that sometimes rheumatism in the limbs suddenly disappears and dysentery supervenes, while, in other cases, the dysentery suddenly ceases and the wrists and knees swell and become painful, (p. 273.) Undoubtedly, therefore, STOLL had actually observed cases in which dysentery was complicated by rheumatism as we now understand it. STOLL studied dysentery during the summers of 1776–9, and gives in chap. 11 several autopsies, in two of which he describes the colon as inflamed and thickened, and mentions that its glands were tumefied, [pp. 345 and 346.] From these autopsies it was that he arrived at the conclusion that ulceration of the intestines is very rare in dysentery: "In cadaveribus dysentericorum nunquàm offendi suppuratam plagam, ut ideircò perraro existimem intestinorum ulcera ex dysenteria," [p. 323.] Of course the views of STOLL exclude the idea of contagion. He asserts that he never has seen it attack physicians or nurses attending to dysenteric patients, and that although the dejecta are offensive in odor, and invite putrid diseases, such as hospital fever, yet the notion that they produce dysentery in those who are exposed to them is not supported by observation. [*Op. cit.*, p. 327.]

‡ Compare *Rat. Medendi*, Pars I, Ann. 1776, Maius, p. 77 *et seq.*, ed. cited in last note. § See note † *supra*.

‖ Among others, I may mention D. OPPENHEIMER—*Diss. de Catarrho et Dysenteria*, Halle, 1783, which I have not seen; the author is said to take the ground that dysentery is a catarrh of the intestinal canal. See the abstract in S. J. L. DÖRING'S *Critisches Repertorium*, Herborn, 1803, S. 95. F. H. BIRNSTIEL—*De Dysenteria Liber*, Manheim, 1786. A. G. RICHTER—*Med. und Chir. Bemerkungen*, Göttingen, 1793, [there is also an English translation, Edinburgh, 1794,]—says that dysentery is "a rheumatic or catarrhous affection of the intestines, particularly of the great guts, and that the proper remedies for the disease are sedatives and diaphoretics," (S. 86.) He thinks that there may be "a specific catarrhous miasma," and remarks: "The influenza has given strong proofs of this," (S. 107.) HUFELAND—*Bemerkungen über die im Herbst, 1795, in und bey Jena ausgebrochene Ruhrepidemie, und den ausgezeichneten Nutzen der Nux Vomica in derselben*, Hufeland's Journal, Bd. I, [1795,] S. 76 *et seq*—expressed the opinion that dysentery is a mere local disease of the large intestine, as gonorrhœa is of the urethra and catarrh of the bronchial mucous membrane, and that indeed it has the greatest analogy with these diseases, (S. 90.) He found the cause in suppressed perspiration, and specially brings forward the influence of cold nights after hot days on individuals previously exposed to the continuous heat of summer, (S. 94.) He uses STOLL'S designation "simple or rheumatic dysentery," (S. 96 and 99) to describe the class of cases most commonly observed by him. Inflammatory complications were not frequent in the epidemic, but putrid complications were more common. In connection with the inflammatory complications, he mentions a post mortem examination in an old man in whom the glands of the large

Nevertheless, he must be admitted to have given undue prominence to the catarrhal form of dysentery to the exclusion of a due consideration of the graver variety, in which pseudo-membranous deposits and ulceration play a prominent part. He presented this one-sided view with great ingenuity, but even his genius would hardly have secured for it the favor it enjoyed, had post mortem examinations been common among his contemporaries.

A broader view was taken at the commencement of the present century by J. P. Frank, who not only anticipated O'Brien, to whom Heubner* has erroneously given the credit of being the first "to bring up the idea of pseudomembranous inflammation of the intestine," but also anticipated Virchow, if not in the application of the word "diphtheritic" to the dysenteric process, at least in an appreciation of the anatomical facts by which this use of the term diphtheritic is justified, so far as they can be observed without the aid of the microscope. Frank asserted† that mere suppression of perspiration produces diarrhœa rather than dysentery; that dysentery consists essentially in an inflammation of the colon and rectum, which may be of various characters, sometimes superficial, sometimes deep; that these diverse inflammations of the lower end of the alimentary canal are strictly comparable to the inflammations of the throat (that is, of the upper end of the alimentary canal) and are produced by similar causes; and that grave dysentery, especially malignant dysentery, is characterized by a condition of the intestinal mucous membrane which exactly resembles the state of the mucous membrane of the throat observed in membranous and ulcerous cynanche,—that is, as his description‡ shows, the disease which we now call diph-

intestine were enlarged to the size of small peas and numerously sprinkled over the surface. The patient died of dysentery after long suffering from chronic diarrhœa, (S. 104.) C. G. SELLE—*Med. Clinica*, Wien, 1797: "The cause of this disease (dysentery) is a special epidemic miasma which causes a sort of catarrh in the intestines," (p. 139.) "It is also frequently observed that rheumatisms and pains in the teeth precede, which disappear as soon as the dysentery sets in," (p. 140.) C. F. HARGENS—*Ueber die epidemische Constitution zu Kiel, besonders die dortige Ruhrepidemie im Jahr* 1798, Hufeland's Journal, Bd. VII, [1799.] St. 2, S. 87; St. 3, S. 130—also speaks of dysentery of the "simple rheumatic character," [St. 2, S. 106.] He states that rheumatic pains were frequent toward the end of the disease, especially in the hip-joints and the lower extremities, sometimes also between the shoulder-blades; often these pains alternated with the dysenteric symptoms, [St. 3. S. 141.] J. H. G. SCHLEGEL—*Epidemische Constitution von Ilmenau; nebst einer allgemeinen Uebersicht von Michaelis*, 1796, *bis Michaelis*, 1798, *daselbst beobachteter Krankheiten*, Hufeland's Journal, Bd. IX, [1800.] St. 1, S. 84—says, in the same spirit, of the dysentery which was epidemic at Ilmenau in November and December, 1797: "Mir schien diese Ruhr rheumatischen Ursprungs zu seyn. Ansteckend war sie nicht," [S. 105.] According to F. LESSER—*Die Entzündung und Verschwärung der Schleimhaut des Verdauungskanales*, &c., Berlin, 1830, S. 278—the doctrine of STOLL was embraced also by PAULITZKY—*Med. Prakt. Beobacht.*, Frankfort, 1784, 2te Sammlung, S. 55; VAN GEUNS—*U. d. epidem. Ruhr besonders des Jahrs*, 1783, Dusseldorf, 1790; VOGLER—*Von der Ruhr und ihrer Heilart*, Giessen, 1797, and VOGEL—*Handbuch der prakt. Arzneiwiss.*, Thl. VI, S. 132. LESSER [*loc. cit.*] makes the same statement with regard to J. P. FRANK; but in this case he does not appear to be at all accurate. FRANK—*De Curandis Hominum Morbis Epitome*, Lib. V, Pars II, § 687–693, [Lib. V, Pars II, of this work was first published, Mauheim, 1807; I quote from the Milan Ed. of 1832, Vol. III, p. 436]—makes the fluxes his 5th class of diseases, and divides them into—1, serous fluxes; 2, mucous fluxes, (including catarrh of the air-passages, blenorrhagia, &c.;) 3, sanguine fluxes; and 4, mixed fluxes, describing diarrhœa and dysentery under this last head. Suppressed perspiration he thinks causes *diarrhœa*—not dysentery—and although rheumatismal symptoms are sometimes observed in the course of dysentery and seem to arrest the flux, yet this is not because the two diseases depend on the same cause, but because a new disease, though it may depend on a different cause, often imposes its law on its predecessor. [*Op. cit.*, p. 443.] FRANK originated a conception of the dysenteric affection, based upon anatomical observation, which is very similar to the modern opinions. See note ‡ *infra*. Among the latest of the writers who have given prominence to the conception of rheumatic dysentery, as taught by STOLL, I may mention EISENMANN—*Die Krankheits-Familie Rheuma*, Bd. III, Erlangen, 1842. S. 353—who describes, under the designation *Myko-Rheuma Coli*, the dysenterica rheumatica of his predecessors.

* HEUBNER, p. 502 of work cited p. 340, *supra*, p. 521 of American transl. O'BRIEN'S book, to which reference is made, is his *Observations on the Acute and Chronic Dysentery of Ireland*, Dublin, 1822, which I have not been able to see.

† J. P. FRANK—*De Curandis Hominum Morbis Epitome*, Lib. V, Part 2. [Edit. cited above, Vol. III, p. 436 *et seq.*] Note particularly his discussion of the causes of dysentery, § 691.

‡ The passage in which these views are expressed [Ed. cited, Vol. III, p. 444] is so noteworthy that I offer the following translation of it: "The disease which attacks the throat, that is, the entrance to the intestines through the fauces, is not different from that which attacks the anus or rectum, that is, the exit of the intestines, and the greatest affinity exists between the many kinds of cynanche and dysentery. In the more severe forms of angina there occurs a sensation of heat, with redness, swelling, tension, a secretion of a humor sometimes purulent, sometimes sanious, continual hawking, a perpetual attempt at swallowing, accompanied by pain, and in all things very similar to the tenesmus about the anus in dysenteric patients. Membranous and ulcerous cynanches agree in almost all things with severe dysentery, but most especially with malignant dysentery; and just as ash-colored spots, dark and livid, gangrenous and fetid, are often seen to occupy the fauces, œsophagus or larynx in the former, so, likewise, these same things are often seen to occupy the rectum or the colon in those whom dysentery has destroyed. Wherefore, as in the latter disease, caruneulæ, pseudomembranes and polyp-like concretions frequently pass out through the anus; in membranous cynanche they are expelled by coughing." I add a transcript of the Latin original of this remarkable passage: "Non alius est, qui guttur, seu *intestinorum* per fauces *introitum*,—quam qui anum rectumve intestinum, seu *intestinorum exitum*, occupet morbus; ac summa plures *cynanchis* species inter atque *dysenteriam* affinitas intercedit. In angina fortiori, sensus ardoris, rubor, inflatio, tensio, puriformis, interdum subcruenti humoris secretio, screatio continua, deglutiendi nisus perpetuus, dolore plenus, ac *tenesmo*, qui ad anum est dysentericis, in omnibus persimilis, occurrunt. *Cynanches membranaceæ, ulcerosæ*, cum *dysenteria gravi*, sed potissime cum *maligna*, vix non in omnibus conspirant; ac sicut maculæ cinereæ, ex livido nigrescentes, gangraenosæ fœtidaeque illinc fauces, œsophagum, laryngem.—ita rectum, vel et colon intestinum, in illis, quos *dysenteria* enecuit, frequenter occupare cernunter Quae hoc in morbo caruneulae, pseudomembranae, concretiones polyposae per anum haud raro secedunt: illae in *cynanche membranacea* per tussin expelluntur."

theria. He not merely spoke of pseudomembranes as being passed per anum in dysentery, but described an autopsy in which he found portions of the transverse and descending colon and rectum coated with pseudomembrane.*

Among the medical writers by whom about this period attention was directed, under one name or another, to pseudomembranous inflammation of the intestine in dysentery, I may also particularly mention Alexander Monro, jr.,† who, using the phraseology which had become current in England under the influence of the teachings of John Hunter,‡ asserted that the effusion of coagulable lymph was a common result in severe inflammation of the intestinal mucous membrane, and made use of this fact to explain the descriptions of post mortem appearances in dysenteric subjects which had previously been published by Baker, Pringle and Donald Monro.

The comparison which Frank had instituted between pseudomembranous inflammation of the intestinal canal and membranous angina, was subsequently adopted by Hildenbrand,§ and, while the subsequent progress of pathological anatomy drew attention in all quarters to pseudomembranous formations in dysentery,‖ it would appear that the analogy pointed out by Frank was never lost sight of in Germany, where the term croupous

* For Frank's description of the pseudomembranes passed in dysentery, see *op. cit.*, Vol. III, p. 439, where he says that very frequently, in all the varieties of dysentery, "a puriform matter, morbidly secreted from the internal surface of the rectum solidifies, and having been converted into pseudomembranes is expelled through the anus in various forms," among which he describes delicate flocculent shreds, carunculæ, long pellicles and polypus-like tubes. That he knew the pseudomembranous formation was not limited to the rectum is shown by his account of the autopsy in the case referred to in the text. "In recto intestino non minus, ac colo sinistro atque transverso inflammationis comparebant vestigia, atque *vera* hinc inde *exulceratio*. Alibi, dictorum canalium superficies interna a pseudomembrana atque variis excrescentiis erat obducta;" [*op. cit.*, Vol. III, p. 445,] which may be translated: "In the rectum, not less than in the descending and transverse colon, traces of inflammation appeared, and here and there true ulceration. In other places, the internal surface of the canals mentioned was coated by pseudomembrane and various excrescences." This description is evidently drawn from nature and by a skilled observer.

† Alexander Monro, Jr.—*The Morbid Anatomy of the Human Gullet, Stomach, and Intestines*, Edinburgh, 1811, p. 119.

‡ Hunter himself, while pointing out that inflamed mucous membranes usually discharge pus, remarks that if this inflammation "becomes more violent, or has something of the erysipelatous disposition, we find that it moves from the suppurative to the adhesive, and throws out the coagulating lymph." He goes on to say that he has observed this on the inside of the intestines in strangulated hernia, &c.,—[*Treatise on the Blood, Inflammation, and Gun-Shot Wounds*, Part II, Chap. II, § 4, London, 1794, p. 242,]—but he does not connect it with dysentery. The exudation of coagulable lymph on the intestinal mucous surface was also described by C. R. Pemberton—*A Practical Treatise on Various Diseases of the Abdominal Viscera*, 2d Edit., London, 1807—who remarks, in Chap. 10, on *Inflammation of the Mucous Membrane of the Intestines:* "This inflammation generally terminates by a throwing out of coagulable lymph, which may be discovered in the evacuations, resembling shreds of boiled macaroni," (p. 188.) I have not referred to this writer in the text, because he did not connect this condition with dysentery. (See his account of dysentery, in Chap. 8.) He furthermore did not very justly appreciate the significance of pseudomembranous inflammation of the intestinal mucous membrane, for he remarks: "When we observe these shreds in the evacuations, we may safely pronounce that the patient will soon recover," (p. 188.)

§ Val. Nob. Ab Hildenbrand—*Institut. Pract. Med.*, Tom. III, p. 326 *et seq.*, Vienna, 1822—in his description of enteritis, says that it may terminate in resolution, gangrene, suppuration, or in the various species of what he calls hypoclepsis, (*i. e.*, morbid transudation, from ὑπό, under, and κλέπτω, to steal.) Of this morbid process he describes two kinds, viz, h. lymphatico-plastica, and h. serosa. (See Vol. II, p. 277.) Among the varieties of hypoclepsis, he mentions that "plastic lymph" may coagulate into pseudomembranes on the mucous surface of the alimentary canal, and may be passed by stool, sometimes even in the form of casts of the intestinal tube, an affection which is strongly analogous to membranous angina, "adfectus anginæ membranaceæ summe analogus," [Vol. III, p. 326.] In a subsequent part of the same work, under the heading Phlegmhymenitis et Febris Catarrhosa, he explains that the term catarrh should belong to the inflammations of all mucous membranes, and censures those who restrict it to the air-passages, (p. 460.) He describes "enteritis catarrhosa," catarrhus intestinalis, as producing dysenteria catarrhosa or diarrhœa catarrhosa, according to its seat and the presence or absence of tenesmus. In this disease it frequently happens that filaments and coagula of lymph, or evident pseudomembranes mixed with shreds of the intestinal tunics, are found in the stools, (p. 475.)

‖ Thus Andral taught in his lectures—*Cours de Path. Interne*, Rec. et réd. par A. Latour, Paris, 1836, Tome I, p. 92—that sometimes in dysentery the mucous membrane of the colon is lined by false membranes—"Quelquefois tapissée par de fausses membranes." Consult also Id., *Précis d'Anat. Path.*, Brussels, Tome I, 1837, p. 413. Gély—*Essai sur les Altérations Anatomiques qui constituent spécialement l'état dysenterique*, Journ. de la sect. de Méd. de la Soc. Acad. du département de la Loire-inférieure, T. 14, 1838, p. 193—described "la production d'une pellicule pseudo-membraneuse"(p. 217) among the lesions which he observed in an epidemic of dysentery in the valley of the Loire. J. Cruveilhier—*Anat. Path. du Corps Humain*, Tome II, Paris, 1835-42—gives an excellent colored plate—Livr. 38, Pl. 3, fig. 2—of the lower extremity of the colon of an individual who died with all the symptoms of acute dysentery, and in whom the mucous surface was completely coated with pseudomembrane—"une pseudo-membrane blanche, morcelée, très adhérente." He also gives another plate representing the lower part of the ileum and the greater portion of the colon of a dysenteric subject—Livr. 40, Pl. 5—which is evidently affected by pseudomembranous inflammation, although he does not make use of that term. His description reads: "The internal surface of the large intestine presented a gangrenous appearance, and, in fact, was a true gangrene; the mucous membrane was transformed into a blackish, thick, adherent, gangrenous layer; you would have said its destruction was the result of the action of sulphuric acid." The text of Livr. 40, accompanying this plate, contains a general discussion of the pathological anatomy of dysentery, which the author regards, not as an inflammation of the follicles, but as a general erythematous, or erysipelatous inflammation of the mucous membrane. Meanwhile, in Germany, we find the comprehension of the subject gradually assuming its modern form. In illustration, I may refer to C. G. Neumann—*Von den Krankheiten des Menschen*, Spec. Theil, Bd. I, Berlin, 1836, S. 289 *et seq.*—who divided fully-developed dysentery into: 1, simple, or as it may be called catarrhal, that is, rheumatic; 2, inflammatory. The latter may terminate in gangrene or in various metamorphoses of the intestinal coats, sometimes in the formation of pseudomembranes—"Es erzeugen sich zuweilen falsche Membranen," (p. 291.) Neumann, however, objected to the use of the word catarrhal—"Dysentery is never strictly catarrhal, for its seat is not the mucous coat of the colon, but its nervous coat," (*i. e.*, its submucosa.) "A disease of the mucous membrane alone produces diarrhœa," (p. 289.)

inflammation, made classical by the work of Rokitansky,* was applied to the dysenteric process by various authors, among whom Finger† may be mentioned as having published, in 1849, an excellent account of dysentery as observed at the Hospital of Prague, in which he separated the disease there observed into two varieties, one due to intestinal catarrh, and the other to croupous inflammation of the intestinal mucous membrane, and gave descriptions of these varieties which closely correspond with the modern views.

This subdivision of dysentery into a catarrhal and a diphtheritic variety is not without a certain degree of correspondence with some of the subdivisions adopted by the older medical writers from clinical considerations. Thus, of the three grades indicated by Galen,‡ and insisted upon by medical writers of the sixteenth and seventeenth centuries, such as Fernelius, Forestus, Hildanus, Sennertus, Rolfincius and Ettmüller,§ the first, in which the dejecta consist of mucous, whitish, viscid matters, supposed by the ancients to be fatty, with or without blood, corresponds to our catarrhal dysentery; while the second, in which shreds and pellicles are mixed with the stools, and the third, in which thicker membranes, supposed to consist of the coats of the intestines themselves, make their appearance, correspond to diphtheritic dysentery of more or less severity. The former, Sennertus, following the teachings of Galen, called "dysenteria fiens," the latter, "dysenteria facta;"‖ expressions which may be regarded as almost synonymous with catarrhal and diphtheritic dysentery.

A similar correspondence, though perhaps not quite so clear, may be noted between the subdivision adopted in this chapter and that into benignant and malignant dysentery (d. benigna et d. maligna) which is indicated by Amatus, Forestus, Schenckius, Sennertus

* CARL ROKITANSKY—*Handbuch der Path. Anat.*, Wien, 1841–46. I cite the transl. of the Sydenham Society, London, 1849–54, Vol. I, p. 134 *et seq.* This author, however, only admitted croupous exudation upon "the mucous membrane of the intestines, and of the colon in particular, as representing one form of dysentery," (p. 136;) and although he regarded the dysenteric process as allied to the croupy form of inflammation of the intestinal mucous membrane, (Vol. II, p. 63,) yet he treats of it as a special affection, analogous rather "to the corrosion of the mucous membrane produced by a caustic acid," (p. 88.) See also his article—*Der dysenterische Prozess*, etc.—Œsterreich. Jahrb., N. F. Bd. XX, (1839,) p. 81 *et seq.*—in which this idea is fully elaborated, and the suggestion made that the lesions of dysentery are caused by an abnormal acidity of the blood, developed in the affected mucous membrane, or some other *atrium morbi*, (p. 97.) The account of dysentery in the first edition of his Pathological Anatomy is condensed from this article. In the last edition of this great work—*Lehrbuch der Path. Anat.*, Bd. III, Wien, 1861, S. 207 *et seq.*—Rokitansky has somewhat modified his views, for he describes dysentery in connection with "diphtheritic inflammation" of the intestine, and speaks of "diphtheritische Dysenterie," (p. 206,) though he still dwells on the comparison of the process with the effects produced by caustic substances, and especially by caustic acids, (p. 210.)

† FINGER—*Die während den Jahren* 1846-48, *in Prager k. k., allg. Krankenhause beobachteten Epidemien. III, Die epidemische Ruhr*, Prager Vierteljahrschrift, Bd. XXIV, (1849, Bd. IV,) S. 125. "The local lesion was manifested in two forms: A, as *intestinal catarrh*, in which the intestinal follicles principally were involved, (follicular inflammation or ulceration;) B, as dysentery (Ruhr) or *croupous inflammation of the intestinal mucous membrane*. Nevertheless, both these forms of the local affection appear to us to be merely different stages of development of one and the same disease, or as the expression of the same blood-crasis from which the inclination to inflammatory affections of the intestinal mucous membrane and its glands results." The epidemic described by FINGER was also observed by BAMBERGER—[S. 384 *et seq.*, *op. cit.*, p. 266, *supra*]—and served as the basis of his well known description.

‡ See especially *Comm. in Hippoc. Aph.* IV, 26, [Ed. Kühn, XVII, B, p. 691,] and *De Loc. Affect.*, Lib. VI, Cap. 2, [Ed. Kühn, VIII, p. 382.]

§ The description of FERNELIUS—*Pathologia*, Lib. VI, Cap. 10, [p. 187, Edit. cited on p. 337,]—is so succinct that I offer a translation: "At first, indeed, the mucus of the intestines (intestinorum mucus) is discharged, next the fatty matter which adheres to them on the inside is voided with a small quantity of blood; and this is the first species of dysentery. The second is when the internal tunic of the intestines is scraped, and pellicles and fibres of it appear mixed in with the stools. The third, when the ulceration penetrating and eating in more deeply, the flesh itself and proper substance of the intestine drops out putrid or corrupted." Compare P. FORESTUS—*Obs. et Cur. Med.*, Lib. XXII, Leyden, 1596, Obs. 31, Scholia, p. 346, and FABRICIUS HILDANUS—*De Dysenteria*, (1602,) Cap. 2, [in Opera, Frankfort, 1646, p. 668,]—the latter writer teaches that the first two stages are curable, but that the last is the condition described by HIPPOCRATES in Aph. IV, 26, as mortal. In this he follows the commentary of GALEN quoted in the previous note. SENNERTUS—*Pract. Med.*, Lib. III, Pars 2, Sect. 2, Cap. 7, [in Opera, Paris, 1641, Tom. III, p. 127;] ROLFINCIUS—*Epitome Meth. Cognoscendi et Curandi*, etc., Lib. III, Cap. 17, Jena, 1655, p. 292, and MICHAEL ETTMÜLLER—*Colleg. Pract. de Morb. Humani Corporis in genere*, Pars I, Cap. 9, [in Opera, Lyons, 1690, p. 126,]—also describe these three grades.

‖ SENNERTUS says, [passage cited in note § *supra*:] "Illam Galenus γιγομένην, Fientem dysenteriam, hanc γεγονύιαν & κατασκευασθείσαν, Factam et consummatam nominat." In the margin, by a misprint in the edition cited, the reading "Dysenteria Fient & Facta" occurs. In the Wittenberg editions of the Pract. Med. of 1648 and 1656, Lib. III, p. 334, the marginal reading is "Dysenteria Fiens & Facta." The passage of GALEN to which SENNERTUS refers is contained in his Commentary on Aph. IV, 26, (see note ‡ *supra*.) and, after describing the three stages, says of the last: "Καθ'ὸν ἤδη χρόνον οὐκέτι γίνεσθαι τὴν δυσεντερίαν, ἀλλ'ἤδη γεγονέναι καὶ κατεσκευάσθαι φαμέν. At which time we do not say that dysentery is still developing, but that it is already developed and fully formed." According to this passage, "Dysenteria Facta" would correspond only to the third grade described in the text, and "Dysenteria Fiens" would include the first and second, that is, catarrhal dysentery and the milder cases of diphtheritic. It may be added that the present participle Fiens, which does not occur in classical Latin, is given in the Lexicon of FACCIOLATUS and FORCELLINUS, [London, 1828, Vol. I, p. 779,] on the authority of *Diomedes*, Lib. I, pp. 352 and 377. I may add that ZACUTUS—*Praxis Hist. Lib. Ult.*, [1642, in Opera, Lyons, 1649, Tom. II, p. 634,]—who also describes the three grades after GALEN, applies the term factam to the last grade only, and does not use the participle fiens, but says: "Quo tempore dysenteriam dicimus factam, et constructam, non verò in fieri, ut 4, Aph. 26 dictavit Galenus."

and Willis,* and more formally expressed by Ettmüller, Dolæus and Hoffmann.† The same remark applies to the subdivision into sporadic and epidemic dysentery, formulated in the writings of Sennertus, Ballonius and Ettmüller,‡ and recently insisted upon by Jaccoud and Barrallier;§ to the subdivision, into sthenic and asthenic, adopted by J. P. Frank,‖ and that into "dysenterie légère" and "intense," employed by Chomel and Blache and other modern French writers.¶

But no correspondence exists between the subdivision into catarrhal and diphtheritic dysentery and that into red and white dysentery, which is based solely upon the presence or absence of blood in the dejecta. According to Sprengel,** this distinction was first made by Nonus, in the tenth century; but the chapters he refers to in proof of this assertion †† merely contain an abstract of the teachings of Galen‡‡ with regard to the differences between dysentery properly so called and various other bloody discharges from the bowels, which some of his predecessors, in his opinion erroneously, had embraced under the designation dysentery. If these chapters are to be regarded as making the distinction in question, it dates back to Galen, and, indeed, even to the epoch of the Hippocratic writings;§§ but it

*See AMATUS—*Curat. Med.*, Cent. III, 90, [Venice Ed., 1557, p. 488,]—the heading is: "Curatio nonagesima, in qua agitur, de dysenteria contagiosa, et pestilenti." Compare P. FORESTUS—*Obs. et Cur. Med.*, Lib. XXII, Leyden, 1596, p. 393,—headed: "Obs. 38. De dysenteria quadam contagiosa et pestilenti." J. SCHENCKIUS—*Obs. Med. Rar.*, (1584–97,) Frankfort, 1609, Lib. VI, *De Variis Pestilentibus Defluxionibus*, Obs. VI, p. 861, *Dysenteria Epidemica Maligna*—describes an epidemic of dysentery which, in the year 1583, prevailed from the latter part of summer till the end of the autumn, and which he says was "satis maligna, longe lateque grassans." He briefly describes also the epidemic chronicled by Gregory of Tours. SENNERTUS—*Pract. Med.*, Lib. VI, Pars 2, Cap. 5, [in Opera, Paris, 1641, Tom. III, p. 997,]—speaks of the epidemic dysentery of the years 1513 and 1624 as "dysenteria maligna," remarking: "Et solent istæ dysenteriæ sæpe adeo malignæ esse, ut paulò post in pestem degenerent." WILLIS says—*De Med. Operat. in Corpore Humano*, Sect. III, Cap. 3, p. 80, [in Opera, Geneva, 1680,]—that the ordinary London dysentery was not very malignant, ("non admodum maligna,") but that at other times it is virulent, and, as it were, pestilential. The marginal reading is: "Affectus hic aut mitior aut malignus est."

†MICHAEL ETTMÜLLER—*Colleg. Pract. de Morbis Humani Corporis in Genere*, Pars I, Cap. 9, [in Opera, Lyons, 1690, p. 125,]—says: "Alia sit benigna, alia maligna;" that the first is, for the most part, without fever, and occurs sporadically; that the second is accompanied very generally by malignant fever, and is often epidemic and contagious. DOLÆUS—*Encyc. Med. Dogm.*, Lib. III, Cap. 5, [in Opera, Frankfort, 1703, p. 234,]—"Dysenteria est vel benigna, vel maligna." HOFFMANN—*Med. Rat. Syst.*, Tom. IV, Pars III, Sect. II, Cap. 7, [in Opera, Geneva, 1740, Tom. III, p. 152,]—"Ipsa vero dysenteria dividitur in benignam atque malignam." F. L. I. VALLEIX—*Guide du Médecin Praticien*, 5me Édit., Tome IV, Paris, 1866, p. 34—divides dysentery into *non fébrile*, which he says has been described as benignant, and is always sporadic, and *fébrile*, which has been called malignant, grave, &c., and is almost exclusively epidemic.

‡SENNERTUS remarks—*Pract. Med.*, Lib. III, Pars 2, Sect. 2, Cap. 7, [in Opera, Paris, 1641, T. III, p. 127,]—"Sunt et aliæ dysenteriæ differentiæ, quod nunc est epidemia, nunc ex morborum σποράδων numero." BALLONIUS—*Consil. Med.*, Lib. II, (1636,) Cons. 23, [in Opera, Geneva, 1762, Tom. III, p. 214,]—says: "At dysenteriarum aliæ sunt populares, aliæ non." See also ETTMÜLLER, *loc. cit.* in note † *supra*.

§S. JACCOUD—*Traité de Path. Interne*, 2me Édit., Paris, 1872, Tome II, p. 327—makes three varieties: d. sporadique, d. endémique, and d. épidémique. The same subdivisions are adopted by A. BARRALLIER—Art. *Dysentérie* in Nouv. Dict. de Méd. et de Chir. Pratiques, Tom. XI, Paris, 1869, p. 729.

‖Dysenteria sthenica et d. asthenica. See J. P. FRANK, *De Cur. Hom. Morb. Epitome*, Lib. V, Pars 2, § 690, [Milan Ed., 1832, Tom. III, pp. 437 and 440.] This distinction is adopted by COPLAND—Art. *Dysentery* in Dict. of Pract. Med., London, 1858, Vol. I, p. 693 *et seq.*—as his principal subdivisions of acute dysentery.

¶CHOMEL *et* BLACHE—Art. *Dysentérie* in Dict. de Méd., 2me Édit., Tom. X, Paris, 1835, pp. 556 and 558. So also the *Myko-Rheuma Coli* of EISENMANN—see note to p. 343, *supra*—corresponds to catarrhal dysentery, while his *Colo-Typhus*—see note to p. 336, *supra*—corresponds to the diphtheritic form.

**KURT SPRENGEL—*Geschichte der Arzneykunde*, 3te Aufl., Bd. II, Halle, 1823, S. 316.

††THEOPHANES NONUS—*Epit. de Cur. Morborum*, Greek and Latin, Bernard's Ed., Gotha and Amsterdam, 1794–5, Cap. 167 and 168, Tom. II, p. 34 *et seq.*, or in the Strasburg Ed. of 1568, pp. 188–191. The passages referred to may be translated thus from the Greek text: Cap. 167. "On Dysentery. An ulceration of the intestines is called dysentery. This is caused sometimes by the transmutation of a tenesmus, sometimes by bilious and acrid secretions. The symptom is the discharge of bloody matters and scrapings, (ξύσματα,) and this occurs when the putrid membranes of the intestines are discharged, (ὑμένας ἐκ τῶν ἐντέρων σηπωμένας καταφέρεσθαι.)" * * * Cap. 168. "On bloody Dysentery, (Περὶ αἱματηρᾶς δυσεντερίας.) Dysentery is called bloody, whenever blood is discharged either pure, or resembling the washings of flesh recently killed, or feculent (τρυγῶδες) or black." * * *

‡‡Compare, for example, GALEN, *III Comm. in Hippoc. Epidem.* III, § 70, [Kühn's Ed., XVII, A, p. 725.] where, speaking of bloody dysentery, (δυσεντερίαις ταῖς αἱματηραῖς,) he remarks: "We have learned that these are two-fold; that the first variety results when the intestines are eroded by ulceration, the second when there is an abundance of blood discharged through the veins pertaining to the intestines." The same view is expressed in more detail in *De Sympt. Causis*, Lib. III, Cap. 7, as explained in note ‡ to p. 336, *supra*, where he subdivides the bloody discharges from the bowels which are not properly dysenteric into three varieties, and distinguishes them from dysentery properly so called. The same distinctions are taught in *Comm. IV in Hippoc. de Articulis*, § 38 and 39, [Ed. Kühn, XVIII, A, 724–731,] and various other passages.

§§Thus the term red dysentery [ἐυσεντερ.ὴ ἐρυθρή] is applied to bloody stools in HIPPOCRATES, *Epidem.*, Lib. II, near the end of Sect. 3, [Ed. Littré, Vol. V, p. 121,] in a paragraph which is substantially the same as *Aph.* V, 65, [Ed. Littré, Vol. IV, p. 559.] The Commentaries of GALEN on these two passages are particularly instructive. [For the first, see Ed. Kühn, Tom. XVII, A, p. 459; for the second, Tom. XVII, B, p. 877.] See also, besides the Hippocratic passages referred to in the last note, a passage in the *Prenotions of Cos*, in which bloody dysentery (αἱματώδης) is contrasted with bilious dysentery, (χολώδης,) [Ed. Littré, V, p. 687.] This distinction between dysentery from ulceration and bloody dysentery is also made by PAULUS ÆGINETA—Lib. III, Cap. 42, [Transl. of Syd. Soc., London, 1844, Vol. I, p. 525.]—who uses the very same adjective to express the bloody variety that NONUS employs. [Compare the Basel Greek Ed. of 1538, p. 97.] It is repeated by THEOPHILUS [in the 7th century]—*De Retrimentis Alvi*, Cap. XI, [bound with his *Lib. de Urinis*, Greek and Latin, Leyden, 1703, p. 260,]—who, after explaining that bloody stools may result not only from ulceration of the intestines, but also from disease of the liver or rupture of bloodvessels, adds that the latter accident occurs quite frequently, and that such fluxes of blood are called by the vulgar "Asclepiasmus," (Ἀσκληπιασμός.)

must be observed that Nonus could not have had this distinction in view, since he mentions blood as an ingredient in the stools of both dysentery proper and bloody dysentery; in the first the blood is mingled with the scrapings of the intestines which are discharged by stool; in the second the evacuations are composed of blood alone, either pure or variously modified by disease. In point of fact, it appears, from the statements of Felix Plater and Sennertus,* that the subdivision of dysentery into a red and white species, in accordance with the presence or absence of blood in the stools, was of German origin, having been adopted by these writers from the German vernacular. Thus introduced into medical language, it has been employed by many notable writers,† but has deservedly fallen into disuse during the present century,‡ because blood may be either present or absent in almost every stage of the disease, and without regard to its severity or character in other respects.

Without entering upon a discussion of the various other subdivisions of dysentery proposed by medical authors, some of which, however, are subjoined in the footnote,§ the general course of the catarrhal and diphtheritic varieties will next be briefly sketched, after which some of the more important symptoms will be separately considered, and their relation to each of the two principal forms of the disease discussed.

---

*FELIX PLATER—*Prax. Med.*, (1602-8,) *De vitiis*, Lib. II, Cap. 11, [Basel Ed., 1736, Tom. III, p. 791,]—says of bloody dysentery: "Our people (nostri) call it *Rote Ruhr Schaden*, or *Rotlauff*, from the redness of the blood;" but when mucous discharges predominate, "then the Germans are wont to call it white dysentery, *Weisse Ruhr*." SENNERTUS—*loc. cit.*, [in Opera, Paris, 1641, Tom. III, p. 123,]—expresses himself to the same effect: "If the blood predominates, the Germans call the species *die rote Ruhr*. If, however, more of that white mucus than of blood is expelled, they call it *die weisse Ruhr*." With the brief statement of THEOPHILUS [see last note] compare the more elaborate account given by N. LAMBSMA—*Ventris Fluxus Multiplex*, Amsterdam, 1756, Cap. 2, p. 61, and Cap. 9, p. 104.

† For example, MICHAEL ETTMÜLLER—*Colleg. Pract. De Morb. Humani Corporis in Genere*, Pars I, Cap. 9, [in Opera, Lyons, 1690, pp. 125-6,]—tells us that in dysentery, besides sanies and pus with blood, a certain whitish mucus (albicantia mucilaginosa, mucus albicans) is excreted, and that "there is a dysentery which they call white, in which very little bloody matter, but an abundance of mucus is excreted." TH. WILLIS—*Pharmaceut. Rat.*, (1673,) Pars I, Sect. III, Cap. 3, [in Opera, Geneva, 1680, Tom. II, p. 73,]—makes the same species, calling them "aquosa" and "cruenta," and, in a subsequent passage, (p. 77,) speaks of the first as "incruenta." The following extract is from the English translation, London, 1684, p. 51: "For I have often and a great while since observed, that there are two very different sorts of this same Flux, which almost every year is wont to be so rife here about Autumn, and is commonly called in our language, *The Griping of the Guts*; in the one whereof the Stools were watery, and as it were, limpid [or clear] with a sudden weakning of the Body; in the other they are bloudy, but tolerable." So also SYDENHAM—*Med. Obs.*, Sect. IV, Cap. 3, [Transl. of Syd. Society, London, 1848, Vol. I, p. 167,]—mentions that blood was not always present in the stools of the epidemic flux he describes, and says: "Notwithstanding, provided that the motions be frequent, slimy, and attended with griping, the disease is a true bloody flux, or dysentery." According to SPRENGEL [*op. cit.*, Bd. V, S. 337] the distinction between red and white dysentery was treated very fully by J. S. CARL—*Praxeos Med. Ther. Gen. et Spec.*, Halle, 1718, p. 87. I have not seen this work. FRID. HOFFMANN—*Med. Rat. Syst.*, Tom. IV, Pars III, Sect. II, Cap. 7, § 5, [in Opera, Geneva, 1740, Tom. III, p. 152,]—considered this distinction as important as the division into benignant and malignant; and SAUVAGES—*Nos. Meth.*, Amsterdam, 1768, Tom. II, p. 328—admits *dysenteria alba* as his tenth species of dysentery, giving dysenteria incruenta, weisse Ruhr, and griping of the guts as synonyms.

‡ Note, for example, C. G. NEUMANN—*Spec. Path. und Therapie*, Bd. I, Berlin, 1836, S. 287—who remarks "der Unterschied ist unwesentlich."

§ SAUVAGES—*Nos. Meth.*, Amsterdam, 1768, Tom. II, p. 326 *et seq.*—makes the following species: 1, Dysenteria benigna spontanea; 2, d. catamenialis; 3, d. Parisiaca; 4, d. Gravidarum; 5, d. atrabilaria; 6, d. epidemica; 7, d. castrensis; 8, d. simulata; 9, d. Pecorum; 10, d. alba; 11, d. à mesenterii vomica; 12, d. à catharticis; 13, d. syphilitica; 14, d. æquinoctialis; 15, d. verminosa; 16, d. carnosa; 17, d. intermittens; 18, d. scorbutica; 19, d. Polonica; 20, d. miliaris. Besides these, he makes a separate heading of Hepatirrhœa or Dysenteria hepatica, which he divides into—1, Hepatirrhœa vera; 2, h. intestinalis; 3, h. à vulnere; 4, h. Mesenterica; 5, h. scorbutica; 6, h. cruenta; 7, h. intermittens. CULLEN—*Apparatus ad Nos. Meth.*, Amsterdam, 1775, p. 192—retains the same species as SAUVAGES with the exception that he omits 8, d. simulata, and 9, d. Pecorum, and says that 3, d. Parisiaca and 12, d. à catharticis belong rather to diarrhœa. He divides the remaining species into two groups: 1, *Idiopathicæ* and 2, *Symptomaticæ*, of which the first embraces d. epidemica, d. castrensis, d. æquinoctialis, d. verminosa, d. carnosa, d. miliaris, d. intermittens, and d. alba; while the second includes the remaining species. Hepatirrhœa CULLEN included with diarrhœa. SAGAR—*Syst. Morb. Symp.*, (1771,) Vienna, 1776, p. 304 *et seq.*—makes the same species as SAUVAGES, except that he omits 10, d. alba, 11, d. à mesenterii vomica, and 20, d. miliaris, and that he adds d. arthritica. He calls the d. catamenialis of SAUVAGES, d. periodica; his d. à catharticis, d. medicamentosa; his d. Pecorum, d. epizootica; his d. intermittens, d. febricosa, and his d. Polonica, d. trichomatosa. In the case of Hepatirrhœa, he makes the same divisions as SAUVAGES, except that he called h. à vulnere, h. traumatica. FOURNIER et VAIDY—*Dict. des Sci. Méd.*, Tome X, Paris, 1814, p. 315—divide dysentery into acute and chronic, subdividing acute dysentery into d. simple, d. inflammatoire, d. muqueuse, d. gastrique, d. compliquée avec le typhus, d. adynamique, d. ataxique, and d. avec une fièvre intermittente. JOHN MASON GOOD, in his *Nosology*, (1817,) [Study of Med., Am. Reprint. Philada., 1825, Vol. V, p. 36]—makes but two species: 1, d. simplex; 2, d. pyrectica; dividing the last into *a*, eaumatodes, and *b*, typhodes. P. VIGNES—*Traité Complet de la Dysenterie et de la Diarrhée*, Paris, 1825, p. 212—describes a benign form which he subdivides into "inflammatoire," "muqueuse" and "bilieuse;" and a dysentery "de mauvais caractère," of which the varieties are "typhoïde, adynamique, ataxique," and "variétés combinées avec la fièvre jaune, et la peste dite d Orient." He also describes chronic dysentery. M. E. A. NAUMANN—*Handb. der med. Klinik*, Bd. IV, Abth. 2, Berlin, 1835, S. 12 *et seq*—describes 1, die einfache Ruhr, (d. catarrhalis, d. simplex, benigna;) 2, die gastrische Ruhr, (d. gastrica;) 3, die Ruhr mit Wechselfieber, (d. intermittens;) 4, die entzündliche Ruhr, (d. inflammatoria, sthenica;) 5, die faulige Ruhr, (die brandige, die Lagerruhr;) d. nervosa, asthenica, typhosa, septica, putrida, colliquativa, castrensis, pestilentialis; Fluxus virulentus.) H. BRESSLER—*Die Krankheiten des Unterleibes*, Berlin, 1841, Bd. I, S. 497 *et seq.*—describes 1, die einfache Ruhr, (d. simplex, catarrhalis;) 2, die entzündliche Ruhr, (d. inflammatoria;) 3, die gastrische Ruhr, (d. gastrica,) which is subdivided into d. biliosa and d. pituitosa; 4, die typhöse Ruhr, (d. typhosa, septica, putrida, castrensis.) J. BROWN—in *Cyc. of Pract. Med.*, [Am. Ed., Phila., 1845, Vol. I, p. 720]—divides it into "the uncomplicated dysentery of temperate climates," and "tropical dysentery." J. DELIOUX DE SAVIGNAC—*Traité de la Dysentérie*, Paris, 1863, p. 133—makes the following varieties: 1, simple ou catarrhale; 2, inflammatoire; 3, bilieuse; 4, typhoïde; 5, gangréneuse; 6, hémorrhagique; 7, athermique; 8, rheumatoïde; 9, chronique. A. TROUSSEAU—*Clinique Méd.*, 2me Éd., Paris, 1865, Tome III, p. 162—describes, besides ordinary acute dysentery, "la forme bilieuse, d. inflammatoire," "la forme rhumatismale," and a "forme intermittente."

A. Simple Inflammatory Dysentery, (catarrhal dysentery; *Katarrhalische Ruhr* of the Germans.)—Simple inflammatory dysentery very frequently manifests itself during the course of an ordinary acute diarrhœa, which has already progressed, with the usual symptoms, for several days or weeks; but it also occurs as an independent affection, and then, very often, though not always, comes on after more or less protracted constipation. When it occurs as an independent affection it is usually preceded for some hours, or longer, by a sense of malaise, with uneasiness in the abdomen, or sensations resembling those of dyspepsia. To these succeed abdominal gripings, accompanied by a desire to go to stool. Sometimes the first stools are feculent and copious, but not unfrequently they are scanty, mucous, and without feculent admixture from the very first. Comparatively seldom does this milder form of dysentery begin with a chill followed by fever, as often happens in the diphtheritic form.

When the disease supervenes upon diarrhœa the stools sometimes suddenly acquire the dysenteric characters, which, however, more frequently are gradually developed. These characters, however the disease may have originated, are briefly as follows: At intervals abdominal gripings occur, generally in the umbilical region, but often extending thence along the ascending and descending colon, and accompanied by a dull pain in the loins and sacrum. These pains are quite like those which occur in severe cases of acute diarrhœa,* except that they are usually more intense. They are accompanied or followed by an urgent desire to expel the contents of the bowel, but the spasmodic contractions of the expulsive muscles that ensue only succeed, even after prolonged straining, in extruding a little mucus or muco-pus, which may or may not be mixed with blood; and this scanty discharge is not followed by the degree of relief which is noted after the discharges in acute diarrhœa, but painful sensations in the rectum and anus remain, even after a lull takes place in the repeated expulsive efforts. To the griping abdominal pains in dysentery the name of *tormina*, which Celsus applied to the disease itself, has long been given.† The painful expulsive efforts are called *tenesmus*, a term which the Greek physicians and their followers‡ applied to an independent disease. The paroxysms of tormina and tenesmus vary in frequency, with the intensity of the disorder, from every half hour, hour, or even longer intervals, to every few minutes; indeed, in violent attacks they sometimes follow each other at such short intervals that the patient is almost unable to leave the close-stool.

Notwithstanding these violent local symptoms there is often, at least at first, comparatively little constitutional disturbance. The appetite may continue to be normal or nearly so, there may be no complaint of thirst, but slight increase in the frequency of the pulse, and no sensible elevation of the temperature; but there is usually, even in these milder cases, a considerable sense of debility, so that the recumbent posture is desired, although various motives may lead the patient to resist this desire for a time. After the lapse of a day or so, however, and in the severer cases from the very first, the appetite diminishes or is altogether lost, and this is often accompanied by nausea and other evidences of gastric derangement, sometimes even by vomiting. The tongue becomes coated, there is some abnormal thirst, and often a moderate febrile reaction sets in, the pulse, however, seldom exceeding 90 to 100, and the temperature not often rising more than a degree or two above the normal range. The paroxysms of tormina and tenesmus are usually least frequent in

* *Supra*, p. 272. † *Loc. cit.* in note to p. 336, *supra*. ‡ See note to p. 336, *supra*, and p. 338.

the morning and during the early part of the day; they increase in frequency and severity during the afternoon and evening, and continue through the night, almost or altogether preventing sleep. By this disturbing influence, superadded to the depressing effect of the intestinal paroxysms, the patient is rapidly debilitated, and with the increasing exhaustion of the vital powers, anxiety, restlessness and other manifestations of nervous disorder make their appearance.

The disease now usually takes one of three directions: The symptoms may moderate and convalescence set in; they may become aggravated and the case may assume the characters of diphtheritic dysentery; or they may persist, with fluctuations in their intensity, and gradually pass into a chronic flux. In the most favorable cases, convalescence begins about a week from the time the stools first assumed the dysenteric character,* or it may be even earlier. The intervals of rest between the paroxysms of tormina and tenesmus become longer, and the paroxysms themselves less painful; but, usually, the first trustworthy symptom of approaching convalescence is the reappearance of feculent matters in the stools. The passage of consistent fæcal lumps (scybala) along with the dysenteric stools is not infrequent in the early stages of the disease, and may occasionally occur subsequently without being of favorable import; but when the muco-purulent or bloody discharges are replaced by semi-fluid feculent masses of the consistency of gruel or thicker, and of the ordinary fæcal odor, it warrants an expectation of speedy recovery, which is usually fulfilled if the stools continue to retain the feculent character.

In graver cases the dysenteric symptoms persist for ten days or two weeks, three weeks, or even longer, before convalescence sets in. These cases often pass into the diphtheritic form; in fact, as will be presently shown, a sharp catarrhal dysentery constitutes very generally the first stages of diphtheritic dysentery. But although this should not occur, if the disease persists beyond a week or ten days, it, nevertheless, usually produces great constitutional disturbance. The patient is worn out by loss of sleep, by the constant torture of the expulsive efforts, by the impaired nutrition, which, in spite of the wisest regimen, results from his disordered digestion,† and rapidly becomes emaciated. To these causes of exhaustion must be added the fever, which, in the graver cases under consideration, usually makes its appearance early in the disease, often assuming a remittent character, with exacerbations in the afternoon and evening. Sometimes the pulse is full and strong, the face flushed, and the temperature comparatively high, so far as can be judged

* G. B. WOOD—*Treatise on the Pract. of Med.*, 6th Ed., Philada., 1866, Vol. I, p. 714: "In the vast majority of cases, the disease takes a favorable turn between the sixth and tenth days, and the patient recovers." AUSTIN FLINT—*A contribution toward the natural history of acute dysentery; consisting of a report of ten cases observed without medicinal treatment*, The Amer. Jour. of the Med. Sciences, July, 1875—from the analysis of ten cases of acute dysentery observed without treatment, concludes, p. 39: "1, The disease in a temperate latitude tends, without treatment, to recovery; 2, It is a self-limited disease, and its duration is but little, if at all, abridged by methods of treatment now and heretofore in vogue; 3, Convalescence is as rapid when active measures of treatment have not been employed, as in cases actively treated; 4, Relapses do not occur in the cases in which the disease has been allowed to pursue its own course without active treatment; 5, Sporadic dysentery, in a temperate climate, does not eventuate in a chronic form of the disease." All of the ten cases observed terminated in recovery. The most protracted case lasted 21 days, of which 14 were occupied by the preliminary diarrhœa. The case of least duration lasted 6 days. The average duration of nine cases (excluding the one in which there was preliminary diarrhœa) was 10⅓ days. It is evident, from the clinical details of the cases, that these were all examples of mild catarrhal dysentery; and I must hold that this distinguished physician errs in regarding them as affording a picture of "acute dysentery"; they represent only one of its mildest forms. The same author previously published a *Clinical report on dysentery, based on an analysis of forty-nine recorded cases*, Buffalo Med. Jour., Vol IX, [1853,] pp. 109, 136, 193 and 237. These papers were afterwards published as a brochure, the edition of which was unfortunately destroyed by fire, (see paper cited above, p. 27.) The value of this contribution was, however, diminished by the circumstance that it considers dysentery as a morbid entity, and does not attempt to discriminate between the milder catarrhal, and the more severe diphtheritic, forms. It is chiefly valuable from its hints as to the treatment, in connection with which I shall have occasion to cite it hereafter.

† It is an old observation, that the digestion is impaired during the progress of dysentery, especially if fever sets in. NICOLAUS PISO—*De cognoscendis et curandis praecipue internis humani corporis morbis*, Frankfort, 1580, p. 274—observed: "Dysentericus enim propter intestinorum et ventris imbecillitatem, haud multum potest concoquere, præsertim cum febricitat." And this, after all, represents substantially the conclusions arrived at by JULIUS UFFELMANN—*Die Storung des Verdaunngs-processes in der Ruhr*, Deutches Archiv für Klinische Med., Bd. XIV, 1874, S. 228—who has endeavored to arrive at a knowledge of the nature of the digestive disturbances by an examination of the vomited matters (of cases in which vomiting occurs) and of the dejecta, and who has drawn some important indications with regard to the dietetic management of the disease from the phenomena observed.

by the touch, for the clinical thermometer was not in use during the war of the rebellion. Sometimes with high temperature the pulse is frequent and feeble; but in the majority of cases the elevation of temperature, even when persistent, is moderate, and the pulse but little accelerated, though it loses in volume and becomes feeble and compressible. These cases sometimes terminate fatally, death being preceded by considerable emaciation; but it would appear probable, from the record of the autopsies made, that this was comparatively rare during the late war. More commonly, if such cases did not recover or pass into the diphtheritic form, they gradually assumed the characters of a chronic flux. A considerable number of the cases reported as chronic diarrhœa originated in this way.

Vesical tenesmus and prolapsus ani may accompany simple inflammatory dysentery, but are less frequent and less intense than in the diphtheritic variety. In distinguishing these two varieties, the greatest importance is to be attached to the examination of the stools. In simple inflammatory dysentery these consist of mucus, pus and blood variously commingled; but the shreds and flakes of pseudomembrane, and the characteristic sloughs of greater or less dimensions, which can always be recognized by the naked eye or the microscope in diphtheritic dysentery so soon as the infiltrated mucous and submucous layers undergo necrosis and begin to separate, are altogether absent.

B. Diphtheritic Dysentery, (pseudomembranous dysentery; *Diphtheritische Ruhr* of the Germans.)—In a large number of the cases observed during the late war, diphtheritic dysentery began with a simple inflammatory stage, either developed independently or supervening upon an acute diarrhœa. In numerous other instances it was more or less abruptly developed during the progress of a chronic flux, and indeed was a common mode of fatal termination in disorders of that class. These two categories embrace the vast majority of the cases. Occasionally, however, diphtheritic dysentery began with such abruptness and intensity as to countenance the assumption of Heubner* that a primary diphtheritic dysentery may occur without any preliminary catarrhal stage; but this more malignant form of the disease has probably been of more frequent occurrence in certain epidemics elsewhere than in our own camps.

The sketch already presented of simple inflammatory dysentery sufficiently describes the commencement of the large group of cases in which an acute diarrhœa, after lasting a few days or weeks, acquires the characters of that variety of dysentery before passing into the diphtheritic form. In these cases, after pursuing the course above outlined for about a week, instead of the favorable changes which prelude recovery, a more or less gradual aggravation of all the symptoms takes place. The patient grows more and more emaciated, debilitated, and ultimately sinks into a condition of collapse (the dysenteric collapse) with cool surface and extremities, and greatly enfeebled heart's action. With the progress of the disease his tongue becomes brown and dry, or smooth, red and dry, sometimes gashed; the anorexia and thirst become extreme; the abdomen tender to the touch, especially along the track of the colon, sometimes distended with flatus; the countenance sallow, at times it acquires a slight icteroid hue; the expression is anxious, and as one of the effects of the emaciation the features appear shrunken; from the same cause the eyes are sunken in the head, and are apt to acquire a vacant expression or a glassy stare.

*Heubner—Art. *Dysentery*, Ziemssen's Cyclo., Am. Ed., Vol. I, New York, 1874, p. 537, note: "This fact I would particularly emphasize in opposition to *Virchow*, who says, (*Kriegs-typhus u. Ruhr*, Virch. Arch., 52, p. 26,) 'Every dysentery is catarrhal at the outset.' These cases of dysentery where the whole intestine, from the lower part of the ileum down to the end of the rectum, is permeated with a continuous exudation, without any sign of an ulceration anywhere, must surely be regarded as rapid, primary diphtheritic affections."

These symptoms are accompanied or preceded by a change in the characters of the stools, which at first consist of stringy mucus more or less mingled with blood and pus, but now contain a quantity of yellowish or reddish morsels of various sizes, which on microscopic examination are recognized to be necrosed fragments of the diphtheritic layer. At the same time the mucus or muco-pus of the stools is mingled with a thin reddish serum, that sometimes entirely replaces it. In this fluid the morsels of necrosed membrane float, so that the passages have been compared to raw meat minced and stirred up with bloody water. Such stools have a peculiar cadaverous odor which is quite characteristic. About this time usually, though sometimes earlier, the skin around the anus becomes red and excoriated, and in some cases prolapsus ani is developed by the extreme tenesmus. So also, very often the patient begins to complain of strangury and vesical tenesmus. The quantity of urine is generally abnormally small, and proportionately concentrated and high colored; occasionally it is albuminous; sometimes there is almost complete suppression of the secretion.

Notwithstanding the extreme exhaustion of the patient, he often survives till the end of the second or third week from the commencement of the dysenteric symptoms, or even longer. In fact, Heubner is quite right in saying of these cases that they last "an entirely indefinite length of time;"* but usually, when they are protracted beyond the third or fourth week, this circumstance is accompanied by changes in the characters of the stools, which will be described further on. It is only too common for cases which have presented the symptoms just enumerated to terminate fatally. Death may take place at any time, but is, perhaps, more apt to happen during the third or fourth week than earlier or later. Usually, for a day or so before the fatal issue, the stools become brownish, red or blackish, of horribly putrid odor,† and often contain larger fragments of the necrosed mucous membrane than had previously been observed, though this is far from being uniformly the case. The surface of the body also exhales a putrid odor, which no degree of cleanliness can entirely obviate. Persistent hiccough often sets in during the latter stages of serious cases, and is always a symptom of evil omen.

A course quite similar to that just sketched is pursued by those cases which, instead of supervening upon an acute diarrhœa, begin as dysentery from the very first. These cases not infrequently commence with a chill followed by fever, and the abdominal symptoms make their appearance simultaneously or subsequently. In such cases the fever is usually more violent than in the form just described, and the afternoon temperature perceptibly higher.‡ There may be headache and even delirium, with flushed or dusky face and a full, strong, frequent pulse (95 to 110, or more) at the beginning, and this, after a few days, may pass into a fever of a typhoid type, with feeble, very frequent pulse, (110 to 140, or even more,) continued high temperature, sordes on the teeth, subsultus tendinum and muttering delirium. More frequently, however, even the cases which begin with sharp febrile symptoms soon pass into the characteristic condition of more or less complete dysenteric collapse, with but slightly elevated axillary temperature, cool surface and extremities, and a pulse which, although feeble, is either but little accelerated or may be actually slower than normal.

---

* HEUBNER, Am. Transl., *op. cit.*, Vol. I, p. 558.

† The offensive odor of the dysenteric stools is alluded to by ARETÆUS, who ascribed it to the putridity of the ulcers.—*De Causis et Signis Morb. Diut.*, Lib. II, Cap. 9, [Ed. Boerhaave, 1731, p. 60.] CÆLIUS AURELIANUS also mentions it as "gravis fætor."—*Morb. Chron.*, Lib. IV, Cap. 6, [Ed. Amman, 1709, p. 525.]

‡ 102°.5 to 104° Fahr. HEUBNER, Am. Transl., *op. cit.*, Vol. I, p. 553.

When diphtheritic dysentery is developed during the progress of a chronic flux it is prone to occur suddenly and to prove fatal in a few days. The patient is already exhausted by the chronic disorder from which he has suffered for months, and has often reached an extreme condition of emaciation, though he may still be able to be out of bed a part of the day and walk about the wards or hospital grounds. In this condition, after some exposure to cold, some sudden change in the weather, some imprudence in diet, perhaps after going out on pass and indulging in a few hours' debauch, or perhaps quite as often without any assignable cause, the stools suddenly acquire the dysenteric characters. This is often accompanied at first by more or less febrile reaction, but fatal collapse speedily ensues.

In the more protracted cases alluded to above the disease is apt to pursue a less uniform course, and the patient seems better and worse at irregular intervals. The periods of temporary improvement usually coincide with the reappearance in the stools of feculent matters of the consistence of gruel or even of mush, which are more or less mixed up with the muco-pus, pus and blood of the discharges. During the periods of aggravation the feculent matters are apt again to disappear from the stools. These cases may terminate in recovery in the course of six weeks to two months from the commencement of the disease, may at any time prove fatal, or may pass into a chronic flux of indefinite duration.

Convalescence from diphtheritic dysentery is in any case usually a tedious process, and the more so in proportion to the violence and duration of the disease and the degree of exhaustion of the vital powers. Not the least difficulty consists in an extreme sensitiveness of the bowels which is often left behind, so that diarrhœa, or even a relapse of the dysenteric symptoms, is apt to be provoked by slight disturbing circumstances, such as trifling imprudence in diet and exercise, or exposure to the vicissitudes of the weather. With these paroxysms of diarrhœa periods of constipation frequently alternate.

The foregoing sketches present an outline of the symptoms which occur in the most common forms of ordinary uncomplicated dysentery. This picture is sometimes considerably modified by apparent convalescence setting in at any stage of the disease, and followed, after a delusive respite, by fatal collapse;* or still further modifications may ensue when the dysenteric attack is complicated with other diseases, especially by malarial and typhoid fevers, the scorbutic taint or some intercurrent phlegmasia. Some of the more important of these complications will be discussed in a subsequent portion of this section, before which it will be convenient to offer some additional details with regard to a few of the more important symptoms.

* While writing the above paragraph a report was received at the Surgeon General's Office from Assistant Surgeon J. V. R. Hoff, U. S. A., in the case of Chaplain C. L. R., U. S. A., which illustrates this remark. The patient was taken with diarrhœa some little time before dysenteric symptoms set in, and it is stated that about the time the looseness first appeared a disagreeable occurrence had worried him considerably and caused him to become mentally depressed. November 12, 1875, while suffering from the diarrhœa, he took a long, cold and tiresome ride from his post (Fort McPherson, Nebraska) to the North Platte, and after reaching there took to his bed. A physician was called, and dysentery diagnosticated. He subsequently returned to Fort McPherson, where, November 14th, he was placed on sick report, and on the 18th was seen by Dr. Hoff in consultation with Acting Assistant Surgeon C. F. Stevens, who attended him. After giving the history of the symptoms of the case at some length, Dr. Hoff remarks: "To sum up the case: The actual outbreak of the disease, which we may safely assume as occurring at North Platte, November 12th, was preceded by an indefinite constitutional disturbance, irregularity of digestion, loss of appetite, thirst, pain and diarrhœa. On that day the bowels were moved repeatedly, the motions being preceded and followed by severe pain, giving the characteristic tormina and tenesmus of dysentery. The evacuations consisted of muco-bloody masses mixed with hard scybala, and occasionally were apparently of pure blood. The patient soon became pale, and seemed to suffer great mental depression; was irritable and disinclined to the slightest exertion, (which his family informed me was always his manner in sickness,) but did not seem to lose flesh to any great extent. At the time of apparent convalescence the dejections, I am told, became more natural in color and consistence, growing brownish, feculent and less frequent, the pulse became stronger and the mind clearer. At this time I felt safe in prognosticating, with ordinary care, the patient's return to health through a protracted convalescence, and suggested a change of air. December 11th, the picture changed. The disease seemed again to become active; the tormina returned; the passages assumed a blackish color and carrion-like odor, and were mixed with discolored shreds of mucous membrane. The pulse became small and frequent; the extremities cold; the mind slightly wandering. Then the abdominal pain ceased; the disease became adynamic; the thin, black, stinking dejections, though few, were at the last passed involuntarily, and, finally, he died December 24th. No autopsy was permitted."

THE DYSENTERIC STOOLS.*—The great variety of appearances presented by the discharges from the bowels in dysentery result from the admixture of a comparatively small number of ingredients, with regard to each of which a few remarks will be offered. These are: 1, feculent matters; 2, mucus, pus and various admixtures of the two; 3, blood and bloody serum; 4, portions of pseudomembrane and of the necrosed intestinal coats; 5, bacteria and other parasitic forms; 6, accidental matters derived from the food and medicines taken. Of these ingredients, the second are common to simple inflammatory dysentery and the early stages of the diphtheritic variety. The fourth are characteristic of diphtheritic dysentery. The other ingredients may be found under various circumstances at almost any stage of either variety.

1. *Feculent matters.*—As already mentioned, in the majority of cases true feculent matters almost entirely disappear from the stools so soon as dysentery is fairly inaugurated. If diarrhœa has not preceded the dysenteric attack, the first few evacuations are apt to discharge all the feculent matters contained in the lower bowel, and no more are formed until the violence of the disease is spent. The same result is still more thoroughly effected when diarrhœa has been the first stage of the disease. Stoll was therefore right in the main when he classed dysentery among the "morbi alvum occludentes."† Nevertheless, small quantities of feculent matters do sometimes appear in the stools. Thus, when the disease has been preceded by constipation, the hardened fæcal matters impacted in the pouches of the colon may not all be discharged at first, but from time to time during the progress of the disease, especially during its early stages, little rounded balls of hardened fæcal matters, conditioned in size and shape by the pouches in which they have been retained, come away with the evacuations. These small, hard, fæcal masses, which are designated scybala,‡ are by no means invariable concomitants even of the early stages of

* For a general account of the characters of the stools in disease and incidentally in dysentery, see, besides the works referred to in subsequent notes, HIPPOCRATES, *Prenotions of Cos*, [Ed. Littré, V, p. 721,] and *Prognostics*, [Id., II, p. 135;] THEOPHILUS, *De Retrimentis Alvi*, [Greek-Latin Ed., bound up with the *Libellus de Urinis* of the same author, Leyden, 1703;] N. Heilkunde, 1859, I, S. I, with 4 plates.

† STOLL—*Rat. Med*, Pars III, Sect. 4, Cap. 4, p. 284, ed. cited *supra*, p. 342—"Ea certe est dysenteriæ legitimæ conditio, ut hanc morbis adnumeres alvum potius occludentibus."

‡ The Greek word Σκύβαλον properly means merely fæcal matter (stercus) without regard to its degree of hardness or dryness. It is used in this sense by ARETÆUS, for example, in his chapter on dysentery—*De Causis et Signis Morb. Diut.*, Lib. II, Cap. 9, [Ed. Boerhaave, pp. 60 and 61.] He explains that fæcal matters (skubala) when mixed with the bloody discharges may be either dissolved in them, or may be dry and consistent, in the latter case being lubricated with the surrounding fluid. ST. PAUL seems to have used it in the same sense in Philippians, 3, 8: "For whom I have suffered the loss of all things, and do count them but dung, that I may win Christ." The word here translated dung is σκύβαλα. This word is also used by certain writers in a broader sense to mean generally dregs, refuse, &c., as, for example, by DIOSCORIDES in the fifth book of his *Materia Medica*, where, in describing the preparation of Pompholyx, (sublimed zinc,) he directs it to be enveloped in a piece of linen and washed out, and speaks of the sediment which remains on the cloth as σκύβαλον. RUELLIUS, in his version of DIOSCORIDES, translates this word "sedimentum," [I cite the Greek-Latin Ed., Paris, 1549, Lib. V, Cap. 85, f. 283,] while MARCELLUS VERGILIUS translates it "quod vero inutile et durum;" [I cite the Greek-Latin Ed., Coloniæ, 1529, Lib. V, Cap. 43, p. 649.] The division of the different editions into chapters varies greatly; thus GORRÆUS [*vide infra*] cites this passage as Lib. V, Cap. 77, without mentioning the edition, and this reference is repeated by subsequent writers. GALEN—*Comm. IV in Hippoc. de Acut. Morb. Victu*, § 15, [Ed. Kühn, XV, pp. 760–1,]—appears to have been the first to use the word in its modern sense. In speaking of ardent fevers (causus) he applies it to hard fæcal lumps, parched by the inflammation of some viscus, and resembling the droppings of goats. (goats' pills;) but GALEN himself elsewhere uses the word to signify fæcal matter merely, without reference to its character, as in his *Comm. I, in Hippoc. de Humor lib.*, § 12, [Ed. Kühn, XVI, p. 146.] I may add that the comparison of hard balls of fæces to the excrements of goats is probably very old. See the Hippocratic treatise *Prenotions of Cos*, Sect. II, Par. 26, [Ed. Littré, V, p. 689.] where such stools are spoken of as occurring in dropsy. GORRÆUS—*Def. Med.*, [Opera, Paris, 1622, p. 579,]—in defining the term scybala, gives both meanings, but prefers to apply it to very dry excrements formed into a nucleus; and JAMES—*Med. Dict.*, Vol. III, London, 1745—says: "*Scybala*—Excrement indurated in lumps." In this latter sense it has since been generally employed. CÆLIUS AURELIANUS—*Morb. Chron.*, Lib. IV, Cap. 6, [Ed. Amman, 1709, p. 535,]—speaks of the frequent occurrence of condensed fæcal matters [coacta stercora] in the dysenteric stools, but neither he nor subsequent writers for the most part appear to have attached much importance to their appearance until the middle of the last century, when CLEGHORN—*Obs. on the Epidemical Diseases in Minorca*, 1751, (I cite from the 4th Ed., London, 1779, p. 252.]—suggested that possibly they might sometimes be the cause of dysentery, saying, in giving reasons for the use of purgatives in the treatment, that "hardened excrements are, for the most part, either the cause or the consequence of the disease." PRINGLE—*Obs. on the Diseases of the Army*, London, 1752, Part 3, Chap. 6, p. 258—who did not adopt this view of the causation of dysentery, nevertheless attached great importance to the presence of scybala, remarking, in the first edition of his work, that 'they keep up the irritation and protract the disease, when it would otherwise have ceased," and in the last edition [7th Ed., London, 1774, p. 229] substituting the following passage: "The balls of hardened fæces may come away at any time of the disease, but I have observed them mostly in its advanced state, and when I suspected that purging had been too long neglected. I have commonly seen the tenesmus and

dysentery, their presence or absence being related to the degree of the constipation which so often precedes the dysenteric attack.

In cases which begin to improve, whether permanently or temporarily, feculent matters again make their appearance in the stools. This may also happen at any period in the progress of those cases in which the morbid process on which the dysentery depends is limited to the descending colon and rectum, or is so distributed as to leave irregular territories of the mucous membrane of the large intestine in a condition approximating the normal. Usually, however, it is only when the violence of the disease is spent, for the time at least, that feculent matters reappear in the discharges. These matters, then, vary greatly in character, in accordance with the condition of the hepatic secretion and the manner in which the digestive processes are performed in the stomach and small intestine. Deficient hepatic secretion would appear to be a common condition, in consequence of which the feculent matters passed are clay-colored, ash-colored, grayish or whitish;* and with

all other symptoms give way, after they were carried off by a brisk purge. These scybala are of so firm a texture, and so round, that they seem to have been formed in the cells of the colon, and to have lain there from the beginning." MOSELEY—*Treatise on Tropical Diseases*, [3d Ed., London, 1792, p. 233,]—took a very similar view: "Another cause of obstinacy in the flux, is indurated fæces, lodged in the intestines; and though the patient shall have been repeatedly purged, and taken nothing but fluids during his illness, it is amazing what scybala, or lumps of excrement, will sometimes be brought away, by a repetition of the antimonial purgative, after an interval of several days." Meanwhile, L. CHALMERS—*An Account of the Weather and Diseases of South-Carolina*, London, 1776, Vol. II, p. 31—had expressed the opinion that tenesmus and dysentery "for the most part arise in this climate from costiveness;" and CULLEN—*First Lines of the Practice of Physic*, [I cite the Ed. of 1778-79, Vol. II, p. 379,]—sought the proximate cause of dysentery in general in a preternatural constriction of the colon, causing the retention of the fæcal matters, pointing out that when scybala "are voided, whether by the efforts of nature, or, as solicited by art, they procure a remission of all the symptoms, and more especially of the frequent stools, griping, and tenesmus," (p. 373.) So also ANNESLEY—*Diseases of India*, London, 1828, Vol, II, p. 241—regarded accumulations of fæcal matters in the colon as among the most powerful predisposing causes of dysentery; and VIRCHOW—*Unterleibsaffectionen*, Archiv (1852) V, p. 352—who supports this view in an exceedingly ingenious manner, makes fæcal accumulations play an important part in the causation of the disease. In this connection the reader may also consult with advantage the dissertation of PAUL SENEBIER—*Des Scybales*, Paris Thesis, No. 179, 1873—who defines scybala as "Very hard intestinal concretions which are generally globular, of clay-like aspect, and vary in size from that of a bird's egg to that of a large orange, or larger. They are composed of fæcal matters, the liquid part of which has been reabsorbed. In certain cases scybala are incrusted with calcareous salts and thus form enteroliths," (p. 7.) According to the author, scybala are found most frequently in the rectum, next in the cæcum, then in the sigmoid flexure and colon. They may even fill the whole of the large intestine, as in Obs. VIII, p. 20. They are caused either, 1, by mechanical obstructions, or, 2, by physiological causes, such as enfeeblement of the intestinal functions of secretion and peristaltic motion, or augmentation of the absorptive process. See also A. RACIBORSKI—*Les Tumeurs Stercorales*, Paris Thesis, No. 370, 1834—who reports ten interesting cases of notable fæcal accumulation; and the paper of A. H. HENROT—*Des Pseudo-étranglements*, Paris Thesis, No. 94, 1865—in which it is shown how intestinal paralysis may produce obstruction and fæcal accumulation. (Here belong observations 21 to 35.) With regard to the *enteroliths* referred to by SENEBIER, a word may be said. GALEN thought the occurrence of intestinal calculi improbable. He says—*De Loc. Affect.*, Lib. VI, Cap. 2, [Ed. Kühn, VIII, p. 384,]—"Some writers mention that after vehement attempts at stool, preceded by severe pain, certain callous stones have been voided similar to those which originate in the bladder; which I myself have never seen, nor have I ever heard of any one who has." Nevertheless, the occurrence of such calculi has been fully established. Besides the frequently-occurring biliary calculi, concretions of various characters originate in the intestinal canal. The subject is not so connected with dysentery as to make it desirable to discuss it fully in this place, but I may refer to ALEX. MONRO, JR.—*Morbid Anatomy of the Human Gullet, Stomach, and Intestines*, Edinburgh, 1811, p. 25—in whose book the reader will find numerous references to cases scattered through the older literature, and a description of 42 specimens collected by the author's father. A large part of these calculi proved, as was first shown by Dr. WOLLASTON, to be composed of vegetable hairs derived from the oatmeal which forms so important a part of the diet of the laboring classes in Scotland. See ALEX. MARCET—*Essay on Calculous Disorders*, London, 1817, p. 129; and R. QUAIN—*Diseases of the Rectum*, 2d Ed., London, 1855, p. 320. But this is by no means the only variety of intestinal calculi. See the two authors just cited, also BOYER—*Traité des Mal. Chir.*, 4me Éd., Paris, 1831, Tome X, p. 41 *et seq.*—who describes concretions of hardened fæcal matters under the designation "pierres stercorales;" and the interesting dissertation of JULES CLOQUET—*Mémoire sur les Concrétions Intestinales*, [read to the Acad. of Sci., Jan. 29, 1855,] Paris, 1855. This author classes the intestinal concretions of both man and animals as: 1, Concretions of inorganic salts around a hard nucleus (bézoards) comparatively frequent among animals, but rare in man, though they do sometimes occur; 2, Hair balls coated outside by a delicate layer of carbonate and phosphate of lime, (égagropiles.) These are common in ruminating animals, but in man they occur almost exclusively in countries where oatmeal is much used as food, as in Scotland, Brittany, &c. The hairs of the grain, mixed with the imperfectly-prepared flour, mat together in the intestines around the stone of some fruit or any other similar body, as a nucleus. He mentions also the observations of the elder LAUGIER (Mémoires de l'Acad. de Méd., Tome I, Paris, 1828, p. 415) of a concretion composed of the fibres of liquorice root, which the patient habitually chewed, and three cases of true hair balls in individuals who, from a sort of monomania, were in the habit of swallowing hair. 3, Masses of hair without an outside coating. Besides these varieties of concretions, the author mentions as peculiar to the human species, (a) concretions of magnesia in persons who abuse this drug, and (b) rounded, semitransparent, elastic masses of cascine in infants, and even in adults on a milk diet. Consult also COPLAND—*Art. Concretions, Intestinal*, Med. Dict., Vol. I, p. 397; and BAMBERGER—*Kothgeschwülste und Darmsteine*, in Virchow's Handbuch der Spec. Path. und Ther., Bd. VI, Abth. I, Erlangen, 1855, S. 464.

* I still hold to the opinion that stools of the characters indicated are sufficient evidence of a deficiency of biliary matter in the alimentary canal, notwithstanding the hypothetical suggestions of THOMAS INMAN—*Letter to British Medical Journal*, Dec. 15, 1860, p. 985—that the "brown colour of the stools is due to a secretion from the colon," and is no wise dependent on the bile. The only fact brought forward to sustain this speculation is the well known circumstance that the intestinal contents do not acquire the peculiar brown color of fæcal matter until after they enter the colon. ROBERT LAWSON—*Some observations on the urinary and alvine excretions as they appear within the tropics*, British and Foreign Med. Chir. Review, October, 1861, p. 483—favors the same view, stating in support of it that in normal excrement the "epithelium and granular matter" contained in the fæcal mass "is all impregnated with a brown pigment" which "is usually the only colouring matter to be seen, and nitric acid does not produce in it the characteristic reaction of bile." The first of these circumstances has nothing to do with the origin of the pigment; the last I readily admit. Whenever death takes place at the proper stage of digestion, and often at other times, the biliary coloring matter is recognizable as such in the small intestine. In the large intestine of healthy adults, however, it is transformed into the well known brown color, which no longer gives the bile reaction with nitric acid. That, nevertheless, this normal brown color is formed at the expense of the biliary secretion is easily shown by diverting that secretion from the intestinal canal of dogs by

varying digestive energy and diet, the products of the digestive process vary from a uniform pap to a mixture of fragments, which even by the naked eye are recognized to consist of undigested food. Either of these conditions may occur in acute dysentery, particularly in its later stages, and especially in protracted cases. Both of them are common enough in the chronic fluxes.

2. *Mucus and pus.*—Mucus appears in the stools at the commencement of the dysenteric attack in glairy, translucent, sometimes yellowish masses, somewhat resembling the white of an egg to the naked eye. These masses possess considerable cohesion, so that when the attempt is made to lift them with forceps they draw out into strings, and when it is desired to remove morsels for microscopic examination this is best done with the aid of scissors. After a time the mucus becomes more opaque, whitish and yellowish, and is then described as muco-pus; or it may altogether lose its stringy quality and become yellow and miscible with water, and then is properly described as pus.

With the microscope, elements resembling the white corpuscles of the blood are found in all these fluids. They are least numerous in mucus, in which they are called mucous corpuscles; more numerous in muco-pus, and most so in pure pus, in both of which they are called pus corpuscles. As already shown,* there is no specific difference between the mucous and pus corpuscles, which are identical in all essential morphological particulars and originate in the same way. Both, when recent and at the temperature of the body, are capable of the amœboid movements described by Max Schultze† in the white corpuscles of the blood, and in both, when this property is lost by lowered temperature, dilution of the fluid in which they float, lapse of time or other causes, an active molecular dance of the granules they contain sets in, followed by a rupture of the protoplasmic mass with discharge

ligature of the common bile duct, or by the establishment of biliary fistulæ. The stools immediately lose their normal color, and do not regain it so long as the bile is excluded from the alimentary canal. Thus TIEDEMANN and GMELIN, [*loc. cit.*, p. 284, *supra*,] in a number of dogs in which they had ligated the common bile duct, found that after the second or third day the stools became grayish-white or clay-colored ("une teinte d'un blanc grisâtre, argileuse") and retained these characters as long as the animal lived, except in two instances, in one of which after the tenth day, in the other after the fifteenth, the stools regained their normal color. In both these instances it was found on post mortem examination that the bile duct had again become patulous and the bile had once more gained access to the intestine. F. ARNOLD—*Zur Physiologie der Galle*, Mannheim, 1854—established a successful biliary fistula in a dog and found the stools clay-colored while the animal was fed on flesh; subsequently he was fed on rye bread, and the fæces acquired a yellowish-gray color derived from the bread, (S. 15.) The *Report of the Edinburgh Committee on the action of Mercury, &c.*, cited p. 276, *supra*, relates in Part II the particulars of no less than nine successfully established biliary fistulæ in dogs. In every instance (except No. 7, in which mention of the color of the stools was accidentally omitted) it is expressly stated that the fæces became clay-colored. The same circumstance was noted by AUSTIN FLINT, JR., in his successful case of biliary fistula, (*op. cit.*, p. 284, *supra.*) In the face of positive evidence of this kind, the speculations of INMAN and LAWSON appear of little force. LAWSON cites in support of his views the remarks of HENRY HOLLAND—*Medical Notes and Reflections*, Chap. XIII, On some points in the pathology of the colon, Amer. ed., Philadelphia, 1839, p. 109—who has expressed the opinion that "many of the various egesta from the bowels, usually termed bilious," are in fact "separated from the vessels or glands of the larger intestine by exudation or secretion." The ingenious author specifies "the peculiar matter, resembling coffee-grounds" as an example, expresses the opinion that it is "separated in great part in the lower intestines," and adds: "These secretions also which resemble chopped grass or spinach have probably the same origin; and even of the liquid which is called green bile it is doubtful what proportion may come from the liver. The colour of what passes from the bowels is often the effect of changes taking place within the intestine itself," (p. 110.) These conjectures, however, are unsupported by any experimental evidence, and therefore have little value. The "coffee-ground" discharges are shown by the microscope to owe their appearance to the presence of altered blood, but this fact has no connection with the normal color of the stools. LAWSON further cites, in support of his views, a case reported by FRERICHS—*Diseases of the Liver*, Transl. of New Sydenham Society, London, 1860, Vol. I, p. 138, (Obs. No. 6,) in which it is stated that the "colour of the stools was somewhat brownish, not owing, however, to the admixture of bile-pigment, but as shown by the microscope, to numerous epithelial cells containing pigment, derived from the mucous membrane and glands of the intestine." Now this was a case of occlusion of the bile ducts by a cancerous growth; there was intense jaundice; the skin had "assumed a bronze colour;" the urine was "brownish-black." If the observation of FRERICHS was correct, which I do not doubt, the intestinal epithelium had, like the skin, become infiltrated with altered bile-pigment—that is all. LAWSON himself cites, as an observation "more to the purpose," a case of diarrhœa in which the stools were dark-brown, and contained epithelial cells "deeply tinged with a brown colour," although "no blood globule was seen among them," and considers this "conclusive as to the possibility of colouring matter being obtained from the intestine." There is a strange confusion of ideas in all this, for there is absolutely nothing in LAWSON'S case, as he reports it, to show that the epithelial elements observed had not obtained their color after separation by imbibition from the intestinal contents. Normally the intestinal epithelium is quite colorless. In FRERICHS' case the cause of its abnormal color is patent. Now I do not for a moment deny that the stools may become brown in the absence of the products of bile-pigment, from the presence of altered blood, from certain ingesta, &c. AUSTIN FLINT'S dog (*loc. cit.*) on one or two occasions passed "quite dark" stools; (the tint is unfortunately not specified.) But these facts are not to be interpreted as in any way contradicting the general truth that the products of the decomposition of bile-pigment give color to the stools in the normal state, and that variations in the original quantity and quality of the biliary secretion, as well as in the subsequent decompositions which this fluid normally undergoes in the alimentary canal, are important factors in modifying the color of the stools in disease.

* *Supra*, p 278.

† MAX SCHULTZE—*Ein heizbarer Objecttisch, &c.*, [Archiv für Mik. Anat., Bd. I, S. 1.] For a detailed description of similar amœboid movements in the pus corpuscles, see F. v. RECKLINGHAUSEN—*Ueber Eiter- und Bindegewebskörperchen*, [Virchow's Archiv, Bd. XXVIII, 1863, S. 157.]

of the granules and subsequent collapse, as is also readily observed in the so-called salivary corpuscles, which are doubtless of the same nature and origin, and in the white corpuscles of the blood after the dilution of that fluid with water.

The essential difference between mucus and pus, as discharged from mucous membranes, resides then, not in the contained corpuscles, but in the material containing them. Mucus is characterized by the stringy, cohesive nature of this material, and its reaction with dilute acetic acid, which precipitates filaments and flakes of mucin* soluble in dilute alkalies, while pus is characterized by the fact that the corpuscles float in a serum containing albumen. In muco-pus the two substances are mingled in various proportions. These substances may be passed without much admixture of other matters, constituting the mucous or muco-purulent stools; may form a coating to scybala, or may be variously mixed with blood, bloody serum, feculent matters, etc. When the mucus is mingled with watery discharges, as sometimes happens, especially in the early stages of dysentery, or when water is purposely mixed with it, it can often be unfolded into hyaline membranes or shreds which float in the fluid.† Whether the jelly-like bodies often seen, which have been compared to sago grains or frogs' eggs, are ever composed of mucus, appears so doubtful that they will be described under the head of "accidental matters derived from the food and medicines taken." The watery discharges just referred to sometimes also contain more or less albumen, as will be presently described under the head of "blood and bloody serum."

The presence of mucus and pus in the dysenteric stools has been recognized from the earliest times;‡ but the old Greek physicians described also the appearance of a certain fatty substance in the stools, especially during the early stages of dysentery. Mentioned by Hippocrates and Archigenes, and more fully expounded by Galen,§ the belief that fat was an ordinary constituent of the dysenteric stools continued to prevail among medical men until more correct views of the nature of the substance in question were propounded at the commencement of the seventeenth century by Felix Plater, Riverius and Sennertus.‖ It would appear from their writings that most probably the opaque, whitish, muco-purulent

---

* LEHMANN—*Phys. Chem.*, [Transl. of Cavendish Soc., Vol. II, London, 1853, p. 371 *et seq.*]—gives a good account of the chemical relations of mucus. See also SIMON—*Animal Chem.*, [Transl. of Sydenham Soc., Vol. II, London, 1846, p. 73.]

† HEUBNER speaks of these as "shreddy" stools,—Vol. I, p. 549, *op. cit.*, *supra*, p. 310, Amer. transl.,—but these shreds rarely attract attention as such, unless specially searched for, on account of their delicacy. The true shreddy stool is that which contains shreds and pellicles of pseudomembrane and fragments of necrosed mucous and submucous tissues.

‡ Thus in the Hippocratic treatise—*Prænotions of Cos*, Sect. VII, § 606, [Ed. Littré, V, p. 725,]—we are told that phlegm-like (φλεγματώδης) stools, if acute and with cardialgia, indicate dysentery; and in Sect. II, § 455, [p. 687,] that in acute dysentery, when the stools become purulent (πυώδεα) what floats on their surface is very white and abundant. So also CELSUS—Lib. IV, Cap. 15, [Leyden Ed., 1785, p. 179,]—speaks of the dysenteric stools as mixed with mucus: "cum quibusdam quasi mucosis."

§ HIPPOCRATES—*Epidem.*, Lib. III, Sect. 3, § 8, [Ed. Littré, III, p. 87,]—describes the stools in certain cases of dysentery as "bilious, fatty, (λιπαρὰ,) thin and watery." ARCHIGENES, according to ÆTIUS—Tetrab. III, Serm. I, Cap. 43, [Lyons Ed., 1549, p. 399.]—spoke of the fatty matter as appearing in the early stages of dysentery, and supposed it to be derived from the melting of the fat which he erroneously believed to exist normally on the interior surface of the bowel. GALEN—*De Loc. Affect.*, Lib. VI, Cap. 2, [Ed. Kühn, VIII, p. 382,]—taught that the appearance of matter resembling fat (πιμελώδες) in the dysenteric stools, along with the shreds of intestine, (ξύσματα,) was an indication that the large intestine was ulcerated. I find these fatty matters alluded to, and described as occurring in dysentery, by many subsequent writers, among whom I may mention CÆLIUS AURELIANUS—*Morb. Chron.*, Lib. IV, Cap. 6, [Amman's Ed., p. 526,] and ALEXANDER of TRALLES—Lib. VIII, Cap. 9, [Basel Ed. of 1556, p. 455.] FERNELIUS—*Pathолog.*, Lib. VI, Cap. 10, [Paris Ed., 1551, p. 187,]—described and explained these supposed fatty matters almost as had been done by ARCHIGENES and GALEN; but HOLLERIUS—*De Morb. Intern.*, Lib. 1, Cap. 40, Scholia, [Venice, 1572, f. 124,]—while doing the same, pointed out that many persons had deceived themselves and mistaken other substances for fat, and suggested that suspected substances should be thrown on live coals, when fat would melt and give off a characteristic vapor, while fleshy substances would blacken and dry up. This would also serve to distinguish mucus.

‖ FELIX PLATER—*Praxeos*, De Vitiis, Lib. II, Cap. 11, [Basel Ed., 1736, Tom. III, p. 794,]—speaks of mucus and pus as being voided along with blood, &c., in dysentery. He says that the mucus has been falsely taken for fat, and remarks that the common opinion that this has its origin from the fat on the interior surface of the intestines, is erroneous, since there is really no fat there, but only on the exterior surface. RIVERIUS—*Prax. Med.*, Lib. X, Cap. 6, [Opera, Lyons, 1679, p. 301,]—denies that the whitish mucous substance (illud mucosum et album) which is so plentifully excreted in dysentery, mixed with blood and other humors, is fat, nor does he admit that it is either the natural mucus of the intestines or pus from the dysenteric ulcers; he believes it to be rather a peculiar secretion from the diseased surface, and compares it to the discharge which takes place from the eyes in ophthalmia, or from the bronchial tubes in affections of the lungs in which no ulcers exist. SENNERTUS—*Pract. Med.*, Lib. III, Pars 2, Sect. 2, Cap. 7, Quæstio 1, [Opera, Paris, 1641, T. III, p. 184,]—devoted to the subject a dissertation in which he maintains a view almost identical with that of RIVERIUS.

matters, so frequently observed in the stools during sharp dysenteric attacks, constituted what was supposed to be fatty by the ancients. This fatty matter must not be confounded with the suet-like lumps described by Aretæus, and subsequently known as corpora pinguia. These will be more particularly referred to hereafter in connection with the so-called sago-grain bodies.

3. *Blood and bloody serum.*—More or less blood is very often present in the dysenteric stools. It may appear as streaks upon the feculent or mucous masses, or may be more or less intimately commingled with the other ingredients in fluid stools. The quantity may be so small that it can only be recognized with certainty by the microscope, or so large as to threaten death by hæmorrhage. It may result from capillary rupture, conditioned by the intense hyperæmia accompanying the inflammatory process, or from the erosion of larger vessels during the progress of follicular ulceration, or the separation of diphtheritic sloughs and the ulceration which succeeds that process.* In the great majority of cases the hæmorrhage is moderate in quantity, and the blood passed is more or less intimately mingled with the other ingredients of the dejecta. As a rule it is only in those who are constitutionally prone to hæmorrhage, as in scorbutic patients, that bulky hæmorrhages occur producing stools composed entirely of blood.

Blood may make its appearance in the stools during various other diseases than that under consideration. Not only may this occur in diarrhœa and typhoid fever, but also in individuals who are not laboring under any intestinal flux. Hæmorrhoids, eroding ulcers of the duodenum, cancer and tubercular disease of the bowels are familiar illustrations. So also in epistaxis and hæmoptysis, or in cancer and other diseases of the pharynx and œsophagus, blood may be swallowed and make its appearance in the stools; and in hæmorrhage into the stomach from any cause, a portion of the blood may pass downward and be expelled through the intestines.

Besides these various sources of blood in the stools, hæmorrhage from the intestines may occur from rupture of the capillaries of the mucous membrane of the bowel in various conditions in which that membrane itself is not the seat of any recognizable organic disease. This may happen from mechanical obstructions of the portal circulation, such as occur in valvular disease of the heart and in cirrhosis of the liver,† or in consequence of a depraved condition of the blood, as in certain cases of scurvy, yellow fever and hæmorrhagic malarial fever.‡ Hæmorrhages from the intestines also occasionally occur in those who abuse alcoholic beverages, though perhaps less frequently than hæmorrhages from the stomach in the same class of persons. These hæmorrhages are probably determined in most cases by the existence of cirrhosis of the liver, but also in some of those in which the hæmorrhage takes place in the stomachs of spirit-drinkers by congestion, or even chronic inflammation and ulceration of the mucous membrane of that organ from the local irritation. In these

* The latter accident was long ago described by ARETÆUS—*De Causis et Signis Morb. Diut.*, Lib. II, Cap. 9, [Ed. Boerhaave, p. 62,] who says that in some cases a large slough (μεγάλη ἐσχάρη) separating, occasions a considerable aperture in a vein and gives rise to dangerous hæmorrhage.

† F. T. FRERICHS—*Diseases of the Liver*, [Transl. of New Sydenham Soc., London, 1860–1,]—gives a number of cases of hæmorrhage from the stomach, intestines, or both, in various diseases of that organ; for example, in acute atrophy of the liver, Vol. I, p. 214; in chronic atrophy, *ib.*, pp. 268 and 272. In connection with the pigment-liver of intermittent fever, he says, *ib.*, p. 346: "Intestinal hæmorrhages I have observed on three occasions; the bleedings were intermittent, and came on each time with the paroxysm of the fever; they were not affected by any treatment directed against the hæmorrhage, but yielded to large doses of quinine." He states that in cirrhosis of the liver capillary hæmorrhages from the stomach and bowels are not very uncommon, Vol. II, p. 49, but that "exhausting hæmorrhage from the intestinal canal is rare," *ib.*, p. 47. He gives cases of intestinal hæmorrhage in syphilitic disease of the liver, *ib.*, p. 161; in cancer of the liver, *ib.*, pp. 340 and 345, and in disease of the biliary passages, *ib.*, pp. 450 and 540.

‡ WM. A. B. NORCOM—*Hæmorrhagic Malarial Fever*, Raleigh, N. C., 1874, p. 10. Compare W. C. MACLEAN, Art. *Malarial Fevers*, [in Reynold's System of Medicine, Vol. I, London, 1866, p. 72.] "I have seen two cases at Madras, both in officers of the Forest Conservancy department, in which the hæmorrhagic range was most extensive, the patients passing blood from the stomach, bowels, and kidneys."

latter cases a part at least of the extravasated blood may be discharged by stool.* According to Aitken, the inhalation of sulphuretted hydrogen gas may give rise to hæmorrhage from the bowels.†

When the blood discharged proceeds from any point above the pylorus, and even when its source is in the small intestine, it is very frequently much altered in appearance by the influence of the gastric or intestinal contents, the red corpuscles becoming variously deformed, and the fluid when passed being black, brown or greenish, often tar-like in color and consistency, so that, indeed, sometimes it would hardly be suspected to be blood from its appearance to the naked eye, although on microscopical examination the recognition of vast numbers of altered red corpuscles leaves no doubt on the subject. These discharges of altered blood from the bowels have, since the publication of the Nosology of Sauvages, been very generally designated Melæna, a term which, in the Hippocratic writings, is applied to a disease characterized by vomiting of black matters.‡ It may be added that bloody stools of all kinds were included in these writings under the designation of dysentery, while Galen clearly separated those connected with true dysentery from those arising from other causes, attributing the former to ulceration of the bowels, and the latter to plethora, disease of the liver, or the action of black bile.§

In dysentery the source of the hæmorrhage is, most generally, some part of the large intestine, and the blood, unless present in very small quantities, is usually recognized with the naked eye by its red color. Very often, however, the proportion of pure blood that is present is comparatively small, and it is diluted by a comparatively copious transudation of an albuminous fluid, so that the fluid passed may be correctly described as bloody serum. It sometimes appears at the commencement of the disease in the form of watery discharges containing comparatively little albumen, but as the disease progresses the quantity is usually smaller and the percentage of albumen larger. This bloody serum

---

* Thus C. Ph. FALCK—*Virchow's Handbuch der Spec. Path. und Therapie*, Bd. II, Abth. 1, [Erlangen, 1855,] S. 302—says that habitual drinkers suffer "sometimes from chronic diarrhœa, sometimes obstinate constipation, sometimes even from melæna." Surgeon BASIL NORRIS, U. S. Army, has recently communicated to the editor two interesting cases of intestinal hæmorrhage in spirit-drinkers. In the first there was cirrhosis of the liver with occasional bloody stools, and death. In the second, after blood had made its appearance for several days in the stools, there was a sudden and profuse hæmorrhage from the stomach, with copious vomiting of blood. This was checked by the administration of dry persulphate of iron in gelatine capsules.

† "Also from the effects of *sulphuretted hydrogen gas*—a cause of epidemic hæmorrhage from the bowels among the workmen in the mines of Anzin." AITKEN—*Science and Practice of Medicine*, Am. Ed., Philada., 1872, Vol. II, p. 663. I suppose the author to refer to the epidemic described by HALLÉ—"*Obs. sommaires sur une maladie qu'on peut nommer Anæmie, qui a attaqué tous les ouvriers d'une galerie dans une mine d'Anthracite ou charbon de terre, en exploitation à Anzain*," &c., Journ. de Méd. Chir. Pharm., &c., Tome IX, Paris, An. XIII, (1805,) pp. 1, 71, 138. See also Art. *Anémie*, in Dict. des Sci. Méd., Tome II, Paris, 1812, p. 81. But in this description, although black and green stools are mentioned, I do not find that the presence of blood was established or even suggested. OZANAM—*Maladies Épidémiques*, 2me Éd., Paris, 1835, Tome IV, p. 169—describes, also under the name of Anémie, a similar epidemic which occurred among the laborers in the mines of Schemnitz, in Hungary, in 1777–8, and 1785–92. The symptoms were quite like those of the Anzain epidemic, except that "the stools were infrequent (rares,) hard, and coated with an oily-looking substance, (d'un vernis huileux.")

‡ The Hippocratic Treatise *De Morbis*, Lib. II, [Ed. Littré, VII, p. 110,] describes, under the designation Black disease, (Μέλαινα νοῦσος,) an affection in which black matters sometimes exhaling an odor of blood are vomited. Elsewhere in the Hippocratic writings black stools are spoken of, as in *Aphorisms*, Sect. IV, 21 and 25, [Ed. Littré, IV, p. 509,] "stools black like blood." See also *Prorrhetics*, Lib. I, § 85 and 140, [Ed. Littré, V, pp. 533 and 561,] and *Prenotions of Cos*, Sect. II, § 268 and 313; Sect. VII, § 601, 621 and 624, [Ed. Littré, V, pp. 643, 653, 725 and 729.] GALEN explained the Black disease of HIPPOCRATES as originating from black bile—*Linguarum seu Dictionum Exoletarum Hippocratis Explicatio*, [Ed. Kühn, XIX, p. 120,]—and stated that the stools called black by the ancient physicians are not necessarily so from black bile, but often from blood. Compare his *Comm. IV in Hippoc. Aph.* 21 and 23, [Ed. Kühn, XVII, B, p. 681 *et seq.*,] and *De Atra Bile*, Cap. VI, [Ed. Kühn, V, p. 126.] The morbus niger of HIPPOCRATES gave rise during the 18th century to considerable discussion. See, for example, FRID. HOFFMANN—*Diss. De Morbo Nigro*, (originally a thesis of J. C. HERTIUS, Halle, 1701,) in Opera, Suppl. II, Pars 2, Geneva, 1753, p. 103, and R. JAMES—*Med. Dict.*, Vol. II, London, 1745—Articles, *Melæna Nuzos* and *Morbus Niger*. MÉRAT—Art. *Méléna*, in Dict. des Sci. Méd., Tome XXXII, Paris, 1819, p. 191—gives a list of dissertations, with the title "de morbo nigro," by LAUSDEN, 1694; FAUSIUS, 1657; GASSER, 1761; SCHRADER, 1764; SCHOXINGH, 1768; SINGER, 1775; HARTMANN, 1786; GIRARD, 1789; HŒHN, 1795, and KUHN, 1802. Of these I have only obtained access to those by GASSER and HŒHN. Under the head of "Maladie noire," VARNIER—*Jour. de Méd.*, (Feb. 1757,) T. VI, p. 83—described several cases of extreme prostration accompanied by fœtid and black stools. A similar case was published under the same title by VANDERMONDE—*op. cit.*, (May, 1757,) p. 336. Other cases were published by BONTÉ—*op. cit.*, (March, 1758,) T. VIII, p. 222—whose Obs. IV suggested to him the opinion that the disease was of a scorbutic nature. In the same journal GEOFFROY—T. VIII, p. 244—describes a case in which there was both vomiting and purging of "une matière noire comme de l'encre." SAUVAGES—*Nos. Meth.*, Amsterdam, 1768, T. II, p. 332—gave the following definition of Melæna: "Est alvi fluxus materiei nigricantis, atro-rubræ, dejectione, aut vomitione frequenti notatus," and makes seven species, viz: 1, m. splenetica; 2, m. scorbutica; 3, m. atrabilis; 4, m. hæmorrhagica; 5, m. prima, which is the black disease of HIPPOCRATES, whose description he quotes; 6, m. febricosa, and 7, m. hepatirrhoica. SAUVAGES particularly praises the paper of VARNIER cited above. Since the time of SAUVAGES the use of the term Melæna has been more and more limited to the stools.

§ See note to p. 336, *supra*.

is passed mingled with mucus, muco-pus or pus, or, after necrosis of the diphtheritic deposit occurs in diphtheritic dysentery, with shreds of pseudomembrane or of necrosed mucous membrane, and sometimes constitutes an important part of the discharges.

According to Oesterlen,* the mean daily loss of albuminates by stool during the first fourteen days of a dysentery of moderate intensity is from 50 to 60 grammes; the total quantity of matters passed by stool ranging from 1,500 to 2,000 cubic centimetres daily. During the next eight days the daily discharges by stool range from 800 to 1,000 cubic centimetres containing, on an average, 20 grammes of albuminates. So that he estimates the total loss by stool during such a dysentery of three weeks' duration at 30,000 cubic centimetres, containing 900 to 1,000 grammes of albumen. Niemeyer has pointed out that large quantities of albumen may be precipitated by nitric acid, in the matters filtered from the dysenteric stools, even when the dejections have scarcely a reddish tinge, and when only solitary red corpuscles are found under the microscope.† The albumen, therefore, is not merely derived from the blood mixed with the stools, but a true transudation of blood-plasma takes place, and may be so considerable as to contribute largely to the production of the dysenteric collapse, as happens still more strikingly in Asiatic cholera. Partly in consequence of this transudation of blood-plasma, but partly, also, no doubt, in consequence of semi-putrid metamorphoses of the intestinal contents accompanied by the liberation of ammoniacal compounds, the dysenteric stools are usually alkaline. According to Bamberger,‡ carbonate of ammonia is frequently present in them.

4. *Portions of pseudomembrane and of the necrosed intestinal coats.*—The appearance in the stools of portions of pseudomembrane and fragments of the necrosed intestinal coats is characteristic of diphtheritic dysentery. It will be shown, in connection with the morbid anatomy, that in this disease the diphtheritic deposit of granular fibrin infiltrates the mucous and submucous layers of the intestines, and forms also a layer of variable thickness upon the internal surface of the bowel. Soon after its deposit, a process of necrobiosis or necrosis sets in, by which the diphtheritic layer is separated from the healthy neighboring tissue, carrying with it so much of the intestinal coats as may have had their vitality destroyed by the infiltration. Very generally, in those portions of the intestine in which the process is most intense, the sloughing involves both the mucous and submucous coats, so that the circular fibres of the intestine form the bottom of the diphtheritic ulcer; elsewhere the mucous membrane alone may be destroyed, so that the submucosa forms the bottom of the ulcers; or even in some places the degree of infiltration in the mucous membrane may not be sufficient to destroy its vitality, and the pseudomembrane on the surface alone may separate, leaving the mucous membrane but little damaged and in a condition capable of resolution.

The area affected by each of these degrees of the diphtheritic process varies with the severity of the disease. Undoubtedly there are cases so mild that no part of the mucous

*OESTERLEN—*Zur Chemie der Ruhr*, Henle's Zeits. für Rat. Med., Bd. VII, (1849,) S. 253. The figures quoted in the text occur on S. 271-2. They are derived from the examination of the stools in four cases, two of which proved fatal. From the autopsies in the fatal cases, and the symptoms recorded in the others, it is probable that all belonged to the diphtheritic variety of dysentery. The largest daily quantity of albuminates found was 80.9 grammes, the smallest 13.5 grammes. The total quantity of material passed by stool in the twenty-four hours varied from 800 to 3,800 cubic centimetres, but this in several instances included the urine. The albumen was determined by acidulating with acetic acid and boiling, and it would appear that the stools were not previously filtered, for in the table on S. 269 and 270 the column in which the loss of albumen is entered is headed "Albumin und Epithelialgebilden." Nevertheless, making every allowance for this source of error, the results are striking enough, especially when compared with the analysis given by the author of the stools produced by administering calomel and jalap, which contained but 3 3 parts of albumen to the 1,000, and the stools of a patient suffering from typhoid fever, who passed (urine included) 1,000 cubic centimetres of fluid containing 3.9 grammes of albumen in the twenty-four hours. The author concludes that the more violent the disease the richer are the stools in albumen, and vice versa. LEHMANN—*Phys. Chem.*, Transl. of Cavendish Soc., London, 1853, Vol. II, p. 151—says that at the commencement of dysentery the intestinal discharges are poor in albumen, but that in the more advanced stages of cases of moderate violence "the fluid is extremely rich in albumen, being a true exudation of the blood-plasma."

†NIEMEYER—*Lehrbuch der Spec. Path. und Ther.*, 7te Aufl., Berlin, 1868, Bd. II, S. 752. ‡Page 401 of work cited on p. 266, *supra*.

membrane is destroyed; such cases stand on the border line between simple inflammatory and diphtheritic dysentery. More or less destruction of tissue is, however, the general rule in diphtheritic dysentery, except in those extremely intense cases in which death occurs before the diphtheritic layer begins to be thrown off. The slough may separate in fragments of almost any size. Large membranous pieces, from one to several inches long, or membranous tubes of more or less considerable length, are occasionally discharged;* but for the most part the fragments do not exceed a quarter to half an inch in long diameter, and still smaller morsels constitute the usual form. The most common variety of the diphtheritic stool is composed of bloody serum with numbers of these smaller morsels floating in it; they are generally soft, yellowish or reddish, and have been compared to raw minced meat.

When examined microscopically these fragments may prove to consist of the superficial pseudomembrane only, in which case they are composed of granular or indistinctly fibrillated fibrin, through which pus or blood corpuscles may be scattered or aggregated at intervals into heaps; or they may be true diphtheritic sloughs, in which case the glands of Lieberkühn and other characteristic structural elements belonging to the mucous membrane or the submucosa can often be recognized if proper methods of investigation are employed. These elements are generally more or less obscured by the granular character of the diphtheritic material with which they are infiltrated, and by the decomposition which occurred in the sloughs before they were thrown off; and the latter process may even have proceeded to such a degree that nothing can be recognized with the microscope but a granular decomposing mass, even when they are really composed of necrosed mucous membrane. Certainly, at least, portions of membrane having these characters in one part, while in others the elements of the intestinal tissues can be more or less distinctly recognized, are often found in the stools, and a similar continuity may be observed during autopsies in fragments which still adhere to the edges of diphtheritic ulcers. It may freely be admitted that not only in diphtheritic dysenteries of moderate intensity, but even in more severe cases in which sloughing of the mucous membrane is proceeding with great rapidity, many of the morsels found in the stools will prove to consist only of pseudomembrane from the most superficial portion of the deposit, or of granular masses in which all evidences of definite structure have been destroyed by decomposition; yet, it is nevertheless true that even in the milder cases of the diphtheritic form, the observer does not usually examine half a dozen well-selected fragments microscopically without finding one or more in which the anatomical elements belonging to the mucous membrane or submucosa can be plainly recognized in the midst of the granular debris.

Less frequent than this common variety of the diphtheritic stool is the so-called gangrenous stool, in which the necrosed fragments of mucous membrane are larger, often of a greenish or blackish color, and floating in a brownish or blackish slimy fluid of an extremely putrid odor. Various intermediate forms occur between this and the variety first described; the character of the necrosed fragments varying considerably, in accordance with the variations in the morbid process which will be sketched in connection with the pathological anatomy of the disease.

The shreds and fragments of membrane which occur in the stools of diphtheritic dysentery did not fail to arrest the attention of medical men even in the earliest times; they were

* *Vide infra*, p. 362.

mentioned by Hippocrates and Celsus,* and their origin was correctly explained by Aretæus and Galen,† whose views were repeated more or less exactly by almost all the subsequent writers on dysentery until the commencement of the seventeenth century, when Felix Plater ‡ expressed doubts as to the frequency of the appearance of such fragments of the intestinal coats in the dysenteric stools, and Sennertus in an elaborate dissertation § not only enforced the same view with considerable ingenuity, but suggested that when membranous fragments do occur in the dysenteric stools they probably consist only of inspissated mucus shaped in the intestines.

Morgagni in his great work || adopted this view in part only, correctly held, that in some cases the fragments of membrane discharged are portions of the intestinal coats, while in others they are merely false membranes, and supported this opinion by referring to the condition of the intestinal mucous membrane observed after death in such cases. It would seem that his explanation of the second of these two possibilities made a greater impression

* HIPPOCRATES, *Aphorisms*, IV, 26, [Ed. Littré, IV, p. 511:] "If in a person ill of dysentery substances resembling flesh [ὁκοῖαι σάρκες] be discharged from the bowels, it is a mortal symptom." In the treatise on *Prognostics*, §. 11, [Ed. Littré, II, p. 137] the statement is made that stools "of varying characters indicate greater duration of the complaint, but are no less dangerous; such as those which resemble scrapings, [ξυσματώδεα, in the Latin version translated "strigmentosa," Ed. Kühn, I, p. 100,] those which are bilious, those resembling leeks, and the black; these being sometimes passed together, and sometimes singly." The same statement, in almost the same language, will be found in the *Prenotions of Cos*, § 621, [Ed. Littré, V, p. 729, Ed. Kühn, I, p. 344;] the same word is used for the substances resembling scrapings in this passage as in the last, viz: ξυσματῶδες in the Greek text, strigmentosa in the Latin version. See also *Prorrhetics*, Lib. II, § 22, [Ed. Littré, IX, p. 51,] where, after stating that fever, varied stools, inflammation of the liver, hypochondrium or stomach, pain, loss of appetite and thirst are bad symptoms in dysentery, that the patient who has most of these symptoms will die most surely, while he who has fewest will have the best chance of recovery, it is asserted that those who have none of these evil symptoms, even though they pass blood and ξύσματα, may yet get well on the 7th, 14th, 20th or 40th days, or within these periods. CELSUS followed HIPPOCRATES in speaking of fleshy matters as being passed in dysentery: "Interdum simul quædam carnosa descendunt," Lib. IV, Cap. 15, [Leyden Ed., 1785, p. 179.] In Lib. II, Cap. 6, [*op. cit.*, pp. 43–4,] CELSUS paraphrases the passage just quoted from the Prognostics of HIPPOCRATES thus: "Alvus quoque varia, pestifera est, quæ strigmentum, sanguinem, bilem, viride aliquid, modo diversis temporibus, modo simul, et in mistura quadam, discreta tamen repræsentat." In Lib. II, Cap. 8, [*op. cit.*, p. 55,] he remarks that a dysentery is not dangerous even if blood and strigmenta are passed, ("si sanguis et strigmenta descendunt,") so long as fever and the other severe symptoms are absent, which is evidently borrowed from the passage in the Prorrhetics cited above.

†ARETÆUS—*De Causis et Signis Morb. Diut.*, Lib. II, Cap. 9, [Ed. Boerhaave, p. 60,]—in the detailed account he gives of the dysenteric stools, states that when the lower bowels are ulcerated, matters resembling flesh (σαρκοειδέα) and shreds (ξυσματώδεα) as it were of the intestines are found in the stools. From ulcers of the cæcum large red pieces of flesh are discharged. If the ulcers in the lower bowel grow worse, it sometimes happens that a long piece may come away "resembling the sound intestine." He explains that the bowels have two coats, that it is only the inner one which comes away, that subsequently the external coat which remains intact may granulate and cicatrize. This he says happens only in ulcers of the lower bowel. GALEN mentions in various places the occurrence in the stools of scrapings of the intestines, (ξύσματα.) See, particularly, the detailed description in *De Locis Affect.*, Lib. VI, Cap. 2, [Ed. Kühn, VIII, p. 382 *et seq.*] In the same place also he speaks of the passage of scabs of ulcers. (ἐφελκίς.) GORRÆUS—*Def. Med.*, [in Opera, Paris, 1622, p. 230,]—says of the word ephelkis, used in this passage, that it is applicable to external as well as to internal ulcers, and cites as examples "the scabs (crustulæ) coughed up from the lungs, and those passed by stool from the intestines." DAREMBERG—*Œuvres de Galien*, T. II, Paris, 1856, p. 668—translates it "une fausse membrane." Note also GALEN'S *Comm. in Hippoc. Aph.* IV, 26, [Ed. Kühn, XVII, B, p. 691,] in which he explains that the ξύσματα are derived from the internal membranous surface of the intestines, which he compares to the cuticle of the skin, while the fleshy matters mentioned by HIPPOCRATES are portions of the very substance of the intestines, and says that when large pieces of this kind are passed the disease is fatal, because the reparative powers are not adequate to replace the tissue removed. Compare further *De Loc. Affect.*, Lib. I, Cap. I, [Ed. Kühn, VIII, p. 6,] *Comm. IV in Hippoc. de Artic.*, § 39, [*op. cit.*, XVIII, A. 730] and *Comm. III in Hippoc. de Acut. Morb. Victu.*, § 30, [*op. cit.*, XV, 686.] CÆLIUS AURELIANUS—*Morb. Chron.*, Lib. IV, Cap. 6, [Ed. Amman, 1709, p. 525,]—speaks of the passage of ramenta, fleshy matters (carnosa) and membranes of considerable length. The two former figure in the descriptions of the dejecta given by ALEXANDER of TRALLES, Lib. VIII, Cap. 9. The word ξύσματα, variously translated as strigmenta and ramenta, which occurs in these and similar passages, originally designated matters rubbed off from the skin, as in the bath and during gymnastic exercises. These skin impurities were sometimes used for medicinal purposes both externally and internally. See R. JAMES, Art. *Strigmentum*, Med. Dict., Vol. III, London, 1745. FERNELIUS, HILDANUS (*loc. cit.*, *supra*, p. 345, note §) and many other writers of the sixteenth century and the beginning of the seventeenth, repeated the statements of GALEN with regard to this subject with but little modification.

‡ FELIX PLATER—*loc. cit.* in note to p. 347, *supra*. His language is: "Nonnullis pro ramentis intestinorum accipitur, quæ tamen si prodeunt, quod rarum, ea membranea esse necesse est."

§ SENNERTUS—*Pract. Med.*, Lib. III, Pars 2, Sect. 2, Cap. 7, Quæst. 3: "An pinguedo et ramenta intestinorum tanta, ut vulgo fertur, in dysenteria excernantur?" The author refers to the case observed by MEICHSNERUS, which will be found in SCHENCKIUS—*Obs. Med. Rar.*, Frankfort, 1609, p. 389, Lib. III, De Dysenteria. Curatio, Obs. 4—of a man suffering from dysentery who often passed ramenta and membranes of the intestines a span long, and yet recovered, and to a similar observation attributed to HERCULES SAXONIA, *Pantheon*, Lib. III, Cap. 23, in which a membrane an ell long (!) was passed, and yet the patient recovered. He expresses great doubt as to the accuracy of such observations, saying that he had never seen such membranes or ramenta in the dysenteric stools himself, or found among dysenteric patients or their attendants any one who had; if membranes are ever passed they must consist of an altered mucous concretion shaped in the intestines. SENNERTUS, in support of his view, speaks of J. CRATO, *Consil.* 201, as having, before PLATER, looked in vain for ramenta in a case of dysentery; but on examining this article I find that CRATO—*Consil. Med.*, collected by L. Scholz, Frankfort, 1598, p. 579—merely states, in regard to a case which he reports, that the other symptoms led him to regard it as one of dysentery, although the stools were not like those usually seen in dysentery, and no ramenta were observed.

|| MORGAGNI—*De Sedibus et Causis Morborum*, Epist. XXXI, § 19 *et seq.*—cites from SENNERTUS the observation of MEICHSNERUS and SAXONIA referred to in the last note, and points out that the latter observation is probably not correctly reported, as SAXONIA in a subsequent work had made complaints about the publisher of the Pantheon, and in his *Prælect. Pract.*, Pars 2, Cap. 19, [in Opera Pract. Padua, 1658, p. 177,] does not mention the case, although he states that he had seen four dysenteric patients in whom portions of intestine exceeding three or four fingers in measure were passed, and that of these two recovered. Besides these cases, MORGAGNI cites others of various kinds by TULPIUS, LANCISIUS, &c., some of which will be referred to in a subsequent note, and gives at length the case of a certain Jew, observed by himself, who at the decline of a malignant fever passed per anum a thick membrane, which he saw hanging out from his anus, six fingers' breadth in length, which subsequently separated spontaneously, and the patient recovered. The conclusion cited in the text will be found clearly stated at the commencement of § 20.

upon his immediate successors than his lucid account of the first, for medical opinion was soon carried to the extreme of believing that ulceration of the intestine is very rare in dysentery,* an opinion which has gradually been corrected by the progress of pathological anatomy during the present century. Especially during the last thirty years, by the use of the compound microscope in the investigation of the dysenteric stools and of the intestinal mucous membrane in fatal cases, has it been shown beyond further doubt that the double explanation of Morgagni was correct, and that the ancients were right after all in teaching that in severe cases of dysentery portions of the inner coats of the intestine separate by sloughing, though it must be confessed that they appear to have applied this explanation erroneously to fragments of pseudomembrane in the stools as well as to genuine sloughs.†

Whatever doubts may be felt at the present time as to the exact nature of the large membranes discharged in individual cases, as for example those of Tulpius, Apinus and others,‡ recorded before the introduction of the modern exact methods for determining the character of membranes passed by stool, it must be admitted that similar cases have been observed during the last thirty years as to which no such doubts are warranted. The case of Tulpius finds a parallel in those investigated by Dickson, the accurate Jeffries Wyman and other recent physicians,§ whose ability to decide the nature of the substance under consideration

* Compare STOLL, *loc. cit.*, in note to p. 342, and FOURNIER et VAIDY, Art. *Dysenterie* in Dict. des Sci. Méd., T. X, Paris, 1814, p. 319.

† The Greek physicians made use of the varying characters of these sloughs in their attempts to distinguish, in cases of dysentery, whether the small intestine was ulcerated or the large. They attached great importance to this question, for if the large intestine were ulcerated they hoped to reach the seat of the disease by injections, while if the small intestine were ulcerated this could only be done by medicines given by the mouth. GALEN, *De Loc. Affect.*, Lib. VI, Cap. 2, [Ed. Kühn, VIII, p. 383;] ALEXANDER of TRALLES, Lib. VIII, Cap. 9, [Basel Ed., 1556, p. 451.] The characters on which they relied to make this distinction were: 1. The appearances presented by the shreds and membranes passed. The small intestine being thin and delicate, while the large intestine is thick and fleshy, fleshy, thick pieces could only be discharged when the latter was ulcerated. Thin, delicate shreds or scrapings might come from the large intestine, but in that case they would not be thoroughly mixed up with the discharges as they would be if they came from the small intestine. ARETÆUS, ARCHIGENES, GALEN, ALEXANDER of TRALLES. 2. In like manner the blood in the stools would be black and otherwise altered if it came from the small intestine; bright and pure if it came from the large. In the first case it would be intimately mixed up with the discharges; in the latter case it would float on the surface, or be only imperfectly mixed. ARCHIGENES, GALEN. 3. Discharges proceeding from the small intestine would be thin and bilious; those from the large would be thicker and often contain hard lumps of condensed fæcal matter, or would be watery and devoid of smell. ARETÆUS, ARCHIGENES, CÆLIUS AURELIANUS. 4. If the ulceration were seated in the small intestine the pain would be in the region of the umbilicus or above it; if it were seated in the large intestine the pain would be lower down. ARCHIGENES, CÆLIUS AURELIANUS. 5. If the ulceration were in the small intestine some time would elapse before the griping pain was followed by a stool; if it were in the large intestine the pain would be promptly followed by the stool. Moreover, a pain in the small intestine is more acute; that in the large intestine is dull. ALEX. of TRALLES. Some of the Greek physicians went so far as to attempt to discriminate between the ulcerations of the several parts of the small and large intestines, and gave symptoms which they supposed to show whether the ulceration was seated in the jejunum, or lower down in the small intestine, (ileum,) in the colon or the rectum. ARETÆUS, ARCHIGENES, ALEX. of TRALLES. These efforts recall more modern attempts in the same direction. See p. 270, *supra*. On the subject of this note consult, besides the passages cited from GALEN and ALEXANDER of TRALLES, ARETÆUS, *De Causis et Signis Morb. Diut.*, Lib. II, Cap. 9, [Boerhaave's Ed., p. 60;] ARCHIGENES, in ÆTIUS, Tetrab. III, Serm. I, Cap. 43, [Lyons Ed., 1549, p. 599,] and CÆLIUS AURELIANUS, *Morb. Chron.*, Lib. IV, Cap. 6, [Amman's Ed., p. 524.]

‡ NICOLAUS TULPIUS—*Obs. Med.*, Lib. III, Obs. 17, [Amsterdam, 1652, p. 214]—relates the case of a man suffering from a violent dysentery who passed by stool the entire mucous membrane of the rectum, which hung out from the anus for two days before it was removed by the attendant. The patient recovered. J. L. APINUS—*De Abscessu Tunicæ Intest. Glandulosæ*, Ephem. Nat. Cur., Dec. III, ann. IX *et* X, (1704–5,) p. 315—relates the case of a soldier 49 years old who, after the premonitory symptoms of continued fever, had a dysenteric attack, with blood and pus in the stools, and passed several tubular substances, one of them a span long, which, after careful examination, the author concluded were portions of the villous coat of the intestine. Here too belongs, I think, the case reported by MOLINELLI—*Comm. Bonon. Scient. Acad.*, II, p. 1, *Medica*, *Obs.*, II, p. 158, [I cite from THOMSON.]—The patient, who had suffered first from griping pains and afterwards from dysentery, passed a substance "not unlike the fungous flesh of ulcers; it was more than a span in length; hollow, and open at the one extremity, but shut at the other. In its cavity, besides some blackish and dry feces, there were contained some calculi, not very numerous, resembling grains of wheat in size, figure, and colour." The patient appears to have recovered. These cases have, as I must think without sufficient reason, been regarded by THOMSON—*Abstract of Cases in which Pseudo-membranous Substances have been discharged from the Bowels*, Edinburgh Med. and Surg. Journal, Vol. 46, (1836,) p. 102 *et seq*, [see note † to p. 365, *infra*.]—as examples of the passage of mere pseudomembranes. It would be fruitless now to discuss this question at length, since the methods of precise investigation which are at present at our disposal did not exist when these cases were recorded. But since parallel cases of modern date can be found, as to the nature of which there can be no doubt, I see no reason to accept THOMSON's view.

§ The case of TULPIUS has its parallel in the following: *Trans. of Path. Soc. of London*, Vol. III, (1850–51,) p. 370: 28—*A portion of the Rectum which, having protruded, had been cut off.* "The person on whom this operation had been performed, had suffered severely from intermittent fever, and was much debilitated from its effects. Whilst a convalescent, he was attacked with acute dysentery: and, during the efforts to relieve the bowels, a prolapse of the rectum occurred, when, experiencing insuperable difficulty in its reduction, he requested a non-professional friend who had called upon him, to be 'so obliging as to cut it off.' This request was complied with, to the satisfaction and present relief of the sufferer. The bowel removed, when examined subsequently, was found to have been cut off by an irregular and oblique incision, so that it was of the extent of three inches on one side, and but an inch and a quarter on the other. On a close examination, it was found that the specimen was composed of all the tissues of the gut. Urgent symptoms set in on the second day after the removal, when more of the rectum was extruded, and subsequently removed by operation, in consequence of the impossibility of treating it by any other method. The patient subsequently recovered." Dr. BEITH, for Mr. DICKSON, 18th of November, 1851. *Descriptive Catalogue of the Warren Anat. Museum*, J. B. S. JACKSON, Boston, 1870, p. 468: "A portion of intestine that protruded from the

cannot justly be questioned; and the almost forgotten statement of Hillary* in 1759, that sometimes portions of mucous membrane several inches long were found in the stools of dysenteric patients in the West Indies, seems probable enough in view of the careful observations of Chuckerbutty,† made at Calcutta during 1864–5, with the advantage of all the modern appliances for such examinations. A striking example of the other possibility, the passage of large fragments of the diphtheritic layer alone, will be found in case 861, in Section III of this chapter.‡ In that case the cast, which was tubular in form, and "composed of pseudomembranous lymph in which no traces of the structure of the mucous membrane could be detected," was fourteen inches long. The specimen is still preserved at the Army Medical Museum.

In this connection it will be of interest to allude briefly to a form of diarrhœa characterized by the appearance in the stools of membranous substances, which sometimes even take the form of simple or branching tubes; a disease which has attracted considerable attention, and been described under various names, such as tubular looseness, or diarrhœa tubularis; chronic pseudomembranous gastro-enteritis; follicular, duodenal and colonic dyspepsia; fibrinous diarrhœa; chronic pellicular inflammation of the intestinal mucous membrane; chronic croup of the intestines; mucous disease of the colon; chronic muco-colitis; mucous disease, and membranous enteritis.§ Of these various appellatives, tubular

anus, after much straining, on the sixteenth day of dysentery, and was cut off with a pair of scissors; a few drops of blood only following the incision. The patient, aet. six months, had prolapsus daily for the first six days, and occasionally afterward, but in the course of three months was quite well. The specimen is about four inches in length; and was found by Dr. J. WYMAN to consist of mucous membrane, vessels, and areolar tissue. He also found what he supposed to be circular muscular fibres under the microscope; and in the preparation he has passed bristles into an artery, and a vein. It was stated that, two or three days after the removal of this portion, a second was expelled by the natural efforts, about an inch in length. 1855." Here too belong the cases reported by CATTELOUP—*Obs. de Dysenterie Aigue avec détachement de la membrane muqueuse du gros intestin*, Recueil de Mémoires de Méd., &c., T. 57, (1844,) p. 66—who found adhering to the internal surface of the sigmoid flexure in one soldier dead of dysentery a cylindrical membrane about 32 centimetres long, while in the transverse colon of another he found a ribbon-like slough resembling a false membrane 35 centimetres long and 55 millimetres wide. These pieces were submitted to Inspector BÉGIN, who carried them to the museum at Val-de-Grâce, where they were examined microscopically by Prof. LACAUCHIE, who found that they contained the proper tissues of the mucous membrane of the colon, and hence were not mere pseudomembranes. Consult also the well-considered remarks of AUG. HASPEL—*Maladies de l'Algérie*, T. II, Paris, 1852, p. 77—under the heading "Détachement de la muqueuse," who has himself made similar observations. To these may be added the case reported by L. FROMONT—*Des Gangrènes du Tube Intestinal*, Ann. de la Soc. de Méd. de Gand, (1858,) T. 36, p. 169—of a soldier who, while suffering from facial erysipelas, was attacked by dysentery, and, in the very offensive stools, passed a number of fragments of mucous membrane, the largest being tubular, between 40 and 45 centimetres long with walls 2 millimetres thick. On the autopsy, a curious malformation of the colon (figured in three plates) was observed at the splenic curvature. At that point there was a pouch resembling the cæcum in form, from which the descending colon originated by two separate tubes. From this point down to the sphincter ani it was found that the mucous membrane of the colon was entirely missing.

* WILLIAM HILLARY—*Obs. on the Changes of the Air and the Concomitant Epidemical Diseases in the Island of Barbadoes, and a Treatise on the Diseases of the West India Islands*, &c., (1759,) 2d Ed., London, 1766, p. 216.

† S. G. CHUCKERBUTTY—*Cases Illustrative of the Pathology of Dysentery, with Remarks*, Indian Annals of Med. Sci., No. XIX, 1865, p. 90. This paper contains 41 cases in which the stools were critically examined, and 38 post mortem examinations. Sloughs of mucous membrane were observed in the stools in a number of cases; the largest in case 8, p. 95; one about 5 inches long by 2½ broad, a second 3 inches long by 1 broad, and a third 4 inches long by 2 broad. In case 40, three dark sloughs were passed in one day, the largest 4 inches long, the others 1½ inch each. Both in cases in which sloughs had been observed in the stools, and in some in which they had not, sloughs were observed after death still adhering to the mucous membrane. The practical method of conducting the examination of the stools, on p. 152, is worthy of commendation. Consult also, in this connection, the cases and autopsies reported by CHARLES MOREHEAD—*Clinical Researches on Disease in India*, 2d Ed., London, 1860, p. 258—under the head of "The separation of parts of the mucous coat in shreds and tubular portions." He states that eight cases, in which tubular sloughs several inches (the longest about one foot) in length were passed by patients laboring under dysentery, came under his own observation, and that STOVELL—Trans. Med. and Phys. Society, Bombay, N. S., No. 3, p. 29—has reported four similar cases. Of these twelve cases six died, three recovered, and in three the result was unknown. In one of the fatal cases death did not take place until three months, in another not until five months after the separation of the slough. I note the following specimen in the *Catalogue of the Museum of the Royal College of Surgeons of Edinburgh*, 1836, p. 198: "No. 1610. A large slough, apparently the inner membrane of the intestine, which came away by stool from a patient who had dysentery, and who yet recovered."

‡ *Supra*, p. 257. The specimen is No. 382, Medical Section, Army Med. Museum. I suppose the following to be a similar, though probably much smaller specimen: *Catalogue of the Anat. Museum of the Univ. of Edinburgh*, 1831, p. 72, "I, 112. Portions of the fibrine of the blood, of the shape of the cells of the colon, voided in a case of dysentery."

§ J. MASON GOOD—*The Study of Medicine*, Cl. 1, Ord. 1, Species 7, Vol. I, Philada., 1825, p. 162—"Diarrhœa tubularis, tubular looseness." ROCHE, SANSON et LENOIR—*Nouv. Éléments de Path.*, T. I, (Paris, 1844,) p. 512—"Gastro-entérite pseudo-membraneuse chronique." T. J. TODD—*Cycl. of Pract. Med.*, (Am. Reprint, Philada., 1845,) Vol. II, p. 653—"Follicular duodenal dyspepsia;" p. 663, "follicular colonic dyspepsia." JOHN GRANTHAM—*Facts and Obs. in Med. and Surg.*, (London, 1849,)—"Fibrinous diarrhœa," p. 203. J. Y. SIMPSON—*Obstet. Mem. and Contributions*, Am. Sci., (1864,) Vol. 38, p. 459. ANDREW CLARK (Report of Clinical Lecture by)—*Mucous Disease of the Colon*, Lancet, Dec. 17, 1859, p. 614. S. O. HABERSHON—*Functional Disease of the Colon*, &c., *Chronic Muco-Colitis*, Lancet, Jan. 4, 1868, p. 7. WALTER WHITEHEAD—*Mucous Disease*, The British Med. Jour., Feb., 1871, p. 143. An article which deserves censure for deficiency in proper references to authorities cited. J. M. DA COSTA—*Membranous Enteritis*, Am. Journ. of the Med. Sci., Oct., 1871, p. 321.

diarrhœa, proposed by John Mason Good, not only antedates the others, but seems least objectionable as implying no theory whatever. When the membranous substances do not present any trace of a tubular form the designation membranous diarrhœa might be used with propriety. The term membranous enteritis, proposed by Da Costa, is objectionable because it is equally applicable to diphtheritic dysentery.

Tubular diarrhœa occurs most frequently in hysterical women or hypochondriacal men, who, after suffering with nervous and dyspeptic troubles or other evidences of ill health for a variable period, become subject to attacks of colicky abdominal pains, sometimes accompanied by a hardness or tumefaction of some portion of the abdomen, and followed by the evacuation of the pseudomembranous substance, which comes away in shreds or tubes, sometimes in considerable quantity, and usually accompanied or followed by loose, feculent, watery, muco-purulent or bloody stools. The evacuation of the membranous matter is followed by relief from abdominal pain and other pressing symptoms, but very frequently this relief is only temporary, and other paroxysms ensue at variable intervals. The individual attacks generally last a week or more, and the intervals between them vary from a few weeks to several months in duration. In some of the cases reported but a single paroxysm is recorded, in others the disease appears to have been almost continuous for a considerable period of time. Of the women affected, a number were suffering at the time from some uterine disorder. A few cases are recorded as having occurred among children.*

Fernelius,† so far as I can ascertain, was the first to describe this affection. He reported two cases, one of which proved fatal, and recognized the true nature of the abnormal intestinal secretion, which he described as inspissated mucus, (*pituita concreta, pituita lenta.*) These cases were cited and commented upon by various medical writers,‡ and attention being thus directed to the subject, additional cases were observed and recorded from time to time. A number of these will be found, together with a masterly discussion of the various other kinds of membranous substances which may be passed by stool, in the thirty-first Epistle of Morgagni.§ Since his time numerous additional cases have been published, and the subject has been discussed by several able writers.‖ Among those who have

---

* As, for example, one of the cases of DA COSTA [*op. cit.* in previous note] and four reported by THEODOR CLEMENS, *Ueber den Darmkrup der Kinder.*, Journ. für Kinderkrankheiten, Bd. XXXIV, (1860,) S. 30. The "Mucous Disease" of children, described by EUSTACE SMITH—*Wasting Diseases of Infants and Children*, 2d ed., (London, 1870,) p. 173—in which large quantities of mucus are passed by stool, can hardly be the same disease, since no mention is made of the passage of shreds or membranes.

† FERNELIUS—*Pathолog.*, Lib. VI, Cap. 9, [Paris, 1554, p. 181.] The first of the cases referred to in the text was that of the Embassador of Charles V. The passage of the false membrane, which was tubular, was preceded by a tumor in the abdomen. In the second case a similar tumor was noticed, but nothing was passed, and the patient died. On the autopsy the colon was found so stuffed with concreted phlegm (infarctum pituita concreta) that nothing could pass. I must confess to having been disappointed by the perusal of passages in some of the older writers which have been cited as probably referring to the morbid condition in question. Thus AUTENRIETH and UHL [*Diss. de Pseudang.*, &c., p. 14, *vide infra*] cite ARETÆUS and CÆLIUS AURELIANUS as referring to this disease, which appears to me a misinterpretation of the passages indicated. ARETÆUS—*De Causis et Signis Morb. Diut.*, Lib. II, Cap. 8—merely explains the causes of colic in accordance with the humoral pathology, saying, it "is formed from cold and thick humours, and a copious and glutinous phlegm," (Transl. of Syd. Soc., London, 1856, p. 352;) while CÆLIUS AURELIANUS—*Morb. Chron.*, Lib. IV, Cap. 7—simply says, in describing the symptoms of colic, that if the disease grows worse "vomiting of thick humors, which the Greeks call phlegm, occurs." J. M. DA COSTA—*op. cit.*, *supra*—cites PAULUS ÆGINETA as referring to a similar disease. I have not been able to verify this statement, and a personal application to Dr. DA C. failed to elicit the desired reference. These membranes and tubes must not be confounded with Zusmata; see notes to p. 361, *supra*.

‡ See, for example, SENNERTUS, *Pract. Med.*, Lib. III, Pars 2, Sect. 1, Cap. 5: "De rebus præter naturam in intestinis repertis." In this chapter, under the head of "pituita," the cases of FERNELIUS, cited in the last note, are quoted, his explanation adopted, and an additional case, that of the celebrated Lipsius, added. [See list of cases, *infra*.] I must think TODD [*loc. cit.* in note § to p. 363] altogether misrepresents SENNERTUS when he describes this disease as his third variety of colic; for in this description—*Pract. Med.*, Lib. III, Pars 2, Sect. 2, Cap. 2—under the heading, "De colica ab humoribus crassis, et viscidis in tunicis intestinorum hærentibus," the author expressly denies that phlegm, &c., adhering to the mucous surface of the intestine, could give rise to the colic under consideration, and argues that therefore an accumulation of phlegm must take place in such cases in the very substance of the intestinal coats. In this connection I may also cite VAN SWIETEN—*Comm. in H. Boerhaave Aph.*, § 719, [T. II, Leyden, 1745, p. 373.] who also cites the cases of FERNELIUS, in his article on "Diarrhœa febrilis," and speaks of the disease under discussion as one in which "glutinous concretions" are formed in the intestines and passed by stool. See also VAN SWIETEN'S article, "Morbi ex glutinoso spontaneo," § 69 *et seq.*, [*op. cit.*, T. I, p. 95.]

§ MORGAGNI, Epist. 31, [see note to p. 361, *supra*.] The author shows that membranous substances may be passed either when there is dysentery or when there is not, and describes three kinds of such membranes: 1, gangrenous sloughs of the intestinal coats; 2, false membranes; 3, sloughs with false membranes adhering to them. Such of the cases cited in this epistle as belong to membranous diarrhœa will be included in the list of cases presented below.

‖ See note § to p. 363, and the authors cited in the list of cases below.

systematically collected these cases, Autenrieth* and Thomson† may be particularly commended. The essay of the latter appeared in 1836, and as no similar collection of the more modern cases has been made, references to those which have been brought to my notice have been subjoined in a foot-note.‡

Clinical and microscopical examination of the membranous matters passed in tubular diarrhœa shows that they are chiefly composed of inspissated mucus, as was originally supposed by Fernelius. With this a fluid more or less albuminous in character is often mingled, but fibrin is seldom present in any considerable quantity. Dilute acetic acid does not dissolve the membranes or cause them to become swollen and transparent, while they freely dissolve

* Under the direction of H. F. AUTENRIETH, two dissertations were published in 1831, which cover the whole subject of membranous substances passed by stool. The first by J. PLATZ—*Diss. de dejectione portionis intestinorum per alvum, non semper mortifera;* the second by M. UHL—*Diss. de pseudangomorphosi in tubo intestinali;* both at Tubingen. The first of these essays contains two series of cases, viz: 1, those in which portions of the intestinal canal, including all the coats, have been passed, as in ileus and hernia; 2, cases in which the mucosa alone has separated by sloughing, especially in dysentery. In the second essay there is a collection of cases in which coagulable lymph was passed in the form of tubes, and a case in which the tubes were branched is given in detail, as to which see note * to p. 367, *infra*. It is explained that tubes of coagulable lymph may be passed: 1, in dysentery; 2, in aphthous fever, and 3, in the peculiar form of diarrhœa which J. MASON GOOD called diarrhœa tubularis.

† The dissertations of AUTENRIETH served as the basis for a still more elaborate discussion of the subject by WM. THOMSON, who in 1835–6 published two essays on the same subject—*Abstract of Cases in which a portion of the cylinder of the Intestinal Canal, comprising all its coats, has been discharged by stool, without the continuity of the canal being destroyed*, Edinburgh Med. and Surg. Journal, Vol. 44, (1835,) p. 296; *Appendix* to the same, id., Vol. 45, (1836,) p. 374, and *Abstract of Cases in which Pseudo-membranous Substances have been discharged from the Bowels*, id., Vol. 46, (1836,) p. 102. In these interesting essays THOMSON has presented almost all the cases cited by AUTENRIETH, with some additional ones, but he expresses doubts "whether there be any morbid process, by which we can suppose the mucous membrane of the intestinal tube to be detached from its other coats, in portions of considerable size, and at the same time of sufficient consistence to retain its membranous character." Accordingly the list of cases in which pseudomembranous substances have been discharged, presented in his second essay, includes those cases which AUTENRIETH had considered separately as cases in which the mucous membrane separated by sloughing. On examining critically the cases included in this list, I find 9 which belong to diphtheritic dysentery, or other diseases and accidents, so that of the 35 cases of which abstracts are given, only 26 can be regarded as belonging to the form of diarrhœa under discussion. Thus case 7, cited from MOLINELLI, and 9, from TULPIUS, [see note ‡, p. 362, *supra*,] are cases of diphtheritic dysentery. Case 10, from MORGAGNI, [see note ‖ to p. 361, *supra*,] case 11, from APINUS, [see note ‡ to p. 362, *supra*,] and case 12, from LECHEVEREL, are of more doubtful character, but certainly not cases of the disease under consideration; while of the five cited by our author (Vol. 46, pp. 105–6) under the head of "Cases of pseudo-membranous discharge in which an examination of the body has taken place subsequently to death," only that cited from ABERCROMBIE [see next note] belongs to this category. Of the four remaining cases, that by A. E. TARTRA—*Essai sur l'Empoisonnement par l'Acide Nitrique*, Paris, 1802, p. 170—is a case of corrosive poisoning which derives its interest only from analogy. That by LEFAUCHEUX—*Obs. sur un sac membraneux faisant partie de l'estomac, rendu par le vomissement*, Journ. Gén. de Méd., T. 23, (1805,) p. 349—and the first of those cited from A. N. GENDRIN—*Hist. Anat. des Inflammations*, Paris, 1826, T. I, p. 633—are cases in which the stomach, not the intestines, was involved; and the remaining case, also from GENDRIN, (*loc. cit.*,) is clearly an ordinary case of acute diphtheritic dysentery.

‡ This list makes no pretensions to be exhaustive, and includes only, whether of ancient or modern cases, those which there seems to be good reason for classing under the head of tubular or membranous diarrhœa. FERNELIUS, *Patholog.*, Lib. VI, Cap. 9; two cases, [see note † to p. 364, *supra*.] VALENTINUS, *Obs. admiranda de ejectione membranarum sanguinolentarum per secessum formam viperæ referentium*, Venice, 1621. I quote from the notice in HALLER'S *Bibl. Med. Pract.*, T. II, p. 497. The case of the celebrated Justus Lipsius in the life of HEURNIUS, prefixed to *Heurnii Opera*, Leyden, 1658. [see SENNERTUS, *loc. cit.*, in note ‡, p. 364, *supra*.] GODFR. THOMASIUS, *De int. intest. tunicæ ejectionibus*, Ephem. Med.-Phys. German., (1696,) Dec. III, an. 3, Obs. 190, p. 319. C. BERTHOLD BEHRENS, *De membranis per anum secedentibus*, ib., an. 5 et 6, Obs. 34, p. 77. ROSINUS LENTILIUS, *Appendix ad Dec.* III, an. 3, Ephem. Med.-Phys. German., p. 88, *ad Obs.* 68. J. M. HOFFMANN, *De Diarrhœa cum excretione pellicularum plurimarum*, ib., Dec. III, an. 9 et 10, Obs. 60, p. 124. Case reported by BIANCIARDUS in a letter to LANCISIUS, in *Diss. de triplici intestinorum polypo*, (1710,) in Lancisi Opera, Geneva, 1718, T. II, p. 268. J. M. VERDRIES, *De pelliculis, intest. tunicæ similibus, excretis*, Ephem. Med.-Phys., (Frankfort and Leipsic, 1712,) Cent. I, Obs. 91, p. 177. J. J. TREYLING, *Vagina entero-morpha per anum excreta*, Act. Phys.-Med. Nat. Cur., T. V, 1740, p. 436, Obs. 126; this case is particularly interesting, because the imperfect microscope of the time was called into requisition, and proved adequate to show that the cast was not a portion of the walls of the colon, as was at first supposed. THOMAS SIMSON, *Separation of the villous coat of the intestines in diseases*, Edinburgh Med. Essays and Observ., Vol. V, Part 2, (1744,) p. 656. J. GOTTLIEB BAUER, *Epist. de Molis Intestinorum*, Dresden, 1747; in HALLER'S *Disp. ad Morb. Hist. et Cur.*, T. III, p. 461. L. L. FINKE, *De Morbis Biliosis Anomalis*, Monasterii Westphalorum, 1780, p. 30; one case; note his remarks on the characters of the matter passed. J. KÄMPF, *Abhandlung von einer neuen Methode, die Krankheiten im Unterleibe, etc., zu heilen*, Leipsic, 1784; Krankheitsgeschichte 43, p. 453; 46, p. 463, and 64, p. 486, (three cases.) PERCIVAL, *Memoirs of the Medical Society of London*, Vol. II, (1789,) p. 60. *Eine merkwürdige, noch dauernde Krankheit einer Dame*, Hufeland's Journal, (1799,) Bd. VIII, Stück 2, p. 3. Surg. and Pharm. Repository, Vol. I, 1814, p. 374. DESTRÉES, *Hist. d'une inflammation, etc.*, Jour. Gén. de Méd., T. 68, (1819,) p. 206. RICHARD POWELL, *On certain painful affections of the intestinal canal*, Trans. Coll. Phys., London, (1820,) Vol. VI, p. 106; four cases; all adult females. J. MASON GOOD, *Study of Medicine*, (1822,) Diarrhœa Tubularis, Am. Reprint, Philadelphia, 1825, Vol. I, p. 162. ABERCROMBIE, *Diseases of the Stomach*, &c., &c., Edinburgh, 1828, Case 114, p. 298. This case is interesting on account of the autopsy, in which the whole mucous membrane of the colon "was thickly covered with small spots of a clear white colour, which were remarkably distinguished by their colour from the mucous membrane surrounding them. Few of them were larger than the diameter of large pin heads, and, on minute examination, they were distinctly ascertained to be vesicles, very little elevated, but, when punctured, discharging a small quantity of clear fluid." CHRISTIAN, *Obs. de gastro-entérite couenneuse*, Recuéil de Mém. de Chir., etc., Militaires, T. XXXVII, 1835, p. 297. AUTENRIETH and UHL, *Diss. de pseudangomorphosi, etc.*, cited above; a case in which the tubular membranes were branched. Abstracts of the foregoing cases, except those recorded by FINKE and CHRISTIAN, will be found in the essays of AUTENRIETH, THOMSON, or both—See note †, *supra*. The following cases have appeared since THOMSON'S publications: LAMIRON, one case, Bull. de la Soc. Anat. de Paris, 16me, an., (1841,) p. 268. BROCA, two cases, *ib.*, 29me, an., (1854,) p. 60. POTAIN, one case, *ib.*, 32me, an., (1857,) p. 163; during the debate on this case, AXENFELD and BLONDEAU each mentioned a case observed by himself. RICHARD QUAIN—*Diseases of the Rectum*, 2d Edit., London, 1855, p. 314—under the heading Alvine Concretions, gives two cases. HUTCHINSON—*Tabular Exudation Casts of the Intestine*, Trans. Path. Soc. of London, IX, (1857–8,) p. 188—one case. GEO. HARLEY—*Fibrinous Concretions from the Intestines*, Trans. Path. Soc. of London, XI, (1859–60,) p. 92—one case. A. LABOULBÈNE—*Recherches, etc., sur les affections pseudo-membraneuses*, Paris, 1861, p. 145—one case. VIDAL, *Érysipèle intestinal concomitant à un érysipèle de la face; éxacuation de productions membraniformes et gélatiniformes, etc.*, Gazette des Hôpitaux, Nov., 1862, p. 518. WILLIAMS, (1864.) *Chronic Inflammation of the Intestinal Mucous Membrane*, &c., cited in note § to p. 363, *supra*; a case observed by Mr. O'Donovan and one by Dr.

in a solution of caustic potash. Examined with the microscope, they prove to consist of a hyaline or slightly granular matrix, which becomes fibrillated on the addition of dilute acetic acid, from the precipitation of mucin filaments. Scattered through this matrix are a variable number of cells resembling the white corpuscles of the blood, of columnar epithelial cells, and of modified forms resulting from the vacuolation and partial decomposition of these elements. Debris derived from the food adhere to the surface, or are imbedded in the substance of these membranes. For further particulars with regard to their chemical and microscopical characters the reader may advantageously consult the accounts given by Wilks and Clark, Vidal, Perroud, Beale, Da Costa and Goodhart.*

Hutton; the first of these cases has been separately published by R. W. O'DONOVAN—*On plastic inflammation of the intestine*, The Dublin Hospital Gazette, Vol. I, 1854–5, p. 186. PERROUD—*Note sur les Concrétions Muqueuses Membraniformes dans les Intestins*, Mém. de la Soc. des Sci. Méd. de Lyon, (1864–5,) T. IV, p. 44—six cases. LIONEL S. BEALE—*The Microscope in its Application to Pract. Med.*, 3d Edit., London, 1867, p. 195—one case. JULES GUYOT, *Obs. d'un malade qui, après avoir présenté des symptômes paraissant devoir être rapportés à un étranglement interne, a guéri après l'expulsion par l'anus d'une grande quantité de mucosités intestinales*, L'Union Médicale, T. V, (1868,) p. 511. See also the comments on this case by H. MERLAND DE CHAILLÉ, *Note pour servir à l'histoire de l'entérite pseudo-membraneuse*, op. cit., p. 909, in which the writer makes the following somewhat remarkable statement with regard to the frequency of cases of this kind: "For myself since 1863 I have collected about thirty perfectly authentic examples, with detailed observation and preservation of some specimen-products in alcohol." A. GRISOLLE—*Traité de Path. Interne*, 9me Éd., Paris, 1869, T. II, p. 753—one case in the section "De l'entéralgie." F. SIREDEY—*Note pour servir a l'étude des concrétions muqueuses membraniformes de l'intestin*, L'Union Médicale, T. VII, [1869,] pp. 75, 86 and 101—one case. J. M. DA COSTA—*Membranous Enteritis*, Am. Jour. of the Med. Sci., Oct., 1871, p. 321—gives seven additional cases. JAS. F. GOODHART—*Casts from the intestine*, Trans. of Path. Soc. of London, XXIII, (1871–2,) p. 98—one case. B. VAN VALZAH—*Case of Membranous Enteritis*, Am. Jour. of the Med. Sci., July, 1873, p. 106. WM. M. FINDLEY—*Membranous Enteritis, with cases*, Am. Journ. of the Med. Sci., Jan., 1875, p. 103—three cases; all in females. To the foregoing cases I add, as a matter of interest, the following references to specimens which probably belong to this disease, and which I have found in such museum catalogues as I have been able to consult. *Catalogue of the Anat. Museum of the Univ. of Edinburgh*, 1831, p. 72. "I. 115—Cylindrical tubes, composed of coagulable lymph and viscid gelatinous matter, passed by stool;" "I. 116 and 117—Substances passed by stool, resembling bloodvessels with their branches; were mistaken for worms;" "I. 121 and 123—Bodies resembling arteries, passed by stool." *Catalogue of the Museum of the Royal College of Surgeons of Edinburgh*, 1836, p. 208, No. 1694—"Exudation of coagulable lymph from the mucous surface of inflamed intestine, which is sometimes erroneously considered as a portion of intestine passed by stool." *Catalog der path.-anat. Sammlung zu Giessen*, 1851, S. 20, Schrank Nr. XVIII, 58–61—"Pseudomembranöse, röhrenförmige Ausleerungen aus dem Darm." *Catalogue, Musée Vrolik*, Amsterdam, 1865, p. 394, D. Partie Path., "993, 20—Masse de pseudomembranes, formées dans l'intestin d'une femme, qui en évacuait périodiquement;" "994, 21—Masse pseudomembraneuse évacuée per anum par une fille." J. B. S. JACKSON—*Descriptive Catalogue of the Warren Anat. Museum*, Boston, 1870, p. 473: "2256. A portion of lymph in a tubular form, and removed after death from the intestines." From a man 34 years old, who died after a few days' sickness of meningitis. His bowels having previously been costive, he had several thin, black, fœtid dejections. In the first two of these there were several portions of lymph measuring altogether about a foot in length. Under the microscope they "appeared to consist of a granular and fibroid substance, with epithelium." The mucous membrane of the last two or three feet of the ileum was found much inflamed and covered by a slight deposit of lymph. "The large intestine was also highly inflamed, with thin patches of lymph upon the surface, from one to two inches in diameter." I am not satisfied, however, that this was not a case of intercurrent dysentery. A similar disease to that we have been considering appears to exist also in the lower animals I find in the *Catalog der path. anat. Sammlung des Coll. anat. chir. zu Braunschweig* [Braunschweig, 1854, p. 25] the following entry: Krank. des Darmcanales, etc., No. 38—"Ein 9 Fuss langes, darmförmiges Stück plastischer Lympho einer Kuh per Anum abgegangen;" and in an interesting article on the passage of such membranes in cattle, by TH. CLEMENS—*Ueber die membranöse Darmentzündung der Kühe und deren Beziehungen zum Darmkrup der Kinder*, Journal für Kinderkrankheiten, Bd. XXXIV, (1860,) S. 180—a case related by ENGESSER, in which a cow passed a number of tube-like pseudomembranes which together measured fifteen feet in length.

* WILKS and ANDREW CLARK—*Trans. of Path. Soc. of London*, Vol. IX, (1857–8,) p. 189—examined microscopically the casts from Dr. Dunhill's case, reported by Mr. Hutchinson, (*loc. cit.*,) and made a report to which CLARK added some "supplementary notes," in which he states that he has examined numerous similar specimens chemically and microscopically with the same results. The casts proved to consist of a "gelatinous membraniform matrix, traversed by a coarse network of opaque yellow lines." This matrix was free from fibrillation, but "was fibrillated by acetic acid. Careful washing and compression, yielded a fluid abundantly coagulable by heat and nitric acid." In this matrix numerous cylindrical epithelial cells, lymphoid cells, larger spherical cells, some of them containing vacuoles and granular cells, were imbedded, together with granules, bile pigment and foreign matters derived from the food. The conclusion drawn is, that the casts in this case consisted of altered mucus and albumen, but contained no fibrin, and that they were formed in the large intestine. Dr. CLARK makes three varieties of casts of this kind: 1, consisting of mucus with but little albumen; 2, abundance of albumen and mucus; 3, the same with the addition of fibrillated fibrin. The paper is accompanied with a plate representing the appearances observed. I may mention in this connection an interesting account of the chemical examinations of some casts of this character which long antedates the above, viz: A. T. THOMSON, as reported by G. M. BURROWS, London Med. Repository, Vol. I, (1814,) p. 374, [see last note.] He examined the membranes in a case of this character both chemically and microscopically. It is not surprising that, with the microscope of that time, he found the membranes "composed of a congeries of perfectly round, opaque, beautifully polished globules;" but his chemical examination was more to the point. Among other reactions he observed that very little alteration "except that it appeared to be more firmly coagulated," was produced by acetic acid, and that it dissolved in liquor potassæ. He concluded that it "consisted chiefly of animal mucus, combined with a small portion of albumen, and gelatin," (fibrin?) VIDAL—Gazette des Hôpitaux, Nov., 1862, p. 518, [see last note,]—in a case which he examined, found the membranes composed: 1, of a concrete mucus which appeared somewhat fibrillated in some parts; 2, a great quantity of deformed epithelial cells, some of them grouped irregularly, others grouped so as to represent the orifices or pouches of the glands of Lieberkühn. He regarded the casts as a product of epithelial desquamation of the intestine. PERROUD—*Note sur les Concrétions Muqueuses Membraniformes dans les Intestins*, Mém. de la Soc. des Sci. Méd. de Lyon, (1864–5,) T. IV, p. 44—examined similar concretions in several cases with substantially the same results. He found: 1, hyaline mucus; 2, cylindrical epithelial cells and debris; 3, nuclei; 4, leucocytes; 5, crystals of the ammonio-magnesian phosphate; 6, fragments of hæmatosine and debris of the food. He found the casts completely soluble in caustic potash, partly so in aqua ammoniæ, insoluble in acetic acid or in cold nitric or hydrochloric acids, but soluble in boiling nitric acid and cold sulphuric acid. From these and other reactions he concluded that the concretions consist of mucus combined with a little albumen. LIONEL S. BEALE—*The Microscope in its Application to Pract. Med.*, 3d Edit., 1867, p. 195—examined the membranes passed in such a case, and says that they were "composed of a very firm mucus, in which numerous cells of epithelium from the large intestines were imbedded." J. M. DA COSTA—*Membranous Enteritis* [cited in last note]—substantially agrees with the foregoing, but says that in his own microscopical examinations the epithelial cells were sparingly present. He gives at length the details of the chemical examinations of several specimens by Dr. H. B. HARE, who concludes that the casts he examined "were composed, in the majority of instances, of mucus; that one or two contained a trace of albumen, and that they contained no fibrin." J. F. GOODHART—*Casts from the intestine*, Trans. Path. Soc. of London, Vol. XXIII, (1871–2,) p. 98—in connection with a case [see last note]—reported to the Patho-

It will be observed that the membranes and tubes in the stools of tubular diarrhœa differ greatly, even from those membranes and casts in the stools of diphtheritic dysentery which are composed of the diphtheritic layer alone, without any portion of the necrosed mucous membrane. The former are composed chiefly of hyaline mucus, the latter of granular fibrin. There seems to be no reason why shreds and membranes of condensed mucus should not occur in the stools of simple inflammatory dysentery, in the early stages of the diphtheritic form, or mingled with other membranes and shreds in the later stages; but in point of fact, when shreds and membranes are found in the dysenteric stools, they usually prove to consist either of necrosed tissue or of granular fibrin. Undigested fragments of food, as in lientery, may, in certain cases, simulate the membranous or even the tubular matters described above, but the difference can be detected at once by the microscope.*

5. *Bacteria and other low vegetable and animal forms.*—That innumerable swarms of micrococci and bacteria, together with a small number of torula-like forms, exist at all times in the healthy stools, and, therefore, as a matter of course abound in the discharges of diarrhœa, has already been mentioned in a previous part of this chapter.† It is not surprising, therefore, that these low forms should have been observed also in great numbers in the dysenteric stools; and since the publication of the theories of Hallier‡ they have been regarded in many quarters as the cause of the disease. This modern speculation was preceded by several similar hypotheses, according to which other minute vegetable or even animal forms were supposed to act as the efficient cause of dysentery; the earliest of these was the doctrine of animalcular contagion, which came into existence soon after the invention of the compound microscope,§ and found advocates among the best medical minds of the seventeenth and eighteenth centuries.

---

logical Society, Dec. 19, 1871, gives some figures of the microscopical appearances [Plate I, Figs. 3, 4 and 5] which are very similar to those in the drawing of WILKS and CLARK, and an account of the chemical reactions which agrees in all essential points with the writers cited above. In addition to the concurrent opinions of the foregoing writers, I must mention that of ARTHUR FARRE, who read before the Microscopical Society of London, June 22, 1842, a paper "*On the minute structure of certain substances expelled from the Human Intestine, having the ordinary appearance of shreds of false membrane, but consisting entirely of confervoid filaments probably belonging to the genus Oscillatoria.*"—The Microscopical Journal and Structural Record, London, 1842, p. 189. The case appears from the symptoms to have been one of the disease under consideration; but the substance passed is described as composed of filaments of nearly uniform size and 1-7000th of an inch in diameter, most of them exhibiting cross lines like those which in Oscillatoria mark the division into cells. A similar observation was made by BROCA—Bull. de la Soc. Anat. de Paris, 29me an., (1854,) p. 60—who in connection with one of his cases speaks of having observed forms resembling the parasitic algæ seen in muguet. When the abundance of bacteria, leptothrix filaments and other low vegetable forms in the normal stools is taken into consideration, it seems somewhat singular that such forms have not figured more conspicuously in the published accounts of the microscopical appearances of these membranous stools.

* Thus, QUEKETT, the distinguished English microscopist, in a communication to RICHARD QUAIN—*Diseases of the Rectum*, 2d Edit., London, 1855, p. 318—describes the case of a woman, who at intervals of a fortnight or three weeks had paroxysms of abdominal pain, which were relieved on passing a quantity of membranous matters and tubes, the mass of which sometimes exceeded an orange in size. On microscopical examination these membranes proved to consist of flakes of areolar tissue and portions of fascia mixed with fat, while the tubes were portions of arteries and veins; the whole mass representing the undigested portions of the *mutton chops* which had constituted the meat diet of the patient. QUEKETT states that he had observed, in all, nine cases of this character, in each of which pieces of arteries were readily detected. "All the patients who voided these substances were, as far as could be ascertained, dyspeptic; and the usual meat diet prescribed by the medical attendants was mutton, in the form of chops." "The short portions of artery which preserve their tubular character when placed in fluid, have invariably been regarded by the patients themselves as joints or fragments of worms, and on this account have excited alarm." QUEKETT thinks that in the case of FARRE [last note] the membranes were of the same character, basing his opinion upon his own examination of the specimen. "Recent investigation, however, has convinced me that all the tubular portions are fragments of arteries and veins, and the membranous ones portions of fasciæ. The transverse striæ, which most of the fibres present, are either the result of cooking or of partial decomposition, as has been pointed out in the case of the yellow elastic tissue of the sheep, the horse, and the giraffe," [p. 319.] CORRIGAN—*Cases of discharge of ligamentous substance from intestines*, Dublin Hosp. Gazette, Vol. I, 1854-5, p. 38—following the directions of QUEKETT, found the membranes passed in two cases to be fragments of yellow elastic tissue, resembling, if not identical with that in the ligamentum nuchæ of the sheep. Does not the simple explanation of QUEKETT account also for the peculiar branching tubes described and figured by SCHÜBLER—*Ueber die polypösen Concremente bei der Ruhr*, (with plates,) Jahrbücher der teutschen Med. u. Chir., Von Harles, Bd. III, Heft I, Nürnberg, 1813, S. 66—who observed them in the stools of several dysenteric subjects during the epidemic at Stuttgart in the summer and fall of 1811; as well as the two similar cases reported, the one also in a dysenteric subject by A. ELSAESSER—*Einige Bemerkungen über die polypösen Concremente bei der Ruhr*, &c., same Journal, Bd. III, Heft I, S. 76—the other in a dyspeptic woman reported by M. UHL—Thesis cited in note * to p. 365, *supra*. All three authors were struck by the similarity of the branching tubes to arteries; but this simple explanation did not satisfy them; and the microscope of those days would hardly have proved adequate for the satisfactory investigation of the tubes in question, even if it had been used, which does not appear to have been the case. The figures given by SCHÜBLER and UHL certainly are most readily accounted for by adopting this view of the nature of the tubes represented. † P. 279, *supra*. ‡ See notes to p. 280, *supra*.

§ The compound microscope was probably invented by HANS JANSSEN and ZACHARIAS, his son, two spectacle-grinders of the town of Middleburg in Holland, somewhere about the year 1590. See the learned discussion of the history of the microscope by HARTING—*Das Mikroskop*, German Transl., Braunschweig, 1866, Bd. III, S. 22 *et seq.* See also QUEKETT—*Practical Treatise on the use of the Microscope*, 2d Ed., London, 1852, p. 1 *et seq.*

The occurrence in a certain skin disease of an extremely minute living creature, so small that it could only be seen by sharp eyes and in a favorable light, had long been known to the common people, who were accustomed to extract the little animal by means of a needle or pin, especially from the hands and feet of the patients. The English called them *wheale-wormes*, the Germans *Süren*, the Italians *pedocelli* or *pedoscelli*, and various other names were bestowed upon them by the common people in different districts. Descriptions of this parasite and of the skin disease which it produces will be found in the writings of Avenzohar, Guy de Chauliac, Benedictus, Ingrassias, Scaliger, Ambroise Paré, Joubert, Fallopius, Mercurialis, Schenckius, Aldrovandus, Thomas Moufet and other writers from the twelfth to the seventeenth century.*

* The fact that the parasite of Itch (*Acarus scabiei*, *Sarcoptes scabici*) is visible to the naked eye makes it probable enough that it was known to the ancients. Two passages in the writings of ARISTOTLE have been supposed to refer to it. One in which he speaks of a minute whitish animal, which he names *Acarus*, (Ἄκαρι,) found in old honey-combs and in dry wood, which he says is the least of all animals—*De Animal. Hist.*, Lib. V, Cap. 32, [Paris Ed., 1848–54, T. III, p. 102;]—and another in which he describes certain lice which are generated beneath the skin, and give rise to small vesicles which contain no pus. But even if it be granted that these passages refer to the acarus in question, it must be admitted that long after the time of ARISTOTLE the physicians remained ignorant of it. GALEN, who appears to have had the best clinical knowledge of scabies of any of the Greek physicians, and who speaks of it under the designation psora (ψώρα) as contagious—*De Diff. Feb.*, Lib. I, Cap. 3, [Ed. Kühn VII, p. 279,]—does not anywhere allude to the parasite, nor is mention of it made by any of the Greek or Roman medical writers or by any of the Arabians except AVENZOHAR. The prince of the Arabians, AVICENNA—Lib. IV, Fen. 7, Tract. 3, Cap. 6; Venice Ed. of 1595, T. II, p. 250—in writing "de scabie et pruritu," seems, however, to come very near the truth when he says: "Et causæ quidem generantes materiam scabiei sunt causæ generantes materiam pruritus, verum ipsæ sunt fortiores et appropinquant causis generantibus pediculos," &c. The first unmistakable account of the itch-acarus in any medical writing was given in the 12th century by AVENZOHAR [or EBN-ZOHR] in a chapter headed, De assoab, qui latine dicitur (dicuntur) pedoscelli, [the word pedoscelli, pedicelli or pellicelli was the vulgar Latin for syrones, cirones or acari; see ALDROVANDUS and the thesis of SCHWIEBE, cited on page 369,] in which he says: "Oritur (oriuntur) aliquando in corpore sub cuti (cute) exteriùs pediculi parvunculi, qui, cum excoriatur cutis, exeunt animalia viva tam parvuncula quod (quæ) vix possunt (possint) videri." In the treatment of this affection he recommends first purgatives, then inunction with oil of bitter almonds and other oleaginous substances—*Theisir*, i. e., *Rectificatio Medicationis et Regiminis*, Lib. II, Tract. 7, Cap. 18, Venice, 1490, fol. 32. [There is in the Surgeon General's library another black-letter edition of this work without date, in which the above is numbered Cap. 19.] I cannot agree with HEBRA—*Hautkrankheiten*, in Virchow's Handb. der Spec. Path. u. Ther., Bd. III, Abth. 1, Erlangen, 1860, S. 410; also New Sydenham Society's English Transl., Vol. II, London, 1868, p. 164—to whose learned history of scabies I refer the reader, that this chapter is not sufficient evidence that AVENZOHAR was acquainted with the itch-mite, and note that, although he gives a translation of the passage cited above, as well as the paraphrase of MOUFET, (*vide infra*,) he does not allude to the treatment recommended by the Arabian author. HEBRA, therefore, regards the two passages which he cites from the *Physika* of SAINT HILDEGARD, written in the twelfth century, [*De Plantis*, Cap. 55 and 110,] as the earliest indisputable references to the itch-mite. In that work they are spoken of as *suren* or *suern*, and the external application of two plants, *myntza major* and *bilsa*, (henbane?) is recommended to destroy them. According to HEBRA, a similar passage occurs also in the *Herbarium* of WILHELM GRALAP, [1456,] in which the *grosz myntz* and *bilsenkrut* rubbed on the parts affected are recommended to destroy süren. I have not had access to either of these works. The following passage occurs in the French version of the *Surgery* of GUY DE CHAULIAC, [1363:] "Les cyrons sont des petits animaux qui en rongeant font comme des sillons de travers entre le cuir et la chair, principalement dans les mains des paresseux"—*La Grande Chyrurgie de* MAISTRE GUY DE CHAULIAC, Bourdeaux, 1672, Traité VI, Chap. III, p. 496, *Des poux et des cirons*. He did not, however, identify this condition with itch, of which he treats in the previous section of the same chapter, *op. cit.*, p. 492. ALEXANDER BENEDICTUS—*De omnium à vertice ad plantam morborum signis, causis*, &c., Venice, 1535, Lib. XXI, Prœmium, I cite the Basel Ed. of 1549, p. 383—writes: "In manibus quidam exilis pedicellus lende minor sub cute serpit, non admodum frequens in capite sub cuti pediculus infantiæ peculiare tædium." J. P. INGRASSIAS—*De Tumoribus præter naturam*, Naples, 1552, p. 351—described them as a species of lice: "Præter hanc vero pediculorum speciem alia est, sub cuticula oboriens, ibique affixa permanens, aut parum deambulans, præcipueque in manibus ac pedibus, frequentiusque in pedibus infantium, non permittens illos quiescere. Dicuntur Arabicè assoab apud Abenzoarem, à nostris vulgò pedicelli, dicunt aliqui pedoscelli. Mirum herclè dictu, quod uti perbellè Abenzoar descripsit, cum excoriatur cutis (ubi scilicet minimus ille ionthus varulusve, cujusdam sudaminis instar apparet) exeunt animalia viva, tam parvuncula, quod vix possunt videri." HEBRA (*loc. cit.*) singularly enough has no doubt that in this passage INGRASSIAS shows his knowledge of the itch-mite, although he denies that AVENZOHAR, from whom INGRASSIAS derived his information, had. JOHANNES LANGIUS is cited by SCHENCKIUS (*vide infra*) as follows: "Syrones inquit Abinzoar sunt pedicelli, Arabibus Assoalat dicti, qui subter cutem et ad manus et crura serpunt, pustulas quoque aqua plenas, sub cute, ubi delitescunt, excitant, qua dissecta, prorepunt animalcula tam parva, ut vix visu quantumvis perspicaci ægre deprehendi possint. De quibus *Arist.* videtur *in libro de natura animalium* ita dixisse: pediculi ex carne gignuntur, quibus affuturis, emergunt pustulæ quædam sine pure exiguæ, quas si purgas, pedieuli exeunt valde exiles." An elaborate article on the subject of this parasite will be found in the curious work of J. C. SCALIGER—*Exotericarium Exercit. Lib. XV, de Subtilitate ad H. Cardanum*, Exerc. 194, § 7, Paris, 1557; I cite the Frankfort Ed. of 1592, p. 631—who gives the following synonyms: "acaris, garapates, pedicellus, scirus, brigans, ricinus, croton, cica, cynoraistes, plata, cæca, cicy," and remarks: "Vix oculis capitur magnitudo. Tam pusillum est, ut non atomis constare, sed ipsum esse una ex Epicuri atomis videatur. Ita sub cute habitat, ut actis cuniculis urat. Extractus acu, super unguc positus, ita demum seso movet, si solis calore adjuvetur. Altero unguc pressus haud sine sono crepat, aqueum que virus reddit." The extraction of the parasite on the point of a needle, referred to by SCALIGER in this passage, was known to the common people. It is alluded to by AMBROISE PARÉ—1575, Lib. 22, Chap. 6: I cite MALGAIGNE'S Ed., Paris, T. III, 1841, p. 270—who recommended this practice in the treatment, "Les cirons se doivent tirer avec espingles ou aiguilles: toutesfois il vaut mieux les tuer avec onguens et decoctions faites de choses ameres et salées." JOUBERT mentions that some of the common people had the knack of extracting them, but regards this practice as ineffectual to cure the disease: "Cyrones peculiariter vulgus acicula extrahit (Germani vocant Seuren graben) sed cum non simul tollatur causa eorum fomes, perseverat affectio. Itaque præstat unguento vel fotu eos extinguere, quo simul tollatur pruritus ille infestissimus." [I cite from SCHENCKIUS, *loc. cit.*, *infra*.] FALLOPIUS—*Opera*, T. II, Tract. 1, *De Ulceribus*, Cap. 26, 1577; I cite the Venice Ed. of 1606, T. II, p. 90—taught that the irritation produced by this parasite constitutes one of the varieties of scabies. The chapter referred to is headed, "De scabici variis nominibus, ac differentiis." In it he describes three species of scabies; the one referred to is the second. He says: "Secunda sunt quædam animalia parva, et quidèm ita parva, ut vix conspiciantur, tamen mulieres colligunt ipsa in summa acie acus, et manifestè apparet, ipsa moveri motu progressivo, etiam si minima sint; dicuntur autèm animalcula ista pediculi, vel pedicelli vulgo, et à barbaris istis syrones," &c. J. MERCURIALIS—*De Morbis Cutaneis, Libri duo*, Lib. I, Cap. 7, 1572; I cite the Venice Ed. of 1601, p. 34—shared the opinion of INGRASSIAS, that our acarus is a species of louse. He says: "nonnulli sunt pediculi, qui parum crescunt, et in superiore cute manent; sed tamen leviter perambulant, et corrodunt, atque isti pedicelli vulgo nuncupantur." The same view was taken by VIDUS VIDIUS—*De curatione generatim*, Lib. VI, Cap. 10, 1587; I cite Opera, Frankfort, 1626, T. II, p. 440—"Tertia species est eorum (*i. e.* of lice) quos recentiores Medici vocant Scirrones, vulgus pelliccllos, quod inter pelliculam et cutem serpunt, sinuantes sibi veluti cuniculos

After the invention of the compound microscope animalcula invisible to the unaided eye were observed in a large variety of putrid substances, and as the notion of the putridity of the humors played a great role in the humoral pathology, the hypothesis suggested by the ingenious jesuit, Athanasius Kircher, [1658,]* that microscopical animacula or vermiculi were the true cause of pestilential diseases, found ready acceptance in certain quarters. The analogy of the itch-mite, studied anew with the microscope, particularly by Hauptmann and Cestoni,† led to the belief that the exanthematous diseases especially owed their origin to an acarus-like parasite; but the doctrine of animated contagion was by no means limited to this class of disorders. It was extended by Christian Langius and Rivinus‡ to the most diverse affections, and undemonstrated

seu vesiculas non suppurantes, quas si quis perforet exeunt albi, adeo tamen parvi, ut vix deprehendi oculis possint, non tamen fugiunt acriorem visum in loco maxime lucido, quod si inter ungues comprimantur, ubi extracti sunt, parvulum quendam sonitum edunt." GUILLAUME RONDELET—*Methodus curandorum omnium morborum*, Frankfort, 1592, Lib. I, Cap. 3, p. 18—in his chapter *De pediculari morbo*, expressed the same opinion: "Tertium, (genus,) quod cyrones vulgò appellant, qui nunquam extra erumpunt, sed semper intra cutim et cuticulam latitant." According to HEBRA, (*loc. cit.*,) the same opinion was expressed still later by SAMUEL HAFENREFFER, [1630.] Several of the foregoing extracts were collected towards the close of the sixteenth century by J. SCHENCKIUS—*Obs. Med. Rar.*, Lib. V, 1597; I cite the Frankfort Ed. of 1609, p. 774—in his article *De Syronibus*, which also contains extracts on the same subject from the writings of GABUCINUS, THOMAS À VEIGA and WIRSUNG. A summary of the knowledge of the day on this subject will also be found in the treatise on insects of ULYSSES ALDROVANDUS—*De Animalibus insectis Libri septem*, Lib. V, Cap. 4, Bologna, 1602; I cite the Ed. of 1638, p. 544,—who combats the idea that "scirrones, eos vocant vulgus pellicellos," are identical with the Acari of ARISTOTLE. The contrary opinion, however, was maintained by THOMAS MOUFET, the English naturalist—*Insectorum Theatrum*, London, 1634, Lib. II, Cap. 23, p. 266—whose learned chapter *De Syronibus* is the last important notice of these mites published before the compound microscope was brought to bear upon the subject. This author was well acquainted with the previous literature of the subject, and cites many of the authorities quoted above, together with some others. He states that these parasites are called in English *wheale-wormes*, and relates the case of the beloved wife of a certain old knight who was so afflicted by them in all parts of her body that at length, worn out by the irritation and loss of sleep, she died. He appears himself to have observed the true situation of the parasite, for he writes: "Syrones istos non in ipsis pustulis, sed prope habitare." He, too, refers to the skill acquired by certain women in extracting the mites, quoting an epistle from a certain Doctor Le Jeune, surgeon to the king, who having tried in vain to relieve a patient afflicted by them, received the help of such an expert: "Tunc amici ad ægrotam fœminam quandam miserunt, quæ coram aeu argentea adeo dextre et nullo cum dolore Syrones extraxit, ut mihi miraculo esset." The foregoing extracts will serve to illustrate the extent to which the knowledge of the itch-mite was diffused before the compound microscope was brought into use, and show that this knowledge both of the parasite and of the mode of extracting it constituted a part of the folks-lore of the peasantry, and probably therefore long antedates all written references to it. For the history of the progress of knowledge on this subject after the microscope was brought to bear upon it, I refer the reader to the learned article by HEBRA already mentioned, calling attention to the circumstance that as late as 1834, when the scientific men of modern Europe had begun to doubt the very existence of this parasite, the Corsican RENUCCI, who taught them once more how to find it, is said to have derived his precious knowledge from the old women of his native land. (HEBRA, *loc. cit.*)

* A. KIRCHER—*Scrutinium Phys.-Med. contagiosæ, luis quæ Pestis vulgò dicitur*, Rome, 1658. In this work he shows that all putridity generates worms, and that since the discovery of the microscope innumerable worms, invisible to the unarmed eye, have been discovered in putrid substances, [Sect. 1, Cap. 7.] "Notum quoque huousque est omnibus, vermes è putridis corporibus scaturire; sed non nisi post admirandum Smicrosopii inventum, omnia putrida innumerabili vermium oculo non armato insensibilium fœtura scatere, cognitum fuit; quod et ego nunquàm credidissem, nisi frequenti multorum annorum experimento id comprobassem," [p. 42.] He concludes from his experiments that each living substance by its putrefaction gives rise to specific animalcula: "Omne vivens ex putredine sua educit animal quoddam naturæ viventis congruum, et à cæteris omnibus differens." He then endeavors to prove (Sect. 1, Cap. 8) that the putrefaction of bodies infected by pest gives rise to effluvia not merely of inanimate but of animated corpuscles: "Animatam minutissimorum et insensibilium animalculorum sobolem," [p. 50.] Of the minuteness of these animalcula or vermiculi he writes: "Sunt autem hi vermiculi pestis propagatores tam exigui, tam tenues et subtiles, ut omnem sensus captum eludant, nec non nisi exquisitissimo smicroscopio sub sensum cadant, atomos diceres; tanta verò identidem repullulant multitudine, ut sub computum non cadant," [p. 141.] More than once he declares that these vermiculi were actually observed in examinations made at his instance of the contents of the bubos of those dead of plague, [p. 142.] As capable of destroying these vermiculi, he recommended dilute sulphuric acid [spiritus vitrioli, p. 185] given internally, both for prophylaxis and cure, much as it has been recommended of late in certain quarters for cholera on account of its power of killing bacteria.

† A. HAUPTMANN—*Tractatus de vira mortis imagine*, Frankfort, 1650. According to HEBRA, (*loc. cit.*,) this writer was the first to make a drawing professing to represent the microscopical appearances of the itch-mite. I have not obtained access to a copy of this tract. SCHWIEBE (cited below) in the preface to his thesis makes the following extract from it: "Cridones, sive Dracunculi, Blattæ, Tineæ, vari et vermiculi illi corrodentes in morbillis, scabie et pustulis. Cyrones sive Acari, quos Germani die Reitliesen appellitare solent, quique Cicatrices causant atque exedunt ex ichore et seroso humore propullulant, quæ insecta omnia mortis quædam sunt species, nisi enim iisdem resistatur, corpus destruere possunt utique." Whence it appears that HAUPTMANN attributed various diseases besides scabies to minute animal parasites. In this he preceded KIRCHER, [*op. cit.*, p. 57,] who was well acquainted with his labors, and cites with praise the tract above mentioned. I name H. CESTONI in this connection because he appears to have been the actual observer, and not G. C. BONOMO or F. REDI, both of whom have received the credit. The observations were promulgated in a letter from BONOMO to REDI, written in 1687. This epistle will be found in the works of REDI—OPERE, 1712; I cite the Milan Ed., T. III, 1812, p. 439—and translated into Latin by LANZONI in the *Ephem. Med.-Phys. German*, Dec. II, an. X, [1691.] Appendix, p. 33.

‡ CHRISTIAN LANGIUS edited in 1659 (Leipsic) an edition of the work of KIRCHER cited above, in his preface to which the germs of his doctrine will be found. He there extends the hypothesis of HAUPTMANN and KIRCHER not merely to "morbilli, variola, febresque petechiales," but also "funesta illa puerperarum furia, purpura," "cephalalgiæ contumaces, pleuritides intolerabili dolore comitatæ, rosiones stomachi et intestinorum, convulsiones epilepticæ, torturæ arthriticæ et hujus farinæ consimilia pathemata." All which he derives "ab exhalationibus et effluviis animatis." In this preface also he promised the publication of a work to be entitled "*Pathologia Animata*," in which his doctrine should be more fully expounded. This, however, did not appear till after his death; it is contained in his collected works—*Opera Omnia*, Frankfort, 1688—under the title *Pathologia Animata, seu Animadversiones in Path. Spagiricam cl. viri P. J. Fabri*, and is a prolix work of nearly 700 pages of small type, in which his favorite "animated putridity" serves as the explanation of almost all diseases. A. Q. RIVINUS, who was professor of physiology and botany at Leipsic from 1691 to 1723, taught this doctrine in his lectures. A glimpse of his views is given in the thesis of his student, J. J. SCHWIEBE—*De Pruritu Exanthematum ab Acaris*, Leipsic, 1722—in which the various exanthematous diseases are each affirmed to be derived from a special acarus. A comparison is drawn with the maculæ on the leaves, &c., of plants which result from the bites of insects, and the hypothesis boldly stated that diversity in the parasite gives rise to diversity in the disease: "Mirum autem non est, symptomata diversa nasci ex ipsa vermiculorum varietate." [p. 17.] Compare, in this connection, the curious work

diversities in the genera and species of the animal parasites were assumed to explain the diversity of the diseases generated, just as has been done of late by the "bacteria fanatics"* in the case of the vegetable parasites. Christian Langius taught that in both diarrhœa and dysentery the intestinal flux is the consequence of the velication and urtication of the mucous membrane by innumerable vermiculi invisible to the naked eye; he affirmed that if the ramenta and strigmenta of the dysenteric stools were examined by the microscope the curious physician would find swarms of these vermiculi in them; and designated the acrid matter, which by its action on the intestinal mucous membrane produces the flux, by the phrase "animated or verminous putridity," which is so conspicuous in his pathology.†

These views were rather speculative suggestions than the fruit of actual observations; but in the case of dysentery the lacking observations appeared to be supplied in 1757 by Nyander's essay, Exanthemata Viva, the publication of which by his teacher, Linnæus,‡ secured for it more attention than it would otherwise have received. The arguments it contained in support of the speculation that acari, similar to those of scabies, cause many grave diseases was no longer novel, but Nyander's statement that his friend Rolander had actually observed myriads of living acari in his own stools, while suffering from a mild dysenteric attack, appeared to be important, because countenanced by the great naturalist. Linnæus, in the twelfth edition of the Systema Naturæ, made a separate species of the Acarus dysenteriæ, and for a time the opinion that dysentery is caused by a minute animal parasite appeared to rest upon the basis of actual observation.

---

of NICOLAS ANDRY—*De la Génération des Vers dans le Corps de l'homme*, Paris, 1700; of which there is in our library an English translation, "*An Account of the Breeding of Worms in Human Bodies*," London, 1701. The author used a microscope sufficiently powerful to enable him to see the spermatozoids, which he described under the head of spermatic worms, (spermatici,) and gives a tolerable figure of them. He asserted that he saw worms in the blood, (sanguinei:) "They keep within the Vessels, and swim in the midst of the Blood, as Vinegar-worms do in Vinegar. They are very slender and small." "'Tis probable, that sometimes when they are too big to be receiv'd by the Veins, they remain in the Flesh, where they occasion Fellons, Risings, and sometimes an universal Scab," (p. 85.) So also there were Elcophagi that "gnaw Ulcers;" Venereal Worms (venerei) that "occasion all the Symptoms of Venereal Diseases," (p. 89.) "Cancers are all full of imperceptible Worms," (p. 198,) which indeed cause the disease; and so also "Worms may occasion Tumors and Excrescencies in the Body, as they do in the Leaves of Oak," &c., (*loc. cit.*) Our author was not quite certain of the doctrine of HAUPTMANN and KIRCHER that worms are the cause of "Malignant Fevers," though he evidently inclined to that belief. (See p. 109.) See also the second letter of HARTSOEKER, appended to this work, [p. 216,] who remarks: "I believe that Worms occasion most Diseases with which Mankind is attack'd."

* *Bakterienfanatiker*—BIRCH-HIRSCHFELD in Schmidt's Jahrb., Bd. 166, 1875, p. 169. I do not know who deserves the credit of originating this term, which has come into use in Germany of late years and deserves to be perpetuated.

† CHR. LANGIUS—*Pathologia Animata*, [cited above,] p. 464 *et seq.* He urges his views as to diarrhœa especially in connection with the species which accompanies malignant fevers: "Circa symptomaticam diarrhœam, quæ in febribus malignis, præsertim iis, quas exanthemata signant, accidere quandoque solet, id omninò adscribendum advertendumque est, quod verminosa tunc putredo tantoperè redundans atque ferociens intestina seu alvum sic lancinet, vellicet ac urgeat, ut sæva ejusdem proluvies hinc oriatur." With regard to dysentery he says: "Est itaque Dysenteria frequens alvi, sed cruenta, strigmentosa ac purulenta dejectio cum dolore morsuque ventris maximò et intestinorum exulceratione juncta, atque à materia acri erodente et intestinis peculiariter infesta (sub qua phrasi ego animatam ac verminosam putredinem comprehendo) orta;" and again: "Subjiciant quæso Medici curiosi aliquid de ramentis et strigmentis illis, quæ à dysentericis excernuntur, dicto jam smicroscopio, et cum admiratione vermiculorum turmas videbunt." I do not understand him to say that he actually saw these dysenteric vermiculi, but only to express his belief that they would be seen, if looked for.

‡ J. C. NYANDER—*Exanthemata viva*, [June 23, 1757,] Amœnitates Academicæ, T. V, Stockholm, 1760, p. 92. He was familiar with the speculations of HAUPTMANN, KIRCHER and LANGIUS, all of whom he quotes. He described the acarus which causes scabies, and argued that small-pox, whooping-cough, measles, plague and syphilis are of similar origin. Of dysentery he says: "Dysenteria epidemica Scabies est intestinorum interna, ut ex dissectionibus cadaverum, Dysenteria defunctorum, patet." This opinion, however, was not based, as ROKITANSKY has erroneously suggested, (C. ROKITANSKY—*Der dysenterische Prozess auf dem Dickdarme*, Oester. Jarhb., Bd. XX, 1839, S. 83. The same statement occurs in the earlier editions of his *Lehrb. der path. Anat.* See Sydenham Society's transl., Vol. II, London, 1849, p. 83. It is omitted from the 3d revised ed., Bd. III, Vienna, 1861, S. 207,) upon any actual observations of the cadavers of dysenteric subjects, but wholly upon the following considerations: It had been related by BARTHOLINUS that a certain Danish physician, who lived in the previous century at Helsingburg, often suffered from dysentery, and at such times had observed living insects in his stools. A friend of NYANDER, named ROLANDER, who was an entomologist, had himself several mild attacks of dysentery (?) which he cured with rhubarb and paregoric, and was induced during one of these attacks to examine his own stools to see if he could verify the statement of BARTHOLINUS. He asserted that he found in them myriads of animalcula similar to the acari of flour, and discovered their source to be a goblet made of juniper-wood out of which he drank beer at night; multitudes of the acari were found in the fissures on the inside of this vessel. I do not understand that either NYANDER or LINNÆUS ever saw these acari; their existence appears to rest entirely upon the testimony of the sick man. The words of the thesis are: "Hoc facto (*i. e.*, the discharges examined with the microscope) in hisce myriades animalculorum se vidisse, quæque accurate descripta, esse acaros, et acaris quidem farinæ similes, æger dixit." However this may be, LINNÆUS introduced the *Acarus dysenteriæ* as a separate species into the 12th edition of the *Systema Naturæ*, (Stockholm, 1767, T. I, Pars 2, p. 1024,) with a description of its habits, drawn from the statements of ROLANDER; and the doctrine that dysentery is a "scabies intestinorum interna" has been attributed to him by numerous writers from the time of SIR JOHN PRINGLE (*Obs. on the Diseases of the Army.* 7th Ed., London, 1774, p. 256) to the present day. Several of our modern text-books also repeat the erroneous assumption of ROKITANSKY referred to above; but the doctrine was not based upon any such anatomical minutiæ as the great pathologist refers to in the passage cited; it rested chiefly upon the previously propounded doctrine of animate contagion, the only new fact brought forward in support of which was the discovery of the acari, which ROLANDER said he saw. I may add that PRINGLE—*op. cit.*, p. 249—seems to have fallen into an error not unlike that of ROKITANSKY.

But subsequent investigations did not confirm the supposed discovery of Rolander. Those who looked for acari in the dysenteric stools utterly failed to find them, and as the general doctrine of animate contagion lost credit, its application to dysentery passed completely out of sight. What Rolander really saw must remain a matter of conjecture. It is probable enough, in view of the declaration of Lionel Beale, that he also has seen living acari in the discharges from the bowels,* that the statements were made in good faith, with perhaps some exaggeration only as to numbers, and Beale's hint, that acari may fall into the stools after they are passed, is perhaps a sufficient explanation.

Since the modern improvements of the compound microscope have so much facilitated such observations several minute animal forms, belonging to the protozoa, have been observed in the stools of patients suffering under fluxes. I may mention especially the Paramaecium coli of Malmsten, the Cercomonas intestinalis of Lambl and the Amœba coli of Lösch.† It has even been suggested by Malmsten and Lösch that the low forms they have described may act as local irritants and provoke, or at least keep up, the flux, just as the larger parasites of the alimentary canal (intestinal worms) have sometimes been

* Lionel S. Beale—*The Microscope in its Application to Practical Medicine*, 3d Ed., Amer. reprint, Philadelphia, 1867, p. 196—"I have found numerous living acari in matters passed by the bowels, but did not determine the species, nor could I ascertain positively whether they had passed alive from the bowel or had merely fallen into the dejection afterwards." Whether a living acarus swallowed with the food or drink would be passed alive is perhaps a doubtful matter. Certainly its chance of doing so would seem to be best in subjects in whom from any cause the digestion is enfeebled, as in lientery, (whether dysenteric, or resulting from diarrhœa.) Brinton and Blood, however, have published cases in which the larvæ of some undetermined species of blow-fly appear unquestionably to have passed undigested through the intestinal canal of healthy adults—*Larvæ of certain species of blowfly expelled alive from the bowels*, Beale's Archives of Medicine, Vol. III, 1863, p. 133. In Blood's case a purge had been given, but not in Brinton's. This experience seems to suggest the possibility that other low animal forms may occasionally pass through the human alimentary canal alive, but it must be admitted that Beale's observations with regard to the acari lack confirmation. The few acari seen by T. R. Lewis—*Sixth Annual Report of the Sanitary Commissioner with the Government of India*, (1869,) Calcutta, 1870, Appendix A, p. 135—were all dead: "On two or three occasions, semi-disintegrated *acari* were observed in the stools examined, which had, in all probability, been swallowed with the food, in bread perhaps, and passed through the intestinal canal without being very much broken up, as may be seen from the figure." [Fig. 13, Plate 4.] This observer also saw cysts in the stools which "corresponded precisely" with the eggs of acari.

† Leeuwenhœk—*De ortu et defluvio capillorum, &c., &c., de vivis animalculis existentibus in excrementis*, &c., p. 37 *et seq.*, in Anatomin et Contemplationes, Leyden, 1687—described three different kinds of infusorial animalcula in the mucus of the human intestine, for which Ehrenberg—*Die Infusions-Thierchen als vollkommene Organismen*, Leipsic, 1838, S. 331—sought in vain, remarking, "Er scheint *Vibrio Bacillus*, einen *Bodo* oder *Monade* und eine *Acaride* (schleimhautfragment?) gesehen zu haben." Modern microscopists with their improved instruments have been more fortunate. P. H. Malmsten—*Infusorien als Intestinal-Thiere beim Menschen*, Virchow's Archiv, Bd. XII, [1857,] S. 302—found in the discharges from the bowels of two patients an oval, ciliated, infusorial animalcule about the 0.1 of a millimetre in length, which he named *Paramaecium coli*, and of which he has given an excellent figure, [*loc. cit.*, Taf. X.] The first patient was a man 38 years old who had long suffered from lientery. The second, a woman 35 years old, suffering from chronic entero-colitis, of which she died. The infusoria were found in the stools of both cases in great numbers. In the second case, on autopsy, follicular ulcers associated with diphtheritic inflammation were observed in the colon. In this case the contents of the intestinal canal after death were examined for the infusoria, which were found in the large intestine only, where they were most numerous in the mucus which coated the comparatively healthy mucous membrane between the ulcers. The author suggests that these infusoria may possibly by their presence have provoked the fluxes in which they were observed. W. Lambl—*Mikroskopische Untersuchungen der Darm-Excrete*, Prager Vierteljahrschrift, 1859, B. I, S. 51—described, under the name of *Cercomonas intestinalis*, a tiny monad (Plate I, Fig. 2) which he has seen in myriads in the jelly-like mucous discharges of children suffering from diarrhœa in the Franz Josef-Kinder-Spital at Prag. It is a delicate oval object .018 to .021 millimetres in long diameter. For a more minute description and additional figures see, by the same author, *Beobacht. u. Studien aus dem Franz Josef-Kinder-Spitale*, Theil I, 1860, S. 354 *et seq.*, *Die parasitischen Organismen des Darm-Canals*, [Taf. 18,] in which he mentions finding this parasite after death in the small intestine, especially the duodenum, as well as in the large intestine. In this latter work he describes also the occurrence, in the stools of children suffering with enteritis, of minute *Amœbæ*, (the chief mass of their bodies .0045 to .0062 millimetres in diameter,) of *Arcelli*, or flask-like infusoria, (.009 to .013 millimetres in long diameter.) and *Difflugia*, or bladder-like infusoria, (.012 to .016 millimetres in diameter.) C. Davaine—*Traité des Entozoaires*, Paris, 1860, p. vi, et 67—under the designation *Cercomonas hominis*, describes two species of monads similar to the *C. intestinalis* of Lambl, but somewhat smaller; one provided with a caudal filamentary appendage, the other with two such appendages, one at each extremity. He saw the first in cholera stools, the second in the stools of typhoid fever. A critical discussion of the subject will be found in the work of R. Leuckart—*Die Menschlichen Parasiten*, Bd. I, Leipsic, 1863, p. 140—who throws doubt on the nature of most of the supposed animal forms described by Lambl, especially the *Arcelli* and *Difflugia*, and suggests that his *Amœbæ* were really isolated tissue elements, such as white blood corpuscles, &c., which possess an amœboid motion; he admits, however, the *Cercomonas intestinalis* and the *Paramaecium coli*. Quite recently F. Lösch—*Massenhafte Entwickelung von Amöben im Dickdarm*, Virchow's Archiv, Bd. 65, [1875,] S. 196, [also Taf. X, Fig. 1–3.]—has again described *Amœbæ* seen in large numbers in the stools of a man 24 years old who had long suffered from diarrhœa which assumed a dysenteric character, and finally proved fatal. The *Amœbæ*, which were found in the stools in considerable numbers, were roundish or oval when at rest, varied from 20 to 30, or even 35, micro-millimetres in long diameter; when stretched out they sometimes attained 60 micro-millimetres. On the autopsy it was found that diphtheritic dysentery had supervened upon an intestinal catarrh, and diphtheritic sloughs, partly detached, were observed in the lower part of the ileum and in the cæcum. In the descending colon and sigmoid flexure there were numerous cicatrices of follicular ulcers and some unhealed ulcers, also some mucous cysts. Lösch proposed to name this parasite *Amœba coli*. He thinks they played a considerable part in the disease, and if they did not cause it, at least proved a source of irritation and prevented the ulcers from healing. In support of this view he cites several experiments in which one to two ounces of the fresh stools of the patient were injected, both by the mouth and per anum, into a dog, and seemed to provoke in one instance some intestinal catarrh, which he ascribes to the *Amœbæ*. Certainly not a very conclusive mode of reasoning, for the adherents of the bacteria hypothesis would rightly claim that the matter injected was full of vegetable parasites, and that these produced the disease, and indeed any other morbid matters which may constitute the real poison in these cases were evidently also present. Very similar to the figures of *Cercomonas intestinalis* referred to above, are those figured by T. R. Lewis, [p. 150, *op. cit.*, *supra*, and Plates 15 and 16,] which he observed both in the cholera stools and in a liquid stool passed by a healthy individual.

supposed to do;* but the evidence in favor of this view cannot be regarded as at all satisfactory. Here too I may refer to the Distoma haematobium of Bilharz, the ova of which were found by Griesinger† to be present, in great numbers, in the coats of the intestines of subjects dead of Egyptian dysentery. The suggestion that the disease might be produced by their action occurred to that prudent observer, who, however, soon convinced himself that they were by no means a constant concomitant of the dysentery of Egypt, and abandoned the notion of their causal significance. Lastly, I may mention the discovery by Normand‡

* The discovery of intestinal worms in the bodies of those dead of dysentery, and the observation of their presence in the stools of certain cases, long ago gave rise to the idea that these worms were a cause of dysentery. Thus we read in the *Sepulchretum* of BONETUS, Lib. III, Sect. XI, Obs. 21, [Geneva Ed., 1679, p. 860,] an observation borrowed from FONTANUS entitled "*Dysenteria à vermibus excitata.*" See also *Dysenteria animata cum vertigine nocturna*, Ephem. German. Dec. II, an. 7, [1688,] Appendix, p. 158. In the *Commerc. Litterarium Norimbergæ*, an. 1743, p. 53, there is mention of a case reported by J. P. WOLF, under the title "De dysenteria maligna verminosa, cum pustulis squamosis crustæ lacteæ similibus, conjuncta." NICOLAIS DU SAULSAY—*Vandermonde's Jour. de Méd.*, T. VI, [Paris, 1757,] p. 380—described an epidemic of dysentery which prevailed at Fougeres and its vicinity in the latter part of 1756, of which he says that intestinal worms were the principal cause: "On ne peut douter que les différentes especes de vers ne soient la cause principale de cette dyssenterie." Great numbers of worms are said to have been found by SEVOY in the bodies of the victims of this epidemic. In subsequent volumes of the same journal BOUCHER mentions—T. VII, [1757,] p. 236—an epidemic of "la dysseoterie verminеuse" which ravaged the environs of Lille in 1750, and BAUME—T. LXIX, [1786,] p. 257—relates the case of a dysentery of six months' duration cured suddenly by a dose of vermifuge, [helminthocorton;] great quantities of lumbricoid worms were passed, and from that time the patient rapidly recovered. SAUVAGES—*Nos. Meth.*, Amsterdam, 1768, T. II, p. 329—introduced "Dysenteria verminosa" into his nosology, chiefly on the testimony of DU SAULSAY, of whose narrative he gives an abridgement. PLOUCQUET—*Lit. Med. Digest.*, T. I, 1808, p. 424—cites a dissertation by MAY—*Casus de dysenteria verminosa*, Giessen, 1787—which I have not been able to see.

† THEODOR BILHARZ, in Kairo—*Distomum Haematobium und sein Verhältniss zu gewissen pathologischen Veränderungen der menschlichen Harnorgane*, Wiener Med. Wochenschrift, Jan., 1856, S. 49, u. 65. W. GRIESINGER—*Klinische und anat. Beob. über die Krankheiten von Egypten*, Vierordt's Archiv für Physiolog. Heilkunde, Jahrg. XIII, 1854, S. 561, Distomenkrankheit. BILHARZ announced the discovery of this parasite in a letter to VON SIEBOLD, May 1, 1851. Its pathological relations were investigated partly by himself, partly by GRIESINGER; the latter particularly inquired into its supposed connection with dysentery. Good accounts of the subject will be found in the works of F. KÜCHENMEISTER—*Animal and Vegetable Parasites of the Human Body*, Transl. of Sydenham Society, Vol. I, London, 1857, p. 277 *et seq.*; C. DAVAINE—*Traité des Entozoaires*, Paris, 1860, p. 312; R. LEUCKART—*Die Menschlichen Parasiten*, Bd. I, Leipsic, 1863, S. 617; and T. SPENCER COBBOLD—*Entozoa*, London, 1864, p. 197. The latter author designates the parasite *Bilharzia hæmatobia*, regarding it as properly a separate genus. The parasite is "a trematode helminth in which the male and female reproductive organs occur in separate individuals; the male being a cylindrical vermiform worm, measuring only half an inch or rather more in length, whilst the female is filiform, longer, and much narrower than the male, being about four-fifths of an inch from head to tail," (COBBOLD, *loc. cit.*) It has been found especially in the portal system of bloodvessels, and its occurrence has been recognized not only in Egypt, but also in South Africa and the Mauritius, (COBBOLD.) The eggs are oval or oblong, often sharply pointed at one extremity, and measure on the average $\frac{1}{166}$ of an inch in long diameter. While still in the body of the parent the eggs develop into minute ciliated animalcula, which exhibit lively movements; these measure on the average about $\frac{1}{127}$ of an inch in long diameter. This parasite, according to BILHARZ and GRIESINGER, produces a characteristic disease of the urinary organs, of which hæmaturia is a prominent symptom, and which is often accompanied by anæmia and great prostration of the vital powers. The patients frequently die, when bloody extravasations, fungus-like thickenings, even ulceration of the mucous membrane of the bladder are found. The lining membrane of the ureters and renal cavities is also often more or less affected, and the kidneys are sometimes enlarged and congested. According to BILHARZ, (*op. cit.*, p. 63,) these phenomena are due to the females entering the small vesical bloodvessels and there laying their eggs, which obstruct the circulation, giving rise to passive hyperæmia of the adjacent capillaries with consequent exudations, or to ruptures of the vessels through which the eggs or ciliated embryos escape into the tissues, or upon the free surface of the mucous membrane. This explains also the frequent occurrence of the eggs in the urine. Now, the lesions of the vesical mucous membrane just described, are not unlike those of the intestinal mucous membrane in dysentery, and GRIESINGER (*op. cit.*, p. 570) accordingly tells us that when, after March 19, 1852, he not unfrequently found the distoma eggs in the intestinal walls of subjects dead of dysentery, the thought for a moment arose in his mind that this parasite might be the cause of Egyptian dysentery: "da konnte freilich einen Augenblick lang der Gedanke auftauchen, das Distomum möge sich zu den endemischen, acuten und chronischen Dickdarmerkrankungen verhalten wie der Acarus zur Krätze." But such an acute observer did not long indulge this dream. He tells us that he soon found that in numerous cases of Egyptian dysentery the most careful search failed to find the parasite, and that he ultimately convinced himself that the distoma process was a pathological accident which might be superadded to dysentery, but could not be regarded as its cause. According to KÜCHENMEISTER, (*op. cit.*, p. 285.) BILHARZ came to the same conclusion. COBBOLD, (*op. cit.*, p. 203,) in his otherwise excellent abstract of the pathological appearances observed by GRIESINGER in the intestine, has omitted to mention this conclusion. I notice also with regret that the notion that this parasite may stand in a causal relation to dysentery is regarded with favor by AITKEN—*Science and Practice of Medicine*, 3d Amer. from 6th London Ed., Philadelphia, 1872, Vol. I, p. 205; Vol. II, p. 657.

‡ A. NORMAND—*Mémoire sur la diarrhée dite de Cochinchine*, [Archives de Méd. Navale, Jan., 1877, p. 35 *et seq.*] This gentleman is a naval surgeon (médecin de 1re classe de la marine) of whose sincerity I can have no doubt. He publishes a minute description of the parasite, prepared by M. BAVAY, professor of natural history in the Toulon school of naval medicine. From this it appears that there are no generic distinctions between the Anguillula stercoralis and the well-known and widely-distributed Anguillula terrestris, (or A. fluviatilis,) which is famous for its tenacity of life, and which has often been encountered in the intestinal canal of some of the lower animals. BAVAY says: "L'anguillule stercorale peut conserver ce nom qui lui a été donné dès sa découverte; elle diffère en effet fort peu de l'anguillule terrestre, *Rhabditis terricola* de Dujardin (genre *Leptodera* de Schneider), et ses différences ne paraissent pas d'ordre générique. L'espèce seule est nouvelle et peut être caractérisée ainsi: *Rhabditis* (Dujardin) *stercoralis* (nobis), *Leptodera* (Schneider) *stercoralis;* le nom de *stercoralis* lui a été donné en raison de l'habitat qu'on lui connaît," (p. 36.) Then follows an elaborate description, illustrated by an excellent wood-cut, which represents the adult male and female and the young in various stages of development. These so closely correspond to the well known descriptions and figures of the A. terrestris that they need not be reproduced here. NORMAND reports that he has sought in vain for this parasite in cases of diarrhœa contracted in France, or in diarrhœa consecutive to dysentery contracted in any other colony than Cochin China; nay, he admits that it is only in a certain number of Cochin China cases that he has been able to find it, (p. 41;) but these facts do not stagger him. He assumes that in the Cochin China cases in which he sought for it in vain it had previously been present, but had disappeared, or was present in such small numbers as to escape detection, as happened to him several times with patients in whom he afterwards found it. Hence he has no hesitation in speaking of the diarrhœa of Cochin China as "une entéro-colite verminеuse," or in regarding the parasite as its cause. But it is no longer wise to assume that every living organism observed in diarrhœa stools may forthwith be regarded as the cause of the disease. Before that view can be accepted it ought at least to be shown that the pathological condition in question never exists except in the presence of the accused parasite. But we know that the lesions of Cochin China diarrhœa differ in nothing from those of the chronic fluxes of other tropical countries, in which our author admits his parasite does not occur; nor has he made any attempt to reproduce the disease by means of the parasite. While this page is passing through the press I see by the Lancet (July, 1877, p. 139) that Prof. BAVAY has found still another form of *Anguillula*, which he proposes to call *A. intestinalis*, in five cases of Cochin China diarrhœa. The original article (Arch. de Méd. Navale, July, 1877) has not yet reached me.

of a species of Anguillula about a millimetre long, which he has observed in the stools of certain cases of the diarrhœa of Cochin China, and which he supposes to be the cause of that particular form of flux. This latest speculation does not appear to have any more solid foundation than its predecessors.

So far as I know, the earliest suggestion that dysentery might be caused by vegetable parasites in the alimentary canal was made by Baly,* who was induced by the publication, in 1849, of the observations of Brittan and Swayne as to certain forms supposed to be of a fungoid nature, found in the dejecta of epidemic cholera, to publish a drawing he had made in 1846 of similar bodies observed in the dysenteric stools during the occurrence of epidemic dysentery in the Millbank prison. Unfortunately this drawing and the accompanying description are not of such a character as to permit the identification of the objects described. Baly compared them to "the individuals of the genus protococcus," which he said they closely resembled, but their real nature has never been determined.

During the civil war J. H. Salisbury,† in his report to the Surgeon General of the State of Ohio, on the "chronic diarrhœa" of our soldiers, described, under the name of algoid cells, certain forms which he observed in the stools of that disease, and which he compared to Protococcus cocoma. They were perhaps similar to the forms observed by Baly, but the description, in this case also, is too imperfect to render positive identification possible. In the same paper Salisbury gives prominence to the occurrence in the stools of the "yeast plant," (torula forms,) which, together with the carbonic acid produced by the saccharine fermentation of imperfectly digested amylaceous food, especially hard bread, he supposes to act as the chief factors in the production of the chronic diarrhœa. Much as this paper in many respects deserves criticism, its author should be credited with having independently observed the prevalence of torula forms in the lientery of soldiers fed largely upon hard bread, which is certainly a fact, although it must probably be looked upon as a consequence of the disease rather than as its cause.

---

* Wm. Baly—*Note on the presence of peculiar microscopic bodies in the discharges of epidemic dysentery*, The London Med. Gazette, N. S., Vol. IX. [1849,] p. 580. He thought the bodies he figured were very similar, but not identical with those Brittan and Swayne had observed in cholera. If the latter were fungi, as Quekett had supposed, the former were fungi also. He had examined the bloody mucus in two cases of sporadic dysentery without finding them, and thought it uncertain whether they were peculiar to epidemic dysentery or of constant occurrence in it. The paper of Brittan, containing his account of the observations of Swayne and himself, will be found in the same volume, [p. 530,] and the opinion of Quekett in an appended letter. This publication gave rise to considerable discussion. Wm. Budd—*Malignant Cholera*, London, 1849, p. 4—declared that he had detected "the same organisms in great numbers in almost every specimen of drinking-water which I was enabled to obtain from Cholera-districts." George Busk, then president of the Microscopical Society, however, asserted that they consisted of altered blood corpuscles, starch granules, the cellular structure of the inner coat of the bran of wheat, and spores of the *uredo*, or smut of wheat—London Med. Gazette, Vol. IX, N. S., 1849, pp. 692 and 733. M. J. Berkeley, then the most competent authority on the subject of fungi in England, denied that the spores of *uredo* were present, and doubted indeed whether the bodies observed were fungi at all, (*op. cit.*, p. 1035.) The cholera committee of the Royal College of Physicians appointed Wm. Baly and Wm. W. Gull a subcommittee to investigate the subject. They reported that the so-called cholera fungi consisted in part of substances taken as food or medicine and in part of bodies of doubtful nature, but certainly not fungi. They mentioned, among the bodies identified, fragments of vegetable tissue, globules of calcareous matter (from chalk mixtures and other medicines) and altered starch grains, (*op. cit.*, p. 775.) T. R. Lewis—*Sixth Annual Report of the Sanitary Commissioner with the Government of India*, (1869,) Calcutta, 1870, Appendix A, p. 131 *et seq.*—in his comparatively recent examination of the subject adds to these bodies ova of various kinds (of intestinal worms, &c.) as presenting appearances similar to those described.

† J. H. Salisbury—*Chronic diarrhœa and its complications*, Annual Report of the Surgeon General for the year 1864, made to the Governor of the State of Ohio, Columbus, 1865, p. 25 *et seq.* This paper professedly relates to "chronic diarrhœa," but it is evident that under this head the writer embraces all the various forms of dysentery as well as of diarrhœa which occurred among our troops during the war. He asserts that the cause of the disease is primarily a scorbutic condition of the system resulting from camp-diet, and especially from the too exclusive use of hard bread. By this "is produced a highly saccharine or glycogenic condition of the system," in which "cryptogamic (yeast and algoid) plants are developed in vast numbers in the alimentary canal, germinating large quantities of carbonic acid which with the ferment organisms act as a peculiar irritant poison and cathartic," &c., p. 78. He describes the jelly-like lumps, which German writers have compared to frogs' spawn, as "small masses of gelatinous (colloid) matter," and says they are made up of large algoid cells and filaments enveloped in a jelly-like substance. These algoid cells, or colloid cells as he sometimes calls them, resemble several low algoid forms, such as the Protococcus cocoma and the Furfuraria lumbricales of Kützing, or the Lemania incurvata or Vauchesia clavata of Hassall, especially the last-named forms. The yeast plants of which he speaks he says consist of the torula cerevisiæ and a larger species of torula. He also observed the sarcina ventriculi and another smaller celled species of sarcina, and two or three species of confervæ, the latter of which "occur abundantly in all well-marked cases." Occasionally "the vegetating spores and mycelium of a species of penicillium, are met with in the colloid matter." I do not pretend to identify the "algoid cells" of Salisbury, and must remark that a perusal of the report cited and of other papers by the same author has not impressed me favorably as to the trustworthiness of any of his observations. What confidence can be felt in an observer who affirms that he frequently meets in the fluid stools of diarrhœa "masses of highly refractive polyhedral cells," "each cell of which contains a crystal of sugar," and who describes pathological processes pretended to have been observed in the villi (*sic*) of the large intestine?

The more modern speculation that a species of bacteria acts as the cause of dysentery dates back only to the observations of Klob, [1867,] though the existence of these low vegetable forms in the dysenteric stools had previously been mentioned by several writers, of whom the earliest I know is Lebert,* who spoke of the occurrence of "vibrios" in these discharges as long ago as 1845. Klob† found in the stools of dysentery forms very similar to those he had observed in epidemic cholera, viz: spore-heaps [Sporen-Häufchen] or groups of excessively minute granules imbedded in a transparent jelly, [the Zoogloœa of Cohn,] and rod-like bacteria, single, in pairs, in groups, or arranged end to end in chains. Generally these forms were less numerous than in cholera dejecta; in one case, however, he met enormous quantities. He thought, also, that the bacteria rods in dysentery were more slender and longer than those of cholera.

But all the forms described by Klob occur also in the normal stools, and his observations would consequently have attracted but little notice had not the doctrine they suggested been vitalized by Hallier,‡ [1869.] This ingenious speculator applied his micrococcus theory to dysentery also. He frankly admitted that the vegetable forms he found in the dysenteric stools did not differ in any visible way from those he had previously found in the stools of cholera, abdominal typhus and other infectious diseases; indeed he admitted they can be found in ordinary diarrhœa and in the healthy stools. But he claimed by culture experiments to have demonstrated the inherent diversity of the micrococci in all these cases. By proper culture the micrococci of dysentery developed into a genus of fungus, intermediate in characters between the genera Ustilago and Tilletia, for which he proposed the name of Leïosporium dysentericum. I will not occupy space by repeating his description of this plant, because subsequent criticism has shown the untrustworthiness of his methods of culture and thus deprived the observation of all significance.§

Nevertheless the persistence in a modified form of the general hypothesis that bacteria are in some way disease-producers has permitted the survival, in certain quarters, of the doctrine that dysentery is thus caused. This doctrine appeared to be favored by the observations of Basch‖ on the pathological anatomy of the diseased intestine, which will be discussed hereafter, and as late as 1874 received the assent of Virchow,¶ whose splendid rhetoric has lent plausibility to arguments which appeal almost as much to faith as to reason. For it must be admitted that up to the present time no vegetable forms have been observed, in the dysenteric stools, which differ morphologically from those observed in healthy individuals, and that no reasonably convincing evidence of any intrinsic difference, not morphologically expressed, has as yet been brought forward. The doctrine of vegetable contagion in dysentery at the present day may, in fact, be said to be in a very similar condition to that of the doctrine of animalcular contagion when Christian Langius wrote. Whether the modern doctrine will fare any better in the hands of future investigators, than its prototype of the seventeenth century has done in the present age, remains to be seen.

6. *Accidental matters derived from the food and medicines taken.*—The dysenteric stools may be accidentally colored by any of the articles of food or medicine which have been described as producing a similar effect in diarrhœa,* and substances of the most diverse nature, derived from the imperfectly digested food, may find their way into the discharges. Among the ingredients of this character, considerable interest attaches to the little semi-transparent masses which have been compared to grains of boiled sago and frogs' spawn.† These have been supposed by some excellent observers, as Finger, Griesinger, Bamberger, and recently Heubner,‡ to originate in the ulcerated solitary follicles of the colon, and therefore to afford clinical evidence of the existence of follicular ulceration. Virchow, however, has pointed out that if these bodies be treated with iodine they acquire a blue color, and remarked with bitter sarcasm that what has been called sago-like mucus is much more frequently mucus-like sago.§ Moreover it has been shown by Frerichs || that in certain abnormal conditions of the digestive processes the starchy matters of the food are transformed into a tough, stringy, semi-transparent substance very similar to mucus, and the same transformation can be imitated out of the body by inducing lactic acid fermentation in fluids rich in starchy matters. Frerichs observed this condition in the vomited matters and contents of the stomach in certain diseases of that organ, and Virchow ¶ repeatedly noticed it in catarrhal diarrhœa and dysentery.

Heubner has recently reaffirmed the old view of the origin of these bodies, in a somewhat modified form, suggesting that the follicular ulcers serve as moulds into which the mucus secreted by the inflamed mucous membrane is pressed, and, having been moulded into shape, that it falls out again into the contents of the bowels. He admits** that he did not apply the iodine test, being unacquainted with Virchow's views, but appears to think the presence of a few mucous corpuscles, epithelial cells and free nuclei, which he observed in some of these bodies with the microscope, decisive as to their nature. Such elements are, however, too abundant in the intestinal secretions of dysentery not to be likely to become imbedded in altered starchy matter while passing through the alimentary canal.

During the war of the rebellion the frogs'-spawn bodies were abundantly observed both in acute dysentery and in the chronic fluxes. They appear to have particularly arrested the attention of Salisbury,†† who correctly described them as "little jelly-like lumps disseminated through the fecal matters," but erroneously supposed them to be composed of a "gelatinous" or "colloid" substance. I myself not only found that iodine gave a blue color to almost every well characterized lump of the sort tested, but I usually observed with the microscope large numbers of torula-like cells, resembling those which are developed during the fermentation of starchy substances; I must, therefore, regard the opinion of their nature expressed by Virchow as substantially correct.

HEUBNER does not appear to have known that this matter had been fully explained by VIRCHOW in 1853, (Archiv, Bd. V, 329,) although he might have found the reference to this passage in the article he cites.

†† J. H. SALISBURY—*Chronic Diarrhœa and its Complications*. Report of Surgeon General of Ohio for 1864, p. 31. See note to p. 373, *supra*.

Heubner makes another statement in connection with this subject which cannot be accepted without considerable modification. He speaks of the frogs'-spawn bodies as identical with the *corpora pinguia* of the ancients. It has been shown already* that certain varieties of the muco-purulent discharges of dysentery were supposed by the ancients to be fat; and it is possible that the frogs'-spawn bodies may have been similarly regarded by them, though explicit statements on the subject are wanting. It is, however, quite certain that a part at least of the so-called *corpora pinguia* were really fat. Whatever doubts may be felt as to the real nature of the bodies resembling "chopped tallow," which Aretæus† described as sometimes occurring in the dysenteric stools, there can be none as to those which were found to melt with heat, and to burn when thrown on live coals with a bright flame and characteristic odor, by Hollerius, Riverius, Tulpius and Stalpartius.‡

Numerous more modern observations have fully established the occasional occurrence of considerable quantities of fat in the stools. It occurs as a liquid oil, which may or may not solidify after it is voided, or in solid lumps of various sizes, which have been compared to bits of tallow or suet, scraps of candle-fat, adipocere, ambergris, &c. The term *corpora pinguia* more properly belongs to these solid lumps. A few writers, as Forestus, Pringle and Moseley,§ have spoken of their occurrence in dysentery; but almost all the individual cases I have found on record were examples of diarrhœa, and the form of flux in which these bodies occur in the stools may be conveniently designated by the term *diarrhœa adiposa* proposed by Sauvages.‖ Nevertheless a succinct account of the chief facts with regard to such discharges seems desirable in this place, on account of their occasional occurrence in dysentery also.

The origin of the fatty matters found in the stools has been variously explained. The earliest medical observers must have noticed that, in certain disordered conditions of the digestive processes, the fat of the food might pass unaltered through the alimentary canal and make its appearance unchanged in the dejecta. Both Philagrius and Galen alluded to this possibility¶ in a manner which shows that it was fully recognized by the old Greek physicians; but this simple explanation did not appear satisfactory to them in those cases in which the fatty matters passed differed in character from the fat taken with the food, or where it was supposed that the food had contained no fat. In these cases it was believed that the fat in the stools was derived from the adipose tissue of the body melted by the heat of the disease; the fat so melted might make its appearance either in the stools or the urine. In the case of dysentery, already alluded to, it was the fat of the intestines, of the mesentery, or some other abdominal fat that was melted. So also in certain diseases of the kidneys, the fat about these organs melted and appeared in the urine; but in certain fevers and other wasting diseases the fat of the whole body might undergo the same process and make its appearance either in the stools or the urine or both. This colliqua-

* *Supra*, p. 356.

† ARETÆUS—*De Causis et Signis Morb. Diut.*, Lib. II, Cap. 9, [Ed. Boerhaave, p. 69,]—in this passage the substances compared to chopped tallow are said to be white, thick and mucous, (μυξώδεα,) and to occur in those cases in which there are deep ulcers in the lower bowels. They must not be confounded with the large fleshy pieces which he also mentions—see note † page 361, *supra*.

‡ HOLLERIUS—*De Morb. Intern.*, Lib. I, Cap. 40, Scholia. For the other authors referred to, see notes below.

§ P. FORESTUS—*Obs. et Cur. Med.*, Lib. XXII, Obs. 33, Scholia, [Leyden Ed., 1596, p. 368,]—remarks that dysentery is still curable, even after fatty bodies ("quædam corpora pinguia") are excreted. PRINGLE—*Obs. on the Diseases of the Army*, Part III, Cap. 6, 7th Ed., London, 1774, p. 229—says: "I do not know whether they are the same which Hippocrates calls σάρκες, (caruncuiæ;)" but in one case of a dysenteric patient who voided such substances he found they were bits of cheese, whether derived from cheese eaten a fortnight before, or formed in the intestinal canal from milk which had been used for diet by the sick man, he could not tell. He thinks that the corpora pinguia which he "had so often seen in the dysentery" must have been of the same nature. MOSELEY—*Treatise on Tropical Diseases*, 3d Edit., London, 1792, p. 234—says of this supposition that the corpora pinguia are identical with the caruncuiæ, "Certainly they are not;" and regards PRINGLE'S explanation of their nature as erroneous.

‖ SAUVAGES—*Nos. Meth.*, Amsterdam, 1768, T. II, p. 359. ¶ See next note.

tive condition, which was mentioned by Hippocrates and described by Philagrius, was fully discussed by Galen,* whose exposition was long accepted as satisfactory.

Felix Plater† emphasized the possibility of the derivation of fat in the stools from the food, and spoke of its occurrence as a variety of lientery, but did not reject the possible occurrence of colliquative melting. This latter supposed cause was, however, gradually lost sight of, and the source of the fat was sought for in the food alone by Riverius, Stalpartius‡ and most of the writers who have published cases, until the commencement of the present century, when Mérat,§ (1806,) misled by the resemblance of the fatty matters sometimes passed to adipocere, and confounding the latter with cholesterin, suggested the liver as their source.

A few years later Everard Home,‖ (1813,) who was also struck with the resemblance to adipocere, made this circumstance the basis of a suggestion that fat might be produced in the alimentary canal by the metamorphosis of the albuminoid matters of the food. He called attention to the production of ambergris in the intestine of the whale as a parallel case; and suggesting the bile as the agent by means of which the metamorphosis was effected, he adduced several experiments, performed at his instance by Brande, in which fat was produced from muscular tissue digested in bile out of the body at the temperature of 100° Fahr. This suggestion does not appear to have attracted much attention, but the view of Mérat, that the fat in these cases is an anomalous secretion of the liver, was supported by several subsequent writers, among whom Lloyd, Elliotson, (1833,) Reeves (1854) and Copland (1858)¶ may be particularly mentioned.

---

* HIPPOCRATES—*Epidem.*, Lib. III, Sect. 3, § 17, [Ed. Littré, III, p. 105,]—describes a patient suffering from an ardent fever as having "oily urine' and "bilious, fatty stools," and—in *Prognostics*, § 12, [Ed. Littré, II, p. 143,]—observes that fatty matters resembling spiders' web swimming on the surface of the urine indicate colliquation, (*ξύντηξις.*) See also *Aphorism*, Sect. VII, 35, [Ed. Littré, IV, p. 587:] "When the scum on the surface is fatty and copious, it indicates acute disease of the kidneys." PHILAGRIUS—[Date uncertain; according to MANGETUS—*Biblioth. Med.*, T. II, p. 499, Geneva, 1731—he wrote 352 B. C.] in ÆTIUS, Tetr. II, Sermo I, Cap. 90, Lyon's Ed., 1549, p. 265—described, under the heading "De Colliquatione," a febrile condition in which there are offensive stools sometimes resembling bile, sometimes oily or fatty, and not derived from the food, but from the melting of the body. At first the newly formed fat is melted by the heat of the fever, afterwards the more solid flesh. The treatment should consist of cold external applications, cold drinks and cold foods, to diminish the heat of the body. PHILAGRIUS does not mention the appearance of fatty matters in the urine in this disease; but that symptom was fully discussed by GALEN—*Comm. III in Lib. III, Epidem.*, § 72, [Ed. Kühn, XVII, A, p. 737,]—where he suggests that in some cases the urine is not really oily, but only resembles oil, and *Comm. II in Lib. De Humor.*, § 25, [Ed. Kühn, XVI, p. 289.] in which he explains also that in diseases of the kidneys the fat around the kidneys may be melted and appear in the stools without general colliquative disease existing. The same view is expressed in *Comm. in Aph.*, Sect. VII, § 35, [Ed. Kühn, XVIII, A, p. 135.] In several places GALEN teaches that fat in the stools is only a sign of colliquation when the fat is not derived from the food; for example, in *Comm. I in Lib. De Humor.*, § 19, [Ed. Kühn, XVI, p. 188,] and *De Crisibus*, Lib. I, Cap. 11, [Ed. Kühn, IX, p. 593.] His opinions on colliquation with fatty stools will be found in these passages and in *Comm. III in Lib. III, Epidem.*, § 55, [Ed. Kühn, XVII, A, p. 708.] For brief summaries of the views of the Greek physicians on this subject, consult GORRÆUS—*Def. Med.*, in Opera. Paris, 1622, p. 610, Article Ξύντηξις, Colliquatio; and SENNERTUS—*Pract. Med.*, Lib. IV, Cap. 15, Febres Colliquativæ, Opera, Paris, 1641, T. II, p. 750. After a glance at the rich literature (both ancient and modern) of the subject of fatty dejecta, it seems strange to read the remarks of GROSS—*Elements of Path. Anat.*, 2d Ed., Philada., 1845, p. 587—that "although this subject was incidentally noticed by some of the earlier physicians, as TULPIUS and FABRICIUS HILDANUS, it does not seem to have attracted the special attention of the profession until within a comparatively recent period." But what shall be said of the assertion of HABERSHON—*Diseases of the Abdomen*, 2d Ed., London, 1862, p. 371—that "the presence of fatty matters in the evacuations was first noticed by Dr. BRIGHT"!

† FELIX PLATER—*Praxeos, De Vitiis*, Lib. II, Cap. 11, [Basel, 1736, T. III, p. 793.] He says that the dejections are sometimes fatty, resembling oil, butter or other kinds of fat; he has seen them resembling bits of candle-fat. "This dejection is a species of lientery when it proceeds from that which has been eaten, as often happens."

‡ See the cases by these authors cited in the note below.

§ F. V. MÉRAT—*Mémoire sur la Formation de l'Adipocire dans l'Homme vivant*, Mém. de la Soc. Méd. d'Émulation, an. VI, Paris, 1806, p. 400. He says that although in the cadaver all parts of the body may be turned into adipocere, the bile alone contains it in the living animal. Brain tissue or bile digested in alcohol, and then diluted with water, will throw down adipocere in transparent scales. In the liver it occurs in two forms, fatty liver and hepatic calculi; he found it abundant in the white stools of jaundice, and in the fatty stools of a man who died of heart disease. "The adipocere met with in the intestinal canal comes either from the liver or the gall-bladder." Among the causes which favor the development of adipocere in the liver, embarrassment of the respiration, as in phthisis and disease of the heart, plays an important part.

‖ SIR EVERARD HOME—*On the Formation of Fat in the Intestines of living Animals*, Phil. Trans., 1813, Part I, p. 146. Yet it may be remarked that, in one of the two cases communicated by BABINGTON, which his paper contains, the patient was taking olive oil in the dose of two or three ounces at a time, while in the other it is not thought necessary to mention the character of the ingesta.

¶ E. A. LLOYD—*Case of Jaundice with Discharge of Fatty Matter from the Bowels, and a Contracted State of the Duodenum*, Med. Chir. Trans., XVIII, 1833, p. 57—"we were led to infer that it was a morbid secretion of the liver," (p. 62.) JOHN ELLIOTSON—*On the Discharge of Fatty Matters from the Alimentary Canal and Urinary Passages*, Med. Chir. Trans., XVIII, 1833, p. 67; a collection of sixteen cases, of which five, viz: Nos. 9, 12, 13, 14 and 16 had not previously been published. He compares the fatty matters to ambergris, and suggests that their different consistence is simply due to their containing different proportions of elaine and stearine. "The pain at the epigastrium and right hypochondrium experienced in some cases, the jaundice sometimes noticed, the total deficiency of bile in the motions of some of the patients, and the unctuous nature of most biliary concretions,

Meanwhile Kuntzmann (1824) and Bright† (1832) had drawn attention to the existence of notable organic disease of the pancreas in the bodies of individuals who had suffered from fatty evacuations, and similar observations were published by Lloyd and Elliotson,‡ who, however, seem not to have appreciated their significance. These cases were cited by Claude Bernard (1849) and his student Moyse § in support of the theory, previously put forward by Eberle,‖ that the pancreatic juice is the efficient agent in the digestion of fats.

According to Bernard's presentation of this theory, the pancreatic juice has the power, which it alone of the digestive fluids enjoys, of forming an emulsion with the fats, which are absorbed from the intestinal canal in this emulsified condition. Any disease of the pancreas which modifies the quantity or quality of its secretion to such an extent that it is no longer capable of emulsifying the fats, will lead to their appearance undigested in the stools. Bernard succeeded in suspending the pancreatic secretion for a time in two dogs by injecting melted tallow into the pancreatic duct. Both animals passed large quantities of undigested fat in their stools and rapidly became emaciated, although their appetite was voracious. This result appeared to afford convincing experimental proof of the correctness of Bernard's theory of the function of the pancreas and his explanation of fatty discharges from the bowels. Accordingly this theory of the pancreatic function has been accepted by several able physiologists,* and the resulting explanation of fatty discharges has been adopted in various quarters.

---

together with the natural presence of unctuous substances in the bile, may favour the opinion of their hepatic origin," (p. 84.) C. E. REEVES—*On the Presence of Fat in the Excretions*, Edinburgh Monthly Journ. of Med. Sci., XVIII, 1854, p. 201. This paper is particularly rich in references to the literature of the subject, and is the mine from which subsequent writers have borrowed most of their cases. The author discusses the presence of fat in the urine, in the fæces and in vomited matters, and concludes with regard to the fæces that "Fat, as a disease, must, I think, be looked upon as resulting from some change either in the bile itself or from the liver secreting it from the portal vein," (p. 204.) JAMES COPLAND—*Dict. of Pract. Med.*, Vol. I, London, 1858, p. 400; Art. *Intestinal Concretions*. COPLAND gives an explanation which recalls the views of the ancients: "It appears from the history of the cases on record, as well as from those recently observed by Dr. Elliotson and Mr. Lloyd, to be especially connected with disease of the assimilating viscera, and consequently with imperfect assimilation; a portion of the chyle, instead of being changed to healthy blood, assuming an oleaginous state, as not infrequently observed in the serum. The fatty matter thus accumulated in the blood, will, in several states of disease, be eliminated from it by excreting organs—particularly by the mucous surface of the bowels, and by the liver and kidneys—instead of being deposited in the adipose tissue for ulterior purposes," &c.

* KUNTZMANN—*Abgang reines Fettes durch den After*, Hufeland's Journal, LIII, 1821, St. I, S. 106, and LIX, 1824, St. 3, S. 45. The second paper gives the autopsy. A calculus was found in the cystic duct. The pancreas was hardened to a cartilaginous consistence, and was full of whitish, stony concretions of various sizes: its excretory duct was entirely closed. The author distinctly suggests the possibility that the absence of the pancreatic juice may have been the cause of the fatty discharges: "ob dieses durch den Mangel des pancreatischen Saftes bewirkt wurde," etc., (S. 51.) HUFELAND remarks, in a note to this second paper: "This disease, which I myself have also observed several times, represents a new sort of diarrhœa, and I propose to call it *Stearrhœa*." R. BRIGHT—*Cases and Observations connected with Disease of the Pancreas and Duodenum*, Med. Chir. Trans., XVIII, 1833, p. 1—reported three cases of fatty evacuations in which he found on the autopsy "disease probably malignant of that part of the pancreas, which is near to the duodenum; and ulceration of the duodenum itself," (p. 51.) In the same paper he reports a case (No. 6) in which there was scirrhus of the pancreas involving its duodenal extremity, but no discharge of fat. In this case there was no ulceration of the duodenum. He remarks: "I will not even affect to decide, whence the peculiar fatty matter is derived: whether it is to be considered as a vitiated secretion from natural structures, which must here be chiefly mucous membranes; or as a discharge from the diseased and ulcerated parts; or as the product of defective digestion of alimentary matter, depending on the imperfect supply or irregular admixture of the biliary and pancreatic or other secretions, or on the perverted and impeded action of the duodenum," (p. 52.)

† LLOYD'S case is that cited in the last note but one, and ELLIOTSON'S is case 12 in his paper cited in the same note.

‡ CLAUDE BERNARD'S earliest observations (which showed that the fat of the food first begins to be emulsified and absorbed at and below the point of entrance of the pancreatic duct, and therefore much lower in the rabbit than in the dog) were made during the winter of 1846 and communicated to the Academy of Sciences in 1849—*Recherches sur les usages du Suc Pancréatique*, Comptes Rendus, XXVIII, p. 283; see also XXX, pp. 210, 228. They will be found at length in his *Mémoire sur le Pancréas*, Paris, 1856. In this essay he repeats the cases collected by MOYSE (*vide infra*) and cites the case published by ALFRED CLARK [*vide infra*] and one observed by TREMBLAYE, (Recueil des Travaux de la Soc. Méd. d'Indre-et-Loire, 1852.) For his account of the successful experiments on the two dogs referred to in the text, see p. 99 *et seq.* D. MOYSE, *Étude historique et critique sur les Fonctions et les Maladies du Pancréas*, Paris Thesis, (170,) 1852. This essay contains six cases of fatty evacuations with autopsies, viz: BRIGHT'S three cases; LLOYD'S case; ELLIOTSON'S case 12, and a case observed by Drs. GOULD and J. B. S. JACKSON, of Boston, Mass., [see note ‡ to p. 381, *infra*.] MOYSE has been justly reproached with many inaccuracies in his transcript of these cases, [see Med. Chir. Review, July, 1853, p. 163,] which BERNARD, in copying them from him, has not corrected.

§ EBERLE—*Physiologie der Verdauung*, Würzburg, 1834, S. 251—showed by experiment that the pancreatic juice had the power of emulsifying the fats, and suggested this as its principal use in digestion.

‖ J. C. DALTON—*Human Physiology*, 6th Edit., Philadelphia, 1875, p. 175 *et seq.*, also p. 221; AUSTIN FLINT, JR.—*Physiol. of Man; Alimentation*, &c., New York, 1867, p. 342 *et seq.* FLINT cites the observations of BUSCH—*Beitrag zur Phys. der Verdauungsorgane*, Virchow's Archiv, XIV, 1858, S. 140 *et seq.*—as "conclusive" proof of BERNARD'S view that the fats are emulsified by the pancreatic juice alone. The case described by BUSCH was one of intestinal fistula. Fats swallowed appeared at the upper opening of the intestine emulsified; if injected into the lower end, the fats appeared unchanged in the fæces. To argue from this, as FLINT does, is a striking example of the *non sequitur*, since the facts prove as much for the bile as for the pancreatic juice; and I must note that FLINT himself admits elsewhere that "when the bile is diverted from the intestine, the proportion of fat in the chyle is greatly reduced, and a large proportion of the fat taken with the food passes through the intestine and is found in the fæces." (p. 373.)

But notwithstanding all the apparent array of evidence in its favor it would appear that this view of the question is entirely too exclusive. It is admitted on every side that the pancreas enjoys the power, which was attributed to it by Eberle and Bernard, of fitting the fats for absorption; but the investigations of Frerichs, Lenz, Bidder and Schmidt, Lehmann and Colin* would appear to show quite as positively that the emulsifying power of the pancreatic juice is shared by other digestive fluids, such as the intestinal juice, and especially the bile. It has also been shown that if the bile be diverted from the intestinal canal a large portion of the fat of the food passes through undigested and makes its appearance in the stools† very much as in the dogs whose pancreatic secretion was abolished in the ingenious experiments of Bernard.

Moreover, several cases have been reported in which fatty discharges have coexisted with clay-colored stools, jaundice, or both, but in which on the autopsy no pancreatic disease could be discovered.‡ Others are recorded in which extensive disease of the pancreas was found on the autopsy, although fatty stools had not occurred during life; § and even in most of those in which fatty discharges coexisted with disease of the pancreas, as shown by the autopsy, disease of the liver also has been shown to exist, both by the symptoms observed during life, such as clay-colored stools, jaundice or hepatic colic, and the lesions found after

* FRERICHS—Art. *Verdauung* in WAGNER'S *Handwörterbuch der Phys.*, III, Abth. 1, S. 846; E. LENZ—*De Adipis Concoctione et Absorptione*, Dorpat, 1850, p. 45 *et seq.;* BIDDER und SCHMIDT—*Die Verdauungssäfte*, Mitau und Leipzig, 1852, S. 246 *et seq.;* LEHMANN—*Phys. Chemistry*, Transl. of Cavendish Soc., Vol. II, London, 1853, p. 115; COLIN—*De la digestion et de l'absorption des matières grasses sans le concours du fluide pancréatique*, Bulletin de l'Acad. Imp. de Méd., XXII, 1856-7, p. 659. Consult also LONGET—*Traité de Phys.*, 2me Edit., T. I, Paris, 1861, p. 260, and CARPENTER—*Principles of Human Physiology*, 7th Ed., London, 1869, p. 139.

† Thus BIDDER und SCHMIDT [p. 221, *op. cit.*, in last note] found that in dogs with biliary fistulæ by far the largest part of the fat taken as food found its way into the stools. Their experiments are especially valuable, because the *quantity* of fat taken and passed during the time of the experiment was determined by chemical analysis.

‡ PEARSON'S case [No. 13 in ELLIOTSON'S paper, cited *supra* on p. 377] has been cited by EISENMANN [*vide* p. 381, *infra*,] and REEVES [*vide* p. 378, *supra;*] and the latter cites also the case of MÉRAT and three observed by PORTAL, of which, however, only two properly belong here. [See list of cases, p. 381, *infra.*]

§ Besides the cases of this kind which have been recorded since the publication of the views of BERNARD, several observations may be cited in which it is not specially recorded that the stools were examined for fat and none found, but in which the full development of the adipose tissue of the body, mentioned in the account of the autopsies, shows that the fatty matters of the food must have been digested, and therefore that the existence of fatty diarrhœa during life cannot be assumed to have been overlooked. For example, J. G. GREISELIUS—*De Repentina Suavi Morte ex Pancreate Sphacelato*, Ephem. Germ., Dec. I, an. 3, 1672, Obs. 45; DE HAEN—*Opusc. Med. Phys.*, 1780, I, p. 217, [I cite from LONGET'S *Traité de Phys.*, 2me Ed., T. I, Paris, 1861, p. 265.] J. ABERCROMBIE—*Diseases of the Pancreas*, Case XII, Edinburgh Med. and Surg. Journ., XXI, 1824, p. 249; the same case will be found in his *Diseases of the Stomach*, &c., Edinburgh, 1828, Case 143, p. 393; J. DAWIDOFF—*De Morbis Pancreatis Obs. quædam*, Dorpat, 1833, Obs. 2, p. 9; CASPER—*Einiges über den Krebs der Bauchspeicheldrüse*, Wochenschrift f. d. ges. Heilkunde, July, 1836, S. 439. According to LONGET (*loc. cit., supra*) the thesis of BÉCOURT—*Rech. sur le Pancréas*, Strasbourg, 1830, contains several similar cases. To these I may add Case 6, in the paper of BRIGHT, [cited on p. 378, *supra.*] Since BERNARD'S views were published the stools have been examined for fat, but none found in a number of cases of disease of the pancreas. Two of these were reported by H. FEARNSIDE—*Illustrations of Pancreatic Disease*, London Med. Gazette, XI, 1850, p. 967. BERNARD has objected [p. 116, *Mémoire sur le Pancréas*, cited on p. 378, *supra*] that these were cases of acute disease of the pancreas, and that as patients do not usually eat fatty matters in acute diseases, these would not be likely to occur in the stools; I observe, however, that one of FEARNSIDE'S patients had been sick a year and the other two years, and am disposed to think with that gentleman that probably the "disease of the pancreas must have been long in progress." No such objection, however, can be made to such cases as the following, in which cancer of the pancreas was found on the autopsy, while the stools were vainly examined for fatty matters during life: D. R. HALDANE—*Cancer of the Pancreas*, Edinburgh Monthly Jour. of Med. Science, XIX, 1854, p. 77; J. S. BARTRUM—*Case of Scirrhus of the Pancreas and Stomach*, Association Med. Jour., 1855, p. 564; WILKS—*Colloid Cancer of the Pancreas*, Trans. of the Path. Soc. of London, VI, 1855, p. 224; J. M. DA COSTA—*Primary Cancer of the Pancreas*, Proc. of the Path. Soc. of Philadelphia, (1857,) Vol. I, 1860, p. 8; CRISP—*Scirrhus Enlargement of the Pancreas*, Trans. of the Path. Soc. of London, XIII, 1861-2, p. 124; WARD—*Two Cases of Cancerous Disease of the Pancreas*, The Lancet, July, 1863, p. 66; J. B. M. BESSON—*De Quelques Faits Path. pour servir à l'Étude du Pancréas*, Paris Thesis, 104, 1864—2 cases; S. W. GROSS—*Primary Cancer of the Head of the Pancreas*, (1869,) Proc. of the Path. Soc. of Phila., Vol. III, 1871, p. 94; C. B. NANCREDE—*Cancer of the Pancreas*, (1870,) *op. cit.*, Vol. III, p. 158; TARBELL—*Cancer of the Pancreas*, Boston Med. and Surg. Jour., June, 1872, p. 371. These cases might be multiplied if necessary, but the above are sufficient to illustrate the point under discussion. The number of cases of cancer or other chronic organic disease of the pancreas in which the record makes no statement as to the presence or absence of fat in the stools is quite large. Whatever other uses these incomplete observations may serve, it is not logical to appeal to them on either side of this question, for the possibility of oversight cannot be denied. Thus MEISSNER—*Ueber Krebs*, in SCHMIDT'S *Jahrb.*, 1873, Bd. 158, S. 306—cites four cases of cancer of the pancreas in which he says: "The early opinion that oily stools result from diseases of the pancreas was not corroborated." I note, however, that in one of these cases, that of WEBB, [see note, p. 381, *infra*,] oily stools did follow the use of fatty food, while in the three others the original record does not state whether the stools were fatty or not, viz: CHVOSTEK—Wien Med. Wochenschrift, XXII, June, 1872, p. 552; F. H. GROSS—Phil. Med. Times, June, 1872, p. 354, and LUITHLEN—*Memorabilien*, XVII, 1872, 7, p. 309. The reader desirous of studying the general subject of cancer of the pancreas should consult the Thesis of ANCELET—*Essai sur l'Anat. Path. du Pancréas*, Paris Thesis, No. 274, 1856—which gives references to 171 cases of cancer of the pancreas in literature, besides 5 observed by the author; and the later work of the same author—*Études sur les Maladies du Pancréas*, Paris, 1864—in which the number of such cases is increased to 200, in five of which, only, fatty stools are recorded, (p. 74;) also the paper by Dr. J. M. DA COSTA—*Cancer of the Pancreas*, Proc. of the Path. Soc. of Philada., (1858,) Vol. 1, 1860, p. 109—in which 37 cases of cancer of the pancreas are analysed, (with references.) I believe my notes in connection with this subject include all the cases referred to by these authors in which the presence or absence of fat in the stools is definitely noted.

death, such as cancer, gall-stones, obstruction of the common duct, distention of the biliary passages, and the like.*

A consideration of these circumstances would seem to indicate that disease of the liver may play an important part in the causation of fatty diarrhœa; but other observations can be brought forward to show that this symptom may occur during disorders in which the functions of digestion or absorption are impaired, although there is no recognizable disease of either the liver or pancreas. Thus Prout† observed fatty stools in a woman whose only abdominal disease was ulceration of the large intestine. Gull ‡ saw them in the case of a child laboring under strumous disease of the mesenteric glands, in whom, on the autopsy, both the liver and the pancreas were found to be healthy. Bidie § has described a species of acute diarrhœa occurring among soldiers in India, in which he found fatty bodies in the stools. Simon, Heinrich and Bouchardat || have called attention to the occurrence of fatty stools in patients suffering with diabetes mellitus. Heinrich observed the same condition in phthisis pulmonalis. Zimmermann ¶ saw fatty concretions the size of beans, or larger, in the stools of typhoid fever. Lauder Lindsay observed both solid and fluid fat in the dejecta of cholera,** and Widerhofer†† asserts that fatty stools are of common occurrence in the chronic intestinal diseases of children, especially in intestinal tuberculosis.

It would appear, therefore, in a general way that any morbid condition which interferes either with the digestion or the absorption of the fatty matters of the food may be followed by the appearance of the undigested fat in the stools, if the patient continues to take the usual proportion of this substance in his food. Moreover, as has been shown by Ancelet,‡‡ if an excess of fat, beyond the digestive powers of the individual, be swallowed by a perfectly healthy person, the excess will be passed undigested with the stools. The occurrence of fatty dejections is therefore related on the one hand to the capability of the individual for digesting and absorbing fat, on the other to the quantity of fat ingested.

---

* This happened in the cases reported by KUNTZMANN, BRIGHT, (3 cases,) LLOYD, ELLIOTSON'S case 12, EASTCOTT, GOULD and JACKSON, GREENE, the catalogue of St. Bartholomew's Hospital, CLARK, MARSTON, MARCET, HARLEY, ROQUES, SIMPSON, WEBB and BOWDITCH. [See list of cases on next page.] The only cases I have been able to find of fatty diarrhœa with disease of the pancreas, in which the liver was not evidently involved, are the case of TREMBLAYE, cited by BERNARD, and the case of SILVER. In the first there was no jaundice during life; the stools were dark colored; and on the autopsy the liver was found healthy, but there was chronic inflammation and thickening of the coats of the stomach and duodenum. In SILVER'S case there is no record of the condition of the liver or of any organ but the pancreas.

† PROUT—case 14 in ELLIOTSON'S paper, cited on p. 377, *supra*.

‡ GULL—see paper cited in list of cases, *infra*.

§ GEO. BIDIE—*Account of a Species of Diarrhœa, in which the Stools contain Fatty Corpuscles*, Edinburgh Med. Jour., III, 1857–8, p. 149.

|| The coexistence of fatty stools with diabetes had previously been noted by various authors, as BRIGHT and ELLIOTSON, (in their papers cited *supra*.) SIMON—*Animal Chemistry*, Transl. of Syd. Soc., London, 1846, Vol. II, p. 377—analyzed the stools in a case of diabetes. The fæces amounted to 18.5 oz. daily, containing 2 oz. of fat. The patient was taking 2 oz. of cod-liver oil daily, besides meat and eggs, &c., the quantity of fat in the food not being determined. SIMON gives, in the same place, other analyses of the fæces of diabetes, the value of which is impaired by the fact, that although the percentages show an abnormal proportion of fat in the stools, yet neither the total quantity passed daily nor the quantity of fat in the food is stated. HEINRICH—*Fäcalmaterien in Krankheiten*, Haeser's Archiv, VI, 1844, p. 306—gives one case of diabetes and two of consumption with fat in the stools. See also BOUCHARDAT—*De la Pimélorrhée*, Annuaire de Thérapeutique, 1851, Supplement, p. 268. It has been suggested that an atrophy of the pancreas or diminution of its secretion occurs in these cases; and indeed in ELLIOTSON'S case [No. 12 in paper cited *supra*] the pancreas was shown to be diseased on the autopsy; but it must also be noted that a diminution in the secretion of the bile, as indicated by the clay-colored stools, is a prominent feature in most of these cases.

¶ G. ZIMMERMANN—*Eigenthümliche Concretionen in den Stühlen von Typhuskranken*, Deutsche Klinik, 1853, p. 278. This author noticed yellowish-white masses of various sizes in the stools of typhus (*i. e.*, typhoid) patients, and finally selected a case for more exact examination. In this case the concretions were rounded or oval, in size from that of beans to that of hazel-nuts or larger. On chemical examination they proved to consist largely of water, 1,000 parts giving only 237.8 of dry residue; of this 63 per cent. was composed of fat and fat acids, the rest of albuminates and inorganic matter. Under the microscope the author found, besides fat drops, cells and nuclei such as are usually observed in the intestinal contents. SIMON has described a somewhat similar concretion "resembling caseous matter" from a lady suffering from hepatic disorder—*Animal Chemistry*, Transl. of Syd. Soc., London, 1846, Vol. II, p. 385.

** W. LAUDER LINDSAY—*Cases of Cholera; illustrative of the Presence of Fat in the Fæces, &c.*, Edinburgh Monthly Jour. of Med. Sci., XIX, 1854, p. 125—"It thus appears that, in the four preceding cases, fatty matters were found in the fæces on seven different occasions. In five of these they occurred in a solid form, resembling pieces of tallow or suet; in two as a fluid oil." (p. 132.)

†† WIDERHOFER—*Semiotik des Unterleibes*, Jahrb. für Kinderheilkunde, IV, 1870–1, S. 261.

‡‡ E. ANCELET—*De l'Indigestion des Graisses*, Gaz. des Hôpitaux, 1860, pp. 463 and 466. An excellent article, in which the reader will find references to a great deal of the literature of the subject. ANCELET gave 100 grammes of olive oil to a healthy man. Three liquid stools resulted containing an oily substance. ELLIOTSON [paper cited *supra*] observes that castor oil given medicinally is frequently recognized in the stools.

Eisenmann* has revived the old belief that, in some of these cases, the quantity of fat passed is greater than the quantity ingested, and that it must, therefore, in some way be derived from the patient himself, and not merely from his food. He has brought forward once more the opinion of the ancients that the fat of the body may be reabsorbed and excreted from the intestines, and suggested also the possibility of a transformation in the alimentary canal of a part of the starch of the food into fat, as Everard Home† had thought possible in the case of the albuminoid matters. It must be confessed, however, that definite observations in support of any such opinion are wanting.

Whoever peruses the published cases of fatty stools, to which references are given in the foot-note,‡ will not fail to be struck with the absence of any precise determination either of the actual quantity of fatty matters passed, or of the quantity of fat ingested during the same time. In the majority of these cases the quantity of fatty matter passed appears to have been estimated almost as loosely as in one of the cases of Tulpius, who tells us that the amount passed during the patient's illness was so great that it would no doubt have filled several little vessels if any one had collected it; and in the few instances in which an estimate of the quantity passed daily has been recorded, it appears to have been only

* EISENMANN—*Zur Path. des Pankreas*, Prager Vierteljahrschrift für die Prakt. Heilkunde, 1853, Bd. IV, S. 73. This writer, like MOYSE, was a student of BERNARD, and his essay contains abstracts of the same cases MOYSE collected, with the addition of the case of LUSSANA. [See list of cases below.] EISENMANN, however, was so far from accepting BERNARD'S view, that he gives a case of his own, in which no fatty matters were found in the stools, as an illustration of pancreatic disease. He cites the cases of PEARSON, (ELLIOTSON'S case 13,) SCOTT and TULPIUS, [see list of cases *infra*,] as instances in which the quantity of fat passed was greater than could probably have been derived from the food, and suggests that its origin may be either a transformation in the alimentary canal of a part of starchy articles of food into fat, or a reabsorption of the fat of the body and its subsequent excretion. BOUCHARDAT [in paper cited on the last page] also thinks the quantity of fat passed larger than could have been derived from the fat of the food, and thinks the excess is formed by the transformation of the feculent articles of diet. He tells us that in his case he diminished the amount of fat eaten by the patient as much as possible, and that the quantity of fat subsequently passed was greater than the amount of fat contained in the food taken. This appears, however, to be an entirely conjectural statement, as no figures are given.

† HOME—see paper cited on p. 377, *supra*.

Journal, II, 1865, p. 269; LANGDON DOWN—*Case of fatty diarrhœa treated by pancreatic extract*, Trans. of the Clinical Soc. of London, II, 1869, p. 119; ALEXANDER SILVER*—*Fatty degeneration of the pancreas*, Trans. of the Path. Soc. of London, XXIV, 1873, p. 121. In this case the condition of the liver and other organs is not recorded. W. H. WEBB*—*Scirrhus of the head of the pancreas*, Philada. Med. Times, Dec., 1871, p. 86. In this case fatty stools occurred twice

an estimate, and sometimes the estimate of the patient rather than of the physician.* In none of the cases does the quantity appear too great to have been derived from the food, and until some case is produced in which exact determinations of the quantity swallowed and voided by stool show that the latter is really greater than the former, there seems no ground for believing that such fatty discharges have any other source than the food.

Nor has the chemical analysis of the fat discharged in these cases produced any facts incompatible with this view. So long as this examination went no further than melting and burning the substance investigated, the peculiarities of color and consistence observed in some of the cases might seem to warrant the supposition that a new form of fat had been produced unlike the fat of the food; but the more modern analyses by Brande, Bergemann, Prout, Zimmermann, Simon and Marcet,† of the fatty matters passed in similar cases, would seem to show that they possess no characters which cannot be accounted for by a consideration of the various kinds of fat ingested, and of the admixtures and partial decompositions to which it is subjected in the alimentary canal.

---

when fatty food was given. BOWDITCH*—*Fatty dejections for four years; Cancerous disease of the pancreas and liver*, Boston Med. and Surg. Journal, July, 1872, p. 65. In this case the patient had "used much fatty food" by the advice of her physician. She was ordered to avoid fat, and the stools "became copious, rather dark, with small masses of white substance merely, but no positive fat." To the foregoing I may add the following from catalogues of museums: *Catalogue of Anat. Mus. Univ. of Edinburgh*, 1831, p. 73, "I, 119—A quantity of substance resembling spermaceti, passed by a female who had a concretion in colon. Steatrhœa?" I, 122—Same description. *Catalogue of the Warren Anat. Mus.*, by J. B. S. JACKSON, Boston, 1870, p. 488, No. 2320—"Fat, discharged from the bowels of a man æt. 45," &c.; case of Dr. H. K. Oliver. *Path. Catalogue of the Museum of Guy's Hospital—Organs of Digestion*, London, 1857, p. 76, "1893[50]—Numerous masses of fat observed in the evacuation of a patient who suffered from jaundice. Patient under Dr. Bright's care in Job ward. John W., 1835, 1836," p. 115, "1989[50]—Cancer of the pancreas. A case of fatty stools. Mary G." These two cases were observed by Dr. BRIGHT subsequently to the three cited above.

* Of the cases cited by EISENMANN [see note * to p. 381, *supra*] as examples of a greater quantity of fat discharged than could have been derived from the food, that of TULPIUS has been disposed of in the text; in PEARSON'S case [No. 13 of ELLIOTSON'S paper cited on p. 377, *supra*] the quantity passed is stated to have been 2½ oz. of fat and a third of an ounce of oil daily; in SCOTT'S case [see last note] it is simply stated that "fatty substances, in great numbers, about the size of nuts, beans, pease, &c.," were passed. GRISCOM [p. 180 of paper cited in the last note] alludes to a case in which thirty pounds of fat were vomited in the course of a single day, in support of the same view. This is the case reported by GIOVANNI PASQUALI—*Descrizione di un vomito copiosissimo di adipe e sangue*, Annali Universali, XXXVII, Milan, 1826, p. 49—an abstract of which will be found in Johnson's Med. Chir. Rev., July, 1826, p. 247, and in the papers of ELLIOTSON and REEVES, [cited *supra*;] but it may be remarked that in this case the author does not state that thirty pounds of fatty matter were vomited, but this quantity, which was estimated, is affirmed of the total quantity of fluid vomited, including blood, &c. How much of this was fat is not stated. The attack came on after eating to excess; but what was eaten on this particular occasion is not specified, though we are informed the patient was in the habit of feasting during the day and at night, eating hastily large quantities of cold pudding, beans, pork-sausage and salad, (the latter with oil, of course.) In this connection, also, I may refer to the case of HOWSHIP, [see previous note,] in which we are told that "an astonishing quantity" of fat was passed; but as this was the consequence of taking "as much as a pint" of olive oil, it is not surprising. In another case of PEARSON'S [No. 16 in ELLIOTSON'S paper] it is stated that the quantity of fatty matter passed averaged about an ounce and a half daily. In the case reported by HILDANUS [see last note] it is affirmed that the woman discharged above three pounds of fat; but this was during the whole attack, and supposing the quantity to have been exactly determined, there is nothing to show how long it had been in accumulating. In one of BABINGTON'S cases [reported in E. HOME'S paper, see last note] a girl 4½ years old voided from one to three ounces of fat at intervals of 10 or 14 days. In GOULD and JACKSON'S case [see last note] the quantity is stated to have been on an average half a pound daily for six weeks; but this is merely the statement of the patient, who asserted also that he had no discharge of fat except after eating meat or articles cooked in fat; this we are gravely told his wife contradicted. In CLARK'S case [see last note] the quantity passed was usually "about three or four ounces daily, as nearly as we could guess." The greatest quantity on any day "must have amounted to eight or nine ounces." In the case of WELLS [see last note] the quantity was estimated at three gills daily, and in GRISCOM'S case [see last note] about 2½ oz. daily. In none of these cases was it thought worth while to attempt to determine the quantity of butter and other fats ingested, and yet this is the key to the interpretation of such cases. The daily quantity of fat required as food by a male adult, 5 ft. 6 in. to 5 ft. 10 in. in height and weighing 140–160 pounds, is estimated by MOLESCHOTT [I quote from PARKES' *Hygiene*, 3d Ed., London, 1869, p. 163] at about three [2.964] ounces; but this it is well known far understates the actual consumption in many cases. It must be added that most of the cases are also open to the suspicion that, in estimating the quantity, other substances than fat were included; in some of them it is even possible that what was supposed to be fat may have been of an entirely different nature; thus CHAMBERS—*Digestion and its Derangements*, Amer. Ed., New York, 1856, p. 129—tells us that "one example, which has been preserved with great care in the museum of the College of Physicians, turned out, when the museum was put to rights in 1850, not to be fat at all. In fact, microscopic examination showed it to be muscular fibre—a lump of meat washed white in its passage through the bowels of a dyspeptic patient."

† BRANDE [in EVERARD HOME'S paper cited on p. 377, *supra*] examined the translucent wax-like globules, varying in size from that of a pea to that of a grape, which were passed in one of BABINGTON'S cases, and found that they were composed of "olive oil combined with mucus: the latter separated during putrefaction, and the oil was evolved, apparently unaltered." BERGEMANN made a very thorough examination of the fat passed in KUNTZMANN'S case, [cited above on p. 378.] He found it composed of two kinds of fat; one solid at the ordinary temperature of the air (stearine) which, after FOURCROY, he calls adipocere (also Feltstoff) and a fluid oil, (oleine.) When the fatty matter was dissolved in hot alcohol it formed a yellow solution from which the stearine separated on cooling. The proportion of the two substances was very similar to what exists in beef marrow. PROUT examined the fatty matter in several of ELLIOTSON'S cases, [see p. 83 of paper cited *supra*,] and it was doubtless under his inspiration that the latter wrote: "Chemists consider that animal oils are composed of two substances, the one solid and called Stearine, the other fluid and called Elaine, the various proportions of which to each other occasion the different consistence of different oily matters. Upon this diversity of their proportion, therefore, must, I presume, depend the diversity in the consistence of these discharges." In ZIMMERMANN'S analysis of the fatty bodies passed in typhoid fever [see paper cited on p. 380, *supra*] he found margarine. SIMON—*Animal Chem.*, Transl. of Syd. Soc. of London, 1846, II, 386—found margarine, combined with oleine, butyrin and their acids, in a fatty lump passed by a lady who was suffering from bilious sensations. MARCET [paper cited in list of cases *supra*] found bistearate of soda, oleic and margaric acids in the discharges of a patient in whom there was malignant disease of the pancreas, which "apparently so compressed the duct of the gall-bladder that no bile could flow into the intestines." He explains the presence of these bodies by the exclusion from the intestines of the alkaline bile and pancreatic juice, so that "the fatty acids contained in the alimentary canal could not be neutralised."

Monti* has demonstrated the abundant presence of fatty matters in the normal stools of sucking infants, its source being simply the milk which has escaped complete digestion, and there can be no doubt that in dysenteric and typhoid patients, supported on a milk diet, it sometimes happens that the quantity administered is greater than the enfeebled digestive organs can dispose of, and that various forms of fatty matters in the stools, among others fatty concretions of various sizes and consistence, are occasionally derived from this source. I have, myself, several times observed a characteristic form of such concretions in dysenteric patients nourished on milk, especially in chronic cases. These concretions are whitish or yellowish-white internally and of a somewhat cheesy consistence. Externally they are apt to be greenish or brownish, except when the stools are devoid of bile pigment; they melt and burn like fat, but on chemical examination usually prove to have a substratum of coagulated casein in which the fat molecules from the milk are entangled.†

THE TORMINA AND TENESMUS.—The tormina, or griping pains, which accompany dysentery are due to spasmodic contractions of the muscular coat of the inflamed intestines. In their general character, and especially in the circumstance that they come on in paroxysms, with intervals of ease between, these pains resemble those produced by the spasmodic contraction of other layers of non-striated muscular tissue, as, for example, the paroxysms of hepatic and nephritic colic and the uterine pains of labor. The normal peristaltic contractions of the intestinal muscular coat take place without consciousness, but unnaturally violent contractions become painful in proportion to their violence, even when the coats of the intestine are quite healthy, as is well illustrated by the gripings of flatulent colic. Whether in dysentery the inflamed condition of the intestine merely serves to determine violent contractions of the muscular coat, or whether, besides, the sensibilities of the inflamed intestine are abnormally excited, as in the case of external inflammations, so that a given degree of intestinal contraction produces greater pain than it would do if the intestine were not inflamed, is a matter of some uncertainty, but analogy seems to favor the latter view.

The seat of the painful contractions is very generally some part of the colon. Painful contractions of the small intestine, especially of the ileum, are, however, common enough. When the griping has its seat in the colon, it is very apt to be promptly followed by the stool which gives it temporary relief. When it has its seat in the small intestine, it seems reasonable to suppose that some little time would elapse before the stool should follow. The Greek physicians,‡ therefore, believed that the seat of the pain, and the time which elapsed before it was followed by a stool, were symptoms of importance in diagnosticating the part of the intestine which was ulcerated in dysentery. If the pain were at the umbilicus or above it, and if some time elapsed before it was followed by a stool, it showed that the small intestine was ulcerated. If the pain were lower down and promptly followed by

* MONTI—*Ueber die Veränderungen der Dejectionen im Säuglingsalter, etc.*, Jahrb. für Kinderheilkunde, Bd. I. N. F. 1867-8, S. 299. This author, whose statements on this subject I have several times been able to confirm, finds the normal stools of sucking infants constantly contain flocculi of coagulated casein and molecular fat from the milk, (Milchdetritus.) He gives a simple chemical method for these examinations.

† I may add that I have several times seen very similar masses, sometimes of considerable size, vomited by typhoid and dysenteric patients on milk diet; that I strongly incline to the opinion that the presence of an abnormal quantity of fat in the stools is far more common than has generally been supposed, and that I am disposed to believe that the views expressed by the intelligent reviewer of Dr. BRIGHT'S paper are substantially correct. See Med. Chir. Review, XX, 1834, p. 9: "From no very limited field of experience, we can safely say that the phenomena in question—the fatty substances in the evacuations, so far from being a rare, are, on the contrary, a very common occurrence or symptom, in disordered states of the alimentary canal. There is scarcely a day in the week, on which these "fatty substances" are not brought to us by patients, in bottles or in cups, as strange phenomena, and not less terrifying than strange—to them."

‡ This doctrine was most clearly set forth by ALEXANDER of TRALLES. See note † to p. 362, *supra*.

a stool, the ulceration was seated in the large intestine. Both these symptoms, however, so far as they possess any real significance, would point to the seat of the spasmodic contraction or griping, rather than to the seat of the ulceration. Thus, in typhoid fever with extensive ulceration of the small intestine, a catarrh of the colon may coexist accompanied, even if the colon is not ulcerated at all, by spasmodic contractions of its muscular coat promptly followed by stools. But in view of the varying position of the transverse colon, and especially in view of its frequent displacements in dysentery, it is also evident that pain arising from spasm of its muscular coat may be referred either to the umbilical region, or above, or below it. Moreover, the occurrence of a stool sooner or later after the griping pain must depend not only on the seat of the griping and its intensity, but also on the quantity and character of the intestinal contents. It is therefore clear that no very positive indications can be drawn from the considerations indicated.

With the tormina a certain degree of tenderness on pressure along the track of the colon is often associated. This is usually of a moderate character, but often sufficient to enable the physician to determine the position of the transverse colon with considerable certainty, and thus occasionally to recognize during life those displacements of the transverse colon downward which have been described by Annesley.* A high degree of tenderness usually indicates peritonitis, and may be limited to a single spot, or widely diffused in accordance with the extent of the peritoneal affection.

The *tenesmus* has already been commented upon † and its diagnostic value discussed. It consists essentially in an exaggeration of the reflex expulsive efforts by which the bowels are normally evacuated; and is painful in proportion to the violence of the contractions to which the muscles are goaded. In the healthy state these reflex expulsive efforts are conditioned by the accumulation of a certain quantity of fæcal matter in the sigmoid flexure and rectum; but when the mucous membrane of these parts is inflamed, its irritability is increased to such a point that the stimulus of a very small quantity of the altered intestinal contents is sufficient to provoke violent efforts. Moreover, since these morbid excretions are in a condition of intense molecular movement, (commencing putrefaction,) they undoubtedly possess acrid irritating properties, as is well illustrated by the readiness with which they produce excoriations of the skin about the anus, and this circumstance must add to their capacity for provoking intense expulsive efforts.

Towards the close of fatal cases it frequently happens that the irritability of the expulsive muscles becomes quite exhausted, so that these painful efforts are no longer possible. And for a similar reason, or because the muscular coat of the diseased intestine becomes paralyzed, as the sphincter ani often does during the last few days of the disease, the tormina cease. Baglivi‡ supposed this cessation of pain to result from mortification of the bowel, and therefore to be a fatal symptom. Undoubtedly cessation of pain in the last stage of the dysenteric collapse is usually a precursor of death; but the notion that it necessarily depends on sphacelus of the intestines is not supported by pathological anatomy. With the tenesmus a burning sensation in the anus, a sense of weight and dragging in the pelvis, and a dull aching pain in the sacral region are very frequently associated.

---

*JAMES ANNESLEY—*Diseases of India*, London, 1828, Vol. II, p. 89, Chap. 3, Sect. 3, Sub-sect. 1—"Of Elongation and unnatural Positions of the Colon." See also Plates 14, 15, 23, 24, 25, 26, 27, 28, 29 and 30 of this work.

† Pages 337-8, *supra*.

‡ G. BAGLIVI—*De Prax. Med.*, Lib. I, Cap. IX, Lyons, 1699, p. 77—"Those who die of dysentery, almost all die from sphacelus of the intestines. It appears at least three days before death; the extremities begin to grow cold, the pulse is slow and inequal, thirst is no longer urgent, nor is there pain in the affected place; and some a few hours before death sink into delirium."

PROLAPSUS ANI AND PERINEAL ABSCESS.—The intense expulsive efforts very frequently induce more or less prolapsus ani;* and this not merely in children, among whom it undoubtedly occurs most readily, but also in adults. There are no means of ascertaining the frequency of this complication during the late war,† but it was frequently mentioned by those who had the treatment of dysenteries under their direction. No case was reported during the war in which the protruded part sloughed off, an accident which has been known to occur in some rare instances.‡ Occasionally, by the extension of the inflammation from the rectum to the surrounding areolar tissue, periproctitic, or perineal abscesses are developed in dysentery, and this is probably most likely to occur in patients who have previously suffered from hæmorrhoids. In diphtheritic dysentery such abscesses may take on a gangrenous character, and extensive sloughing of the perinæum may occur before death;§ occasionally such abscesses give rise to fistula in ano.

STRANGURY AND VESICAL TENESMUS.—The occurrence of strangury during the progress of dysentery is mentioned by Hippocrates|| in his account of the epidemics of the island of Thasus, and this complication has attracted the attention of the majority of writers on dysentery since his time. It results on the one hand from the concentrated character of the urine, which is generally scanty, of high specific gravity and decidedly acid reaction, and on the other hand from a hyperæmia or actual inflammation of the vesical mucous membrane, especially in the vicinity of the neck of the bladder. In the first condition the urine acts as an irritant to the morbidly sensitive mucous membrane and provokes violent vesical expulsive efforts, a true vesical tenesmus, or spasmodic contractions of the vesical sphincter, which may even determine retention of urine and require catheterization for its relief. Vesical hyperæmia or inflammation, when it occurs, appears to depend primarily on extension by continuity from the rectum, which is favored by the peculiar arrangement of the hæmorrhoidal and vesical bloodvessels.¶ Once established, the inflammation may pursue an independent course, and may even progress beyond the bladder, involving the mucous membrane of the ureters as far as the pelves of the kidneys.**

The milder degrees of vesical catarrh are indicated by an increase in the quantity of mucus in the urine, accompanied by the appearance of a few corpuscles resembling the white corpuscles of the blood, (mucous corpuscles.) When it acquires greater intensity, a stringy mucus or muco-pus comparatively rich in corpuscles is passed, or the mucus may

* This complication of intestinal fluxes was known in the Hippocratic era; see *Prorrhetics*, Lib. II, § 23, [Ed. Littré, IX, p. 55,] where it is said to occur in those who, having hæmorrhoids, are seized with diarrhœa, in children who suffer from chronic dysentery, and in certain old persons.

† In the new form of sick report adopted for our army in 1862, Prolapsus Ani did not appear, the cases being embraced under the head of others of this order, Digestive Organs. This change, however, is of very little moment for the purposes of the present inquiry, since the cases of prolapsus ani, reported as such on the sick report, are not usually dysenteric, but due to other diseases, as hæmorrhoids, &c. Thus, in Table C, Vol. I, Med. Hist., p. 638, 366 cases of prolapsus ani are reported without any deaths; and it appears from Table CI, p. 647, and Table CXII, p. 717, that prolapsus ani was alleged as the cause of discharge from the service in the case of 325 white and 7 colored soldiers.

‡ Such a case will be found in the Philadelphia Med. Museum, Vol. IV, 1807–8, p. 55—*Case of Prolapsus of the Colon, terminating in Death. With the appearances on dissection;* By Dr. WM. RUNKEL. A laborer, aged 23, "had for some days laboured under a diarrhœa, accompanied with tenesmus." "A few hours before I saw him, the colon had come down to the length of nine or ten inches; and by the time I saw him, it was in a high state of inflammation and swelling; there being no possibility of reducing it, I ordered," etc., etc. "On, or about the eighth day, some part of the colon became sphacelated, and on the tenth sloughed off, a small ragged part remaining. The part that had come away, measured 24 inches in length." The patient died on the 17th day. On the autopsy he found "the arch of the colon very much distended, and also in a high state of inflammation; and an abscess in the coats of the rectum, with some sphacelation in the lower part of the colon." Compare note § to page 362, *supra*.

§ In particular I recall the case of a gentleman, 62 years of age, who died of diphtheritic dysentery in the fifth week of the disease, in the year 1870. In this case a sloughing abscess made its appearance on the left side of the anus about ten days before death, and formed ultimately, by the partial separations of the sloughs, a cavity large enough to receive an egg. The surface of the gangrenous patch extended upon the left buttock, and was as large as the palm of a man's hand. The patient, who was a large man and otherwise in robust health when taken sick, had long been a martyr to hæmorrhoids. ANNESLEY—*Diseases of India*, London, 1828, Vol. II, pp. 292 and 294—mentions prolapsus ani as a troublesome symptom in dysentery and speaks of the occasional formation of abscesses in the vicinity of the anus.

¶ See the account of the hæmorrhoidal and vesico-prostatic plexus of veins in GRAY'S *Anat.*, 2d Amer. Edit., Philada., 1862, p. 475.

** FINGER—*Die epidemische Ruhr*, Prager Vierteljahrschrift für die prakt. Heilkunde, IV, 1849, S. 141.

disappear and be replaced by pus, which collects as a sediment when the urine is allowed to stand; but these more intense vesical inflammations are comparatively infrequent.

Vesical tenesmus or strangury may accompany any case of dysentery, whether mild or severe. In some epidemics, indeed, they have been known to occur to the extent of suppression of urine in every case;* but usually the intensity of the vesical symptoms bears some relation to the severity of the dysentery, and hence they are more apt to be troublesome in the diphtheritic form of the disease, while the milder forms of simple inflammatory dysentery sometimes escape the vesical complication altogether. These symptoms may occur at any time after the dysentery is fully established. The latter part of the first week is a common period for their appearance, which, however, may be postponed to the second or the third week, or even later. When mild they often yield promptly to remedies which dilute the urinary secretion and render it less acid; in the severer cases they often persist until convalescence or the final collapse. The same continuity of tissue which favors the development of vesical inflammation in men may give rise in women to catarrhal or even diphtheritic inflammations of the vaginal and uterine mucous membrane.†

The Urine.—As already mentioned, the urine is usually scanty and preternaturally acid. The first circumstance often determines a sediment of urates when it cools; the latter produces the formation of crystals of free uric acid. The occasional presence of mucus, muco-pus and pus from the inflamed mucous membrane of the urinary passages has also been noted. No other abnormities are generally encountered. Albumen is sometimes observed in the urine in intense diphtheritic cases, as occurs also in diphtheria of the throat,‡ but usually when albumen occurs in the urine of a patient suffering from acute dysentery it will be found that he has previously presented symptoms of chronic kidney disease.

Treitz,§ in his essay on the intestinal affections that occur in chronic kidney disease, from the irritant action of the carbonate of ammonia formed in the intestine by the decomposition of urea, which, when the kidneys fail to act is excreted by the intestinal mucous membrane, has suggested that this condition is probably a frequent cause of dysentery, and that, especially in those cases which practitioners ascribe to catching cold, it may be supposed that some affection of the kidneys is the primary lesion. This supposition, which is a purely speculative one, has been sharply criticised by Zimmermann,‖ who,

* See Report of Assistant Surgeon E. Coues, *supra*, p. 63, where this statement is made of the dysenteric cases which occurred at Columbia, S. C., in the fall of 1868.

† Finger, p. 141, *op. cit.*, on last page.

‡ Heubner—in *Archiv der Heilkunde*, XII, 1871, S. 436—states that he did not find albumen in a single one of his cases at Leipsic; but it must be noted that no severe diphtheritic cases occurred among them.

§ Treitz—*Ueber urämische Darmaffectionen*, Prager Vierteljahrschrift, Bd. 64, 1859, S. 143—after describing these lesions in extenso, remarks: "Having been convinced of these facts, the suspicion is aroused that in other forms of dysentery also, especially those which the practitioner willingly ascribes to catching cold, we have to do in the first place with disease of the kidneys. Also, in the epidemic occurrence of dysentery, attention should be directed first of all to the urinary functions. I remember right well some details of the dysentery epidemic which prevailed in Prague in the years 1846 and 1847. Cases were then seen in which the disease ended fatally within three days in the strongest individuals, and in which the common appearances of inflammatory dysentery were not encountered, but sloughing, gangrene and perforation of the intestinal coats quite in the manner in which they occur sporadically in Bright's disease," (p. 195.)

‖ G. Zimmermann (Stabsarzt)—*Zur Lehre vom dysenterischen Process, namentlich über die Betheiligung der Nieren an demselben*, Deutsche Klinik, 1860, S. 407, 415, 426 u. 438—divides dysentery, in accordance with the condition of the kidneys, into four categories. In the first, comprehending the great majority of the cases which terminate in recovery, there is no kidney complication. In the second group of cases the dysenteric symptoms are severe, but for some time uncomplicated; afterward, however, the stools become putrid, "status nervosus, collapsus," and paralytic symptoms set in, accompanied by albumen and casts in the urine; these cases terminate either fatally or in recovery: in the latter event the urine regains its normal characters before convalescence occurs. In the third group of cases the dysenteric symptoms are still more violent at the beginning, and the putrid stools, collapse and paralytic symptoms, accompanied by albumen and casts in the urine, set in very early; these cases speedily terminate in death, and on the autopsy the kidneys are found in the first stage of Bright's disease. In the last group of cases, which may be designated "paralytic" dysentery, putrid stools, collapse and paralytic symptoms are present from the very first; the urine from the very beginning contains albumen and casts; in some cases there is complete suppression of urine, and cramps in the calves occur as in Asiatic cholera; these cases generally terminate fatally, and the kidneys are found exceedingly hyperæmic with the urinary tubules filled with casts, ("die Nierenkanälchen angefüllt mit Exudat, Zellen und Detritus.") But even these cases sometimes terminate favorably; before the violent symptoms have lasted very long, they begin to moderate, the urine gradually becomes normal, and convalescence follows. Each of these grades of kidney complication is illustrated by a selected case reported in detail.

however, admits that in certain cases of dysentery albumen and casts are present in the urine, and the kidneys are found after death to present the initial lesions of Bright's disease. This complication is, however, more common in chronic dysentery, as we shall have occasion to see hereafter.

NAUSEA AND VOMITING.—These symptoms are of frequent occurrence, although some cases run their course without the first and very many without the second. The opinion that bilious vomiting at the commencement of dysentery is a symptom of evil omen antedates the Hippocratic era,* and was probably founded upon the observation of a class of severe cases which commence with bilious vomiting and purging, and are still common enough, especially in malarial regions. These cases are most apt to occur in the summer, during extremely hot weather, and resemble at their commencement the so-called cholera morbus which is so frequent at the same season; subsequently, however, the discharges assume the dysenteric characters, and if the vomiting persists the patient speedily perishes. Such cases were common enough during the civil war. In another group of cases, commencing also with vomiting and purging, the matters vomited contain no bile, are watery, almost colorless, and of a feebly mawkish odor like the discharges of Asiatic cholera; watery purging at the beginning is speedily replaced by discharges of a bloody sanies, and the patient early falls into a condition of extreme dysenteric collapse. Cases of this kind were observed by Finger in the Prague hospital;† they occurred but rarely during the civil war. Both these groups of cases appear to result from the development, simultaneously with the dysenteric attack, of a more or less intense catarrh of the mucous membrane of the stomach.

But vomiting is by no means always of such serious import; very frequently it is merely the expression of a higher degree of that gastric irritability indicated by the nausea which so commonly accompanies the early stages of dysentery. Sometimes it occurs only after the ingestion of food or drink, and can be prevented by the judicious regulation of the diet; at other times no such care exercises any controlling influence. Vomiting frequently sets in also, at some later period of the disease, in patients who were free from it at the beginning. In this case, too, it may be a mere functional disturbance; or it may result from the gradual progress upwards into the stomach of the catarrhal inflammation of the small intestine, which so commonly accompanies the dysenteric process in the colon; or it may be a symptom accompanying the development of intercurrent peritonitis, or the occurrence of extensive sloughing in diphtheritic cases. The judicious practitioner can generally distinguish the nature of the more serious cases, but it is by no means easy or always possible to discriminate between those in which the gastric irritability is a mere functional disturbance and those in which a moderate degree of gastric catarrh actually exists. That the latter is of very frequent occurrence is indicated by the appearances found on dissection.

INDIGESTION.—It seems hardly necessary to mention that dysentery is always accompanied by a diminution of the digestive powers, proportioned to the activity of the disease; but it is sometimes forgotten by the practitioner that, in extreme cases, the scanty digestive fluids may entirely lose their capability of transforming the food, and that nourishment

* *Prenotions of Cos*, § 454, [Ed. Littré, V, p. 687.]

† FINGER—*Die epidemische Ruhr*, Prager Vierteljahrschrift, 1849, Bd. IV, S. 139. In four of these cases death occurred on or before the fifth day. On dissection the stomach was found injected, coated with tough mucus, here and there eroded, or beset with aphthous ulcers, or even coated with pseudomembrane.

well adapted to the less severe forms of the disease may become a positive source of injury. Uffelmann * has pointed out that in intense dysenteric cases, especially those accompanied by persistent fever, with dry mouth and tongue, the scanty saliva is acid in its reaction, and its normal capability of transforming starch into grape sugar is entirely lost. That a similar loss of power is experienced by the pancreatic and intestinal juices, is indicated by the frequent presence of undigested starchy matters in the stools; and an examination of the stools and vomited matters further indicates great diminution or complete annihilation of the power of digesting albuminous bodies and fats in these severe cases. Under such circumstances the most various fermentative and putrefactive changes attack the undigested food in the alimentary canal, and the products of these changes no doubt often act as local irritants and aggravate the disease. Even in less severe cases of dysentery there is still always more or less diminution in the activity of the digestive fluids, in consequence of which, in spite of the most careful alimentation, it is impossible to replace the daily waste of tissue. Hence results the usually rapid emaciation which is so characteristic of the disease.

Nervous disturbances.—The most various nervous disturbances accompany the progress of dysentery. Of these, *insomnia* is one of the first to make its appearance. It results from the frequency of the stools by which the patient is continually disturbed at night; from the pain which prevents sleep even during the intervals of the stools; and from the general restlessness and nervous disorder, which, in the severer cases, ensue from the severity of the local disturbance. Considerable loss of sleep from these causes is undoubtedly an important factor in the production of exhaustion and dysenteric collapse. Restlessness and irritability, depression of spirits, and other manifestations of nervous disorder are common enough in the severer cases. Graver nervous phenomena are not common except in the later periods of fatal cases; subsultus tendinum is then not infrequent, and delirium, convulsions or paralysis, especially of one or both lower extremities, occasionally occur. Of these graver nervous symptoms delirium is perhaps the least common in uncomplicated dysentery, though not unusual when the disease is complicated with typhoid, typho-malarial or remittent fevers; in uncomplicated cases the intellect generally remains clear almost to the very last. *Hiccough* is another nervous phenomenon which occurs chiefly in the graver cases, and very often presages a fatal issue.

Complications.—Some of the more important complications of acute dysentery are next to be considered, viz: peritonitis, whether the result of intestinal perforation or otherwise produced; intussusception of some portion of the intestine, with or without sloughing of the invaginated part; hepatic complications; malarial fevers; typhoid and typho-malarial fevers; scurvy or the scorbutic taint; inflammations of the respiratory organs; rheumatism; tubercular diarrhœa; erysipelas; paralysis, etc.

Peritonitis and Perforation of the Intestine.—More or less hyperæmia of the peritoneal coat of the colon, corresponding to the parts at which the diphtheritic process is most intense or at which ulceration has penetrated most deeply, is of common occurrence in dysentery, as is shown by the record of autopsies. Not infrequently this hyperæmia is aggravated into genuine peritonitis, accompanied by plastic effusions which tend to produce adhesions between the affected portion of the colon and the abdominal walls or the adjacent viscera. This process is especially prone to occur in the cæcum, but it may happen in any portion

* Julius Uffelmann—*Die Störung des Verdauungsprocesses in der Ruhr*, Deutsches Archiv für Klinische Med., Bd. XIV, 1874, S. 228.

of the colon. It is indicated during life by excessive tenderness at one or more points along the course of the colon, and by a steady pain in the same region, which continues to be felt during the intervals between the paroxysms of tormina.

Local peritonitis once established may spread and involve the general surface of the peritonæum with fatal result. This happens especially in severe cases of diphtheritic dysentery in which those constitutional conditions, which favor the accumulation of a feebly coagulating granular fibrine rich in pus corpuscles (migrated white blood-corpuscles) on any surface that may be inflamed, are often established. In such cases exquisite tenderness of the whole abdominal surface and intense abdominal pain of a continuous character become prominent symptoms. The abdomen, previously sunken, becomes tympanitic or filled with fluid; the patient assumes the dorsal decubitus with the knees drawn up; his countenance becomes anxious, his pulse small and frequent, (120–140 or more,) and all the usual symptoms of general peritonitis make their appearance.

But the most frequent cause of general peritonitis as a complication of dysentery is a perforation of the large intestine, resulting from the extension of a dysenteric ulcer by erosion or sloughing. This leads to an extravasation of the intestinal contents which lights up a general peritonitis that is usually fatal.* The perforation most frequently occurs in the cæcum, but it may happen in any portion of the colon. When it occurs in the cæcum it may be preceded or accompanied by the formation of an abscess in the right iliac fossa, (*perityphlitis*,) which may discharge into the intestine or even, in rare cases, through the abdominal parietes.† Peritonitis resulting from perforation cannot be distinguished during life from general peritonitis unaccompanied by this accident. Whether general or local, it may give rise to considerable effusion of serum into the abdominal cavity, which sometimes remains in the form of well marked ascites after convalescence has set in. Such dropsical effusions are, however, much more frequent in the chronic cases.

Intussusception of some portion of the intestine.—It will be stated in connection with the morbid anatomy of dysentery that intussusceptions of the small intestine are frequently observed after death. These, in most cases, are unaccompanied by evidences of inflammation, and are probably phenomena of the death agony; but occasionally intussusception takes place in dysenteric cases during life and gives rise to all the usual phenomena of ileus, which appears then as a complication of the dysenteric process. When we consider the violent character of the peristaltic contractions, indicated by the tormina of dysentery, it seems wonderful that this complication does not occur more frequently. In point of fact, however, it must be very rare, for no cases of the kind were reported during the late war.

The occurrence of ileus during a dysenteric attack might be expected to prove promptly fatal, and from the character of the symptoms might readily be confounded with peritonitis,

* An interesting discussion of the various results of intestinal perforation will be found in the *Canon* of AVICENNA—Lib. III, Fen. 16, Tract. 1, Cap. 2, pp. 810 and 811, Ed. apud Juntas, Venice, 1595. Perforation is said to prove, as a rule, immediately fatal; sometimes, however, fæcal extravasation leads to a condition resembling dropsy, which proves fatal after more protracted suffering, and occasionally the abdominal walls are also perforated, fæcal matter is discharged through the fistula and the patient survives. This last result is to be regarded as a remote possibility which only very rarely happens. Some have asserted that if such a fistula communicates with the jejunum the patient dies of starvation. MATTHEW DE GRADIBUS—*Practica noviter correcta*, Pars II, Cap. 12, Venice, 1502, fol. 285—in treating of dysentery, cites these observations of AVICENNA, and adds: "Ego tamen vidi in Papia unum doctum medicum magistrum Santinum de Filbertis qui hac passione premebatur cum emissione fæcum per ulcus: tamen vixit viginti annis post."

† An admirable description of perityphlitis accompanying dysentery is given by BAMBERGER—S. 406, *op. cit.*, p. 266, *supra*: "In many cases in which the cæcum is the seat of deep ulcers, an inflammation with suppuration occurs in the cellular tissue found in the iliac fossa behind it, *(perityphlitis.)* If the inflammation does not extend to the peritonæum, or if putrid decomposition and pyæmic fever do not set in, a cure often follows through the gradual resorption of the exudation or its evacuation externally. The latter occurs most frequently through the perforated intestine." But it may take place also, though in rare instances, through the abdominal walls. An analogous condition may also occur, but still more rarely, in the left iliac fossa from perforation of the sigmoid flexure, as in a case (No. 173) related by HABERSHON—*Dis. of the Abdomen*, 2d Ed., London, 1862, p. 412—in which the cicatrices of dysenteric ulcers produced a stricture of the sigmoid flexure, above which fæcal accumulation gave rise to perforating ulcers and the formation of an abscess, which opened externally by several fistulæ in the left iliac region.

or even overlooked altogether. These symptoms are obstinate constipation, vomiting, abdominal pain and tenderness; the pain occurring both in colic-like cramps and as a steady pain in the intervals. But since in dysentery the fæcal discharges are usually suppressed, and the occurrence of an intussusception would not interfere with the discharge of mucus, pus, blood and bloody serum from the parts of the intestine below the intussusceptions, the symptom of constipation necessarily loses its diagnostic value; and vomiting so often happens in dysentery that it could hardly even suggest the possibility of ileus. Moreover, the vomiting would rarely acquire the fæcal character, which is so significant when it occurs, because in dysentery the contents of the alimentary canal do not usually possess this fæcal character. As for the colic-like pains of ileus, they differ in nothing from those of dysentery, nor the pain or tenderness from that of local or general peritonitis.

For these reasons should ileus supervene during dysentery it would be very apt to be overlooked, and to be discovered only on the autopsy in fatal cases, except when the intussuscepted portion of the bowel separates by sloughing and comes away by stool during the life of the patient. This occasionally happens in ordinary cases of ileus, and under favorable circumstances such patients may even recover, as is shown by the examples which have been collected by Morgagni, Cayol, Meckel, Autenrieth, Gaultier de Claubry, Thomson, Duchaussoy and Peacock.* There seems, therefore, to be no good reason for doubting the possibility of the occurrence of the same rare accident during the progress of dysentery, as in the instances reported by Sebire and Gautier de St. James, Baillie, Twining and Paterson;† or indeed during the course of an attack of diarrhœa, as in the cases observed

---

* MORGAGNI—*De Sed. et Causis*, Epist. XXXI, § 26. J. B. CAYOL—*Mémoire sur une terminaison particulière de la gangrène dans les hernies*—published by the author as an appendix to his translation of SCARPA on *Hernia*, Paris, 1812, p. 413 *et seq.* J. F. MECKEL—*Handbuch der path. Anat.*, Bd. II, Abth. 1, Leipsic, 1816, pp. 338 and 403. H. F. AUTENRIETH—Tübingen, 1831—Diss. cited on p. 365, *supra*. GAULTIER DE CLAUBRY—*Sur la terminaison de quelques cas de volvulus par l'étranglement et la séparation totale d'une portion souvent considérable du canal intestinal*, Jour. Univ. et Hebdom. de Méd. et de Chir. Pratiques, XII, 1833, p. 373. WM. THOMSON—*Abstract of cases in which a portion of the cylinder of the intestinal canal, comprising all its coats, has been discharged by stool, without the continuity of the canal being destroyed*, Edinburgh Med. and Surg. Jour., Vol. 44, 1835, p. 296, and *Appendix* to the same, *op. cit.*, Vol. 45, 1836, p. 374; see note to p. 365, *supra*; in these papers the author gives very full abstracts of 43 such cases, (including those collected by AUTENRIETH,) in 19 of which the patient either recovered or was still living when the report was made, while 24 proved fatal; and in 18 of these no account of the autopsy is given. Three of these cases were instances of strangulated hernia with the passage per anum of the mortified knuckle of intestine; the rest were cases of ileus, and of these several occurred in patients suffering from diarrhœa or dysentery; see next note. A. P. DUCHAUSSOY—*Anat. Path. des Étranglements Internes*, Mém. de l'Acad. Imp. de Méd., XXIV, 1860, p. 97. The second section of this elaborate paper, p. 148, deals with the subject under consideration. The author, who was not acquainted with the "*Appendix*" to THOMSON'S first paper, states that, besides the 35 cases mentioned in that first paper, he has been able to collect 32 others; but though he makes several interesting statements with regard to them, he does not give references to the individual cases, so that I am unable to decide how many of them are included in THOMSON'S second paper or in the paper of PEACOCK. PEACOCK—*Invagination of Intestine: passage of a large piece of bowel by the rectum; recovery.* Trans. of Path. Soc. of London, XV, 1864, p. 113. In this paper the author cites, besides his own, 19 additional cases not contained in either of THOMSON'S papers, besides one contained in THOMSON'S second paper, which, singularly enough, he appears not to have seen. PEACOCK'S own case recovered, and it is remarkable that of the cases he has collected but two proved immediately fatal.

† SEBIRE et GAUTIER DE ST. JAMES—*Obs. sur une portion des gros intestins, extraite par l'anus*, Jour. de Méd., LXIV, 1785, p. 619—report the case of a man suffering with what his attendants regarded as the bilious dysentery of ZIMMERMANN, who passed per anum several portions of intestine which proved on examination to represent 18 inches of the colon and to consist of all its coats, for it is stated that the attachments to the mesocolon could be distinctly seen. The patient nevertheless made a good recovery. After a perusal of the prolix narrative of this case, I see nothing in it to exclude the opinion that probably only a small part of the length reported consisted of all the coats, and that the rest was made up of sloughs of the mucosa and submucosa and of pseudomembranes. On this supposition the case would not appear more extraordinary than that described by M. BAILLIE—*An account of a singular disease in the great intestines*, Trans. of a society for the improvement of Med. and Chir. Knowledge, II, 1800, p. 149—of a dysenteric patient who is said to have passed a portion of colon about six inches long, in which BAILLIE recognized "the remains of the appendiculæ epiploicæ, and a part of one of the longitudinal bands," and also a considerable portion of mucous membrane coated "with a layer of coagulable lymph." If these specimens are, as THOMSON supposes, (see p. 375, *Appendix*, cited in last note,) the specimens preserved in the Hunterian Museum at Glasgow—*Catalogue of* 1840: Great Intestines, Nos. 43–5, S.—the patient died two years afterward, and a stricture of the colon was found at the point from which the slough separated; but in that case either BAILLIE'S description is inaccurate or the piece he described was not sent to the Museum, for the catalogue describes the portions passed per anum as "portions of the internal coat ulcerated off." THOMSON himself [see paper cited in last note] mentions having seen in MECKEL'S *Museum*, during a visit to Halle in 1825, a specimen catalogued "*Intussuscepta tenuis et crassi pars, dysenteria excreta*," and expresses the opinion that two specimens in the Fort Pitt collection are of the same nature. By his reference I find these specimens in the *Catalogue of the Museum of the Army Med. Dept., Fort Pitt, Chatham*, 1833, described as follows: Digestion, Div. 3, No. 53. "Portion of small Intestine, about seven inches in length, voided per anum." "From John Seary, 13th Light Dragoons, who perfectly recovered, and passed through the Invalid Dépot, at Fort Pitt, some years afterwards;" and No. 99. "Portion of Intestine passed per anum." Both specimens are recorded as from Madras. In the Catalogue of 1845 they are numbered 1116 and 1117. The first is figured in the 2d *Fasciculus of Anat. Drawings in the Museum at Chatham*, London, 1824, Plate VII, Fig. 9. It is not stated in either of the catalogues that these were from dysenteric patients. If, however, THOMSON'S supposition is correct, they would be similar cases to that reported by WM. TWINING—*Diseases of Bengal*, 2d Ed., Calcutta, 1835, Vol. I, p. 151, Case 23—in which a dysenteric boy passed by stool a portion of small intestine five inches long, composed of all the coats together with some smaller fragments, and afterwards recovered. Abstracts of the foregoing cases will be found

by Lembke and Westphal and Valleix,* especially as the same accident has been known to occur in consequence of the exhibition of a drastic cathartic.†

The sudden supervention of pain, vomiting and the other symptoms accompanying the occurrence of an intussusception would be much more apt to arrest attention and lead to an autopsy for the purpose of ascertaining their cause, if they occurred during an ordinary attack of diarrhœa than during dysentery. Accordingly, while in dysentery such cases as that recorded by Lettsom‡ must often escape recognition, the occurrence of fatal ileus during the progress of diarrhœa has been more frequently observed. As examples I may cite the cases reported by Shaw, Harris, Holmes, Todd, Wachsmuth and Mann.§ The occurrence of fatal ileus during the diarrhœa of children has especially attracted attention. Several of the writers on infantile intussusception have adverted to its occurrence during diarrhœa,‖ and recorded individual examples, some of which are mentioned in a foot-note.¶

in THOMSON'S paper, which I have compared with the originals cited and found to be substantially correct. I may add the following cases: R. BROWN—*Case of Sloughing and Discharge of 25 inches of large Intestine in Dysentery*, Trans. of Med. and Phys. Soc. of Bombay, Vol. I, 1838, p. 336. The patient was a soldier of the 3d Troop Horse Artillery, admitted with dysentery, Nov. 30, 1831. Dec. 20, the piece described came away: "on dissection the three coats could readily be separated: the fatty appendices, and the three longitudinal fibrous bands, were distinctly visible." The patient died Jan. 20, 1835. "The large intestines were much shortened, and not a vestige of the sigmoid flexure existed. There were morbid adhesions at the posterior part of the bladder," &c. PATERSON—*Portion of Intestine discharged after Intussusception*, Edinburgh Monthly Jour. of Med. Sci., XVIII, 1854, p. 283. A girl aged nine years had an attack of dysentery; symptoms of ileus supervened, and a portion of intestine ten inches long was passed by stool. The child "made a perfect recovery."

* As examples of this occurrence in diarrhœa I note the following cases: LEMBKE and WESTPHAL—*Diss. qua pars intestini jejuni per guttus inferius excreta salva manente ægri vita describitur*, Gryphiswald, 1741, in HALLER'S *Disp. ad Morb., Hist. et Cur.*, T. III, 1757, p. 503—in which a man suffering from a putrid diarrhœa passed by stool a portion of small intestine, including all the coats, with a piece of mesentery adhering to its side. The patient recovered from all the violent symptoms, but his bowels remained loose; also a case cited by THOMSON, which I have not been able to see in the original—*Racconto di un fatto rarissimo, di considerevole porzione d'Intestino evacuato per secesso, anno* 1805, Alessandria—of a woman suffering from colic, with bilious vomiting and bloody diarrhœa, who passed a portion of the cæcum, with the vermiform appendix attached, by stool. The woman died some six weeks after, and an interesting account of the autopsy is given; and a case reported by VALLEIX—*Note sur un cas d'expulsion par l'anus d'une portion de l'intestin*, &c., L'Union Médicale, Feb., 1850, p. 57—An infant thirteen months old, who had previously suffered from constant diarrhœa, passed a portion of small intestine accompanied by two diverticula which were united to it. Symptoms of ileus, if recognized, are not mentioned, and the result of the case is not given.

† As an example of this accident, I may cite a case reported by GAY—*Intestinal obstruction followed by the separation of a portion of intestine*, Trans. of Path. Soc. of London, VI, 1854-5, p. 193—A child æt. 6 took a dose of salts and senna which acted violently; almost immediately after symptoms of ileus occurred, followed 15 days later by the passage of a portion of the small intestine (including all the coats) about three inches long. The child recovered.

‡ JOHN C. LETTSOM—*History and dissection of an extraordinary introsusception*, Philosoph. Trans., 1786, p. 305—A child 4 years old had cholera morbus followed by dysentery in October; after partial convalescence a relapse of the dysentery occurred in December, "accompanied with a troublesome tenesmus, and a considerable degree of fever." Toward the close of that month, "after repeated vomitings of a dark-coloured fluid, like coffeegrounds," the child died. On the autopsy the ileum, cæcum and vermiform appendix, ascending, transverse and a part of the descending colon, and of the omentum were intussuscepted into the sigmoid flexure and there strangulated. "The cavity of the abdomen also contained more than half an ounce of thin pus;" and the "inclosed intestine was very much diseased, the upper part next the band being highly inflamed, and as it approached the caput coli in the rectum gradually terminated in mortification, so that for three inches from its extremity it was perfectly black." This intussusception was not recognized during life.

§ In all these cases the fatal ileus supervened upon diarrhœa in adults, and on dissection the involuted parts were found inflamed or even gangrenous. WM. SHAW—*History of a case of introsusception*, Philadelphia Med. Museum, II, 1805-6, p. 286. ELISHA HARRIS—*Report of a case of Introsusceptio ilii*, The New York Journal of Med., Vol. V, 1850, p. 333. HOLMES—*Intussusception of the sigmoid flexure of the colon and of the upper part of the rectum*, Trans. of the Path. Soc. of London, VIII, 1856-7, p. 177. R. C. TODD—*Intussusception in a soldier thirty years of age, associated with a polypus of the intestine affected, and with the existence of numerous parasites (the trichocephalus dispar) in the caput cæcum*, Statistical, Sanitary, and Medical Reports, Vol. VI, for the year 1864, (London, 1866,) p. 528. To this case some interesting remarks by Prof. WM. AITKEN are appended, from which I cite the following: "In all the dissections of invagination whose history I have examined, they have either been associated with the diarrhœa of irritation (as from worms, undigested masses of food); or with cerebral lesions (as in the cases of children in whom invaginations are very common); or with ulcers of the intestines, or polypoid growths as in this case," p. 534. A. WACHSMUTH—*Ileus und Enterotomie*, Virchow's Archiv, XXIII, 1862, S. 118. In case 3 of this paper the invagination supervened upon a chronic looseness of the bowels, (2-3 stools daily.) The author also mentions (S. 133) the case of a man 45 years old in whom a sudden attack of diarrhœa (six stools rapidly following each other) was followed by death on the fifth day, with symptoms of ileus. The colicky pains which accompanied the first stools were so sharp that the patient threw himself down and pressed his belly against the ground; and the author suggests that this may have determined the invagination. W. S. MANN—*Case of Intussusception, with remarks*, The Birmingham Med. Review, Vol. I, 1872, p. 213. A widow aged 35 was attacked with vomiting and purging, followed by fatal ileus. The seat of the intussusception was the descending colon.

‖ For example: WM. BRINTON—*Intestinal Obstruction*, London, 1867—who analyzed "about 600 necropsies of such obstruction," (p. 38,) remarks: "In many of the infantile cases, the occurrence of the lesion immediately followed a casual or artificial diarrhœa—a coincidence which also obtained in some of the adults. A proneness to intestinal derangement, especially to constipation or diarrhœa, is also a frequent feature of the previous history," (p. 43.) See also an excellent paper by J. L. SMITH—*Statistical researches relative to the seat, symptoms, pathological anatomy, prognosis, treatment, &c., of Intussusception in children*, The American Jour. of the Med. Sciences, Philada., Jan., 1862, p. 17; and consult MEIGS and PEPPER—*Diseases of Children*, 4th Ed., Philadelphia, 1870, p. 423.

¶ In all these cases the fatal ileus supervened upon diarrhœa in young children, and on the autopsies intussusceptions were found with evidences of inflammation or gangrene of the involuted parts. E. Y. STEELE—*Cases of intussusception in infants*, The Lancet, Vol. I, 1849, p. 680—child aged 6 months, in whom the intussusception followed a "slight diarrhœa," and two other cases in which this antecedent had not occurred. C. CLARK—*On a case of intussusception of the intestines*, The Lancet, Vol. II, 1849, p. 205—child aged 6 months. EDWARDS—*Intussusception of the large intestine—the cæcum protruded through the anus, and the small intestine terminating by a valvular opening at the anus*, Medical Times and Gazette, London,

That a fatal ileus may be produced by the excessive action of a cathartic medicine would seem to be shown by the cases reported by Ballard and Gay.*

Hepatic complications.—More or less disturbance of the secretory function of the liver undoubtedly occurs in the great majority of cases of dysentery. It is usually manifested by a diminution in the quantity of bile which reaches the intestinal canal, as shown by its absence from the discharges from the bowels, which are often deficient in this respect for days or weeks. In other cases, however, the secretory function of the liver appears to be stimulated to excessive action and an unusual quantity of bile is poured into the alimentary canal, giving rise to copious vomiting and purging of bilious matter, especially at the commencement of the dysenteric attack. It appears probable, from a passage in the Prenotions of Cos,† that the term Bilious Dysentery was applied to this latter class of cases by the older Greek physicians even before the time of Hippocrates, and it is still conveniently used in the same sense at the present day.

But bilious dysentery, as thus understood, must be discriminated from Hepatic Dysentery or the Hepatic Flux, terms which the later Greek physicians and their followers, as late as the latter part of the last century, bestowed upon a form of flux characterized by watery discharges discolored with blood, and supposed to depend upon atony or imbecility of the liver. Archigenes ‡ described such a flux as resulting from the ulceration following a hepatic abscess, and compared the putrid sanious stools to the fluid which drains from the bodies of the dead. Aretæus § affirmed that abscesses of the liver sometimes discharge into the intestines, and stated that after this accident watery dejecta often follow, which after a time come to resemble the washings of flesh; but it was Galen || who first broadly taught that stools resembling the washings of flesh are due to atony of the liver, and Alexander of Tralles,¶ adopting the Galenical doctrine, bestowed upon this form of flux the name hepatic dysentery. Under this name it was also described by Paulus Ægineta,** and an article in the dictionary of Gorræus†† shows that this designation was still currently employed in the same sense among the physicians of the seventeenth century. Galen had

---

Nov. 23, 1861, p. 531—child aged 3½ years. J. L. SMITH—*Intussusception of the small intestines in infancy*, The New York Med. Record, June 1, 1866, p. 177—child 4 months old, (case 2.) The paper contains two other cases which did not follow diarrhœa. SCHÜTZ—*Zur Lehre von der Impermeabilität des Darmes*, Prager Vierteljahrschrift für die Prakt. Heilkunde, 1868, Bd. II, S. 10—boy aged 7 years. J. O. AFFLECK—*Two cases of intussusception in children*, Edinburgh Med. Journal, XIX, 1873, Part 1, p. 238—a child of 7 months; case 2, a child of 5 months, recovered. *Extraordinary case of double intussusception*, The Lancet, May 17, 1873, p. 709—child aged 6 months. H. M. MADGE—*A case of ileo-cæcal intussusception in an infant of eight months*, Trans. of the Obstet. Society of London, Vol. XVI, (for the year 1874,) p. 219, London, 1875. R. BELL—*Intussusception of the large intestine; abdominal section*, The Cincinnati Medical News, March, 1876, p. 223—child 16 months old.

* T. BALLARD—*Intussusception of the ileum at the ileo-cæcal valve*, Trans. of the Path. Soc. of London, XVIII, 1866–7, p. 92. In this case the patient, aged 37, had "his bowels habitually loose to the extent of two or three actions in the day." After a hearty dinner he had some abdominal pain, for which he took a dose of castor oil "which operated twenty times." Fatal ileus supervened. Compare note † on the last page.

† The *Prenotions of Cos* are undoubtedly older than HIPPOCRATES, [see Ed. Littré, I, p. 350.] In the passage referred to in the text—*Prenotions of Cos*, § 24, [Ed. Littré, V, p. 687,]—bilious dysentery (χολώδης) is contrasted with bloody dysentery, (αἱματώδης,) the distinction being therefore evidently based on the character of the stools. In the same passage it is asserted that bilious vomiting at the commencement of dysentery is an unfavorable symptom. Bilious stools in dysentery are spoken of in various places in the Hippocratic writings, *e. g.*, *Epidem.*, Lib. III, Sect. 3, [Ed. Littré, III, p. 87;] *Epidem.*, Lib. VII, § 3, [*op. cit.*, V, p. 369.] The celebrated aphorism—*Aph.*, Sect. 4, 24, [Ed. Littré, IV, p. 511,]—that "Dysentery arising from Black Bile is mortal," may be mentioned in this connection. ARCHIGENES (*loc. cit.*, in note ‡ to p. 336, *supra*) explained this aphorism by the statement that intestinal ulcers produced by black bile resemble cancerous ulcers, but ventured to assert that he did not despair of curing dysentery caused by black bile in those cases in which that humor occurs as a critical discharge in the course of fevers. In the Hippocratic treatise *Prorrhetics*, Lib. II, § 22, [Ed. Littré, IX, p. 51,] inflammation of the liver (φλεγμονὴ ἥπατος) is spoken of as a complication of dysentery which indicates the probability of an unfavorable termination.

‡ ARCHIGENES in ÆTIUS—Tetrab. III, Serm. 2, Cap. 5, [Lyons Ed., 1549, p. 627,] *Cura hepatis exulcerati*—after the description referred to in the text, the author remarks that "the inexperienced, deceived by such a flux, may suppose the affection to be dysentery." In the same treatise, Cap. I, ÆTIUS describes a bloody flux resulting from atony of the liver, after GALEN.

§ ARETÆUS—*De Causis et Signis Morb. Diut.*, Lib. I, Cap. 13, [Boerhaave's Ed., p. 42.]

|| GALEN: See passages cited in note ‡ to p. 336, *supra*.

¶ ALEXANDER OF TRALLES—Lib. VIII, Cap. 3 and 4, [Basel Ed., 1556, p. 400 *et seq.*] The phrase used is ἡπατικὴ δυσεντερία. I am astonished that the ingenious ACKERMANN—*De dys. antiq.*, Leipsic, 1777, Lib. I, cap. 3, p. 25—should affirm the rheumatic dysentery of this writer to be a variety of hepatic dysentery; compare p. 340, *supra*.

** PAULUS ÆGINETA—Lib. III, Sect. 42, [Transl. of Syd. Soc., Vol. I, p. 525.] In the Greek text the words employed are ἡπατηρὰ δυσεντερία.

†† GORRÆUS—*Def. Med.*, Opera, Paris, 1622, p. 245, Arts. ἡπατηρὰ δυσεντερία and ἡπατικοί. The latter is the article referred to in the text.

distinguished this form of flux, as well as some other varieties of bloody discharges from the bowels, from true dysentery, and it was probably this circumstance which led to the substitution of the term Hepatic Flux, under which the condition in question was described by Gordonius, Plater. Sennertus, Ballonius, Riverius,* and many other physicians from the thirteenth century to the latter part of the eighteenth.

But meanwhile other forms of flux besides those in which the discharge consists of bloody serum were ascribed to various disorders of the hepatic functions, especially by the Arabian physicians† and their followers; and Gordonius in the Lilium Medicinæ‡ not merely adopted this extension in the signification of the term, but went so far as to affirm that the hepatic flux might proceed from the disease of other organs besides the liver. However contradictory this latter opinion may appear, it was adopted by many subsequent writers, and although resisted by the stricter followers of Galen,§ was accepted in certain quarters as late as the last century, when we meet it, for example, in the Nosology of Sauvages,‖ by whom the term hepatirrhœa was brought into use as an equivalent, and in the Epitome of John Peter Frank.¶

The Galenical conception of the hepatic flux seemed reasonable enough so long as the Galenical doctrine that the liver is the great blood-making organ** continued to secure general belief; but after the discovery of the lacteals and of the thoracic duct this doctrine was successfully assailed by Bartholinus and Glisson,†† and their opinion that the function of the liver was limited to the secretion of bile was almost universally accepted until the modern era of hepatic physiology was inaugurated by the investigations of Magendie, Tiedemann and Gmelin.‡‡ But pathological hypotheses often survive the physiological beliefs upon which they are based, and the doctrine of the hepatic flux continued for a time to find supporters, although Sylvius§§ protested that he had himself never seen a case and knew of no one who ever had, and Ettmüller |||| more cautiously insinuated doubts with regard to the ancient view, and pointed out its incompatibility with the modern conceptions of the functions of the liver.

It received its death blow in 1793, when A. G. Richter ¶¶ revived the almost forgotten explanation which, with some cautious reservations, had been advanced by the ingenious

¶¶ A. G. RICHTER—*Med. und Chir. Bemerkungen*, Bd. I, S. 144, Göttingen, 1793. He held that vomitus cruentus, morbus niger and fluxus hepaticus were merely varieties of intestinal hæmorrhage, and not separate diseases.

Bartholdus,* who sought the origin of the blood, admixed in the discharges of the hepatic flux, in rupture of the intestinal vessels; and the publication of his views was followed by the appearance of a critical article in the Journal der Erfindungen, Theorien und Widersprüche in der Natur- und Arzneiwissenschaft,† which reviewed the literature of the subject and arrived at the conclusion that the hepatic flux ought no longer to be regarded as a separate species of disease. In vain did Portal‡ endeavor to support the use of the term by citing individual cases. The few he was able to collect were merely examples of hepatic abscess discharging into the intestinal canal; but cases of this accident, which had been known even to the Greek physicians,§ afforded no real support to the expiring doctrine, and it has disappeared from the medical literature of the present century except as a matter of history.‖

Meanwhile Degner,¶ in his account of the epidemic of dysentery at Nimeguen** in 1736, brought again into use the term bilious dysentery, [dysenteria bilioso-contagiosa,] which he appears to have employed partly on account of the frequency with which he observed bilious vomiting and purging, especially at the beginning of his cases, but chiefly on account of his belief that a vitiation of the bile was the actual cause of the disease,†† a belief which led him to include under the designation bilious dysentery those cases also in which bile was not mingled with the discharges. This opinion of Degner was after all but a development of the doctrine of Galen,‡‡ still generally accepted in his time, that an acrid bile capable of excoriating the intestinal mucous membrane is the starting point in

---

* G. T. BARTHOLDUS—*Opera Med. Tripartita*, Frankfort, 1717, Pars II, Sect. 2, Cap. 4, § 7, De Vomitu Sanguineo et Fluxu Hepatico. The paragraph cited is so noteworthy that I add a translation: "The hepatic flux was ascribed by the ancients to the liver, but erroneously, for this is repugnant to anatomical laws. It proceeds rather from the mesenteric veins, which, being congested with blood, at last rupture the intestinal coats, and that blackish, more or less serous fluid, is ejected sometimes in considerable quantity, two or three pounds, with prostration of strength and appetite. Yet it is not to be denied that induration of the liver may sometimes produce this flux," p. 94. A somewhat similar view of the probable source of the discharge in hepatic flux will be found in R. A. VOGEL—*Academicæ Prælectiones*, Gottingen, 1772, § 283—who, however, brings forward the case of discharges from abscess of the liver to show that the hepatic source of a flux of this kind should not be rejected in toto. In like manner C. G. SELLE—*Med. Clinica*, Vienna, 1797, S. 420—remarks: "The source of the fluid discharged is not always the liver, but also often, and for the most part, the mesenteric vessels."

† Bd. I, Gotha, 1792-3, St. 4, S. 58, *Ueber den Fluxus Hepaticus;* also conclusion in Bd. II, St. 5, S. 22. An admirable article, the author of which is not named.

‡ ANTOINE PORTAL—*Obs. sur la Nature et le Traitement des Maladies du Foie*, Paris, 1813, Partie 2, Art. 20, p. 579—De l'état du Foie dans ceux qui sont morts du flux hépatique ou de l'hépatirrhée. The cases which he cites are from BONTIUS and LIEUTAUD, viz: J. BONTIUS—*De Med. Indorum*, Leyden, 1642: I quote from the reprint bound up with the *Med. Ægyptiorum* of P. ALPINUS, Leyden, 1718-19, Lib. IV, Obs. 9, De Apostemate Hepatis. This case of extensive hepatic abscess has figured largely in the literature of the hepatic flux. It is also cited in the *Sepulchretum* of BONETUS, Lib. III, Sect. 11, Obs. 25, and in the work of SAUVAGES, [cited on p. 393,] who states that he himself observed a similar case in 1730. The cases from LIEUTAUD will be found in the *Hist. Anat. Med.*, Paris, 1767, T. I, Obs. 714 and 728; the first borrowed from SYLVATICUS, the second from PANAROLUS. Both are given by LIEUTAUD under the head "Purulentia et abscessus hepatis." In this connection I may mention that a case very similar to that of BONTIUS is related by THOMAS JORDAN—*Pestis Phænomena*, Tract. I, Cap. 19, Frankfort, 1576, p. 223. So also two cases are given by BONETUS in the *Sepulchretum*, Lib. III. In the first, Sect. 10, Obs. 6, the case was complicated with diarrhœa and lientery, and among other lesions found after death the intestinal mucous membrane was gangrenous and fetid. In the second, Sect. 12, Obs. 6, in which the patient is said to have had a hepatic flux for ten months, an abscess of the mesentery was found. The four cases of FORESTUS [see note § to p. 393, *supra*] do not throw much light on the subject, since, as usual with his cases, they all terminated in a happy recovery.

§ This is probably indicated by a passage in the *Prenotions of Cos*, Sect. 2, Paragr. 22, § 439, [Ed. Littré, V, p. 683, or Ed. Kühn, I, p. 308;] but certainly the passages cited above, (p. 392,) from ARCHIGENES and ARETÆUS, leave no doubt as to the knowledge which the Greek physicians possessed of this accident.

‖ See the Article *Flux Hépatique* by RÉNAULDIN in the Dict. des Sci. Méd., T. XVI, Paris, 1816, p. 45, and the Article *Fluxus Hepaticus* by HUFELAND in the Encycl. Wörterbuch der med. Wiss., Bd. XII, Berlin, 1835, S. 344. M. E. A. NAUMANN—*Handbuch der med. Klinik*, Bd. V, Berlin, 1835, S. 35—describing the rupture of hepatic abscesses into the intestinal canal, says that often after the first discharges "a diarrhœa similar to flesh-water obstinately remains, (Fluxus Hepaticus, Hepatirrhœa:)" and he mentions a similar discharge as occasionally observed during the progress of chronic hepatitis, [S. 44.] H. BRESSLER—*Die Krankheiten des Magens und Darmkanals*, Berlin, 1841, Bd. I, S. 480: Fluxus Hepaticus, Leberfluss—is one of the latest writers who treats of it under a separate head. His account is compiled chiefly from FRANK, VOGEL and RICHTER, (cited above.) That various hepatic diseases, by mechanical obstruction of the portal circulation, may produce a degree of congestion of the intestinal mucous membrane favorable to the production of intestinal hæmorrhages is not to be denied. This may happen in acute and chronic atrophy of the liver, in cirrhosis, in the pigment-liver, in syphilitic disease of the liver, in cancer of the liver, &c. Compare F. T. FRERICHS—*Clinical Treatise on Diseases of the Liver.* Transl. of New Syd. Soc. of London, 1860-1, Vol. I, pp. 220, 268, 346; Vol. II, pp. 36, 45, 161, 306 and many other places. But these hæmorrhages are usually pure blood, or blood variously mixed with the intestinal contents, and not the peculiar discharge supposed to characterize the hepatic flux. Besides the works cited in previous notes, the reader may consult the following dissertations: J. L. LOSS—*Disp. de Dysenteria Hepatica*, Leyden, 1706; A. CHR. EÜLHARDT—*Diss. exhibens Fluxum Hepaticum vulgò Die Leber-Ruhr*, Erfurt, 1728; F. G. GEORG—*Diss. de Dysenteria Hepatica*, Halle, 1747; F. A. DUESTERBERG—*Diss. de Fluxu Hepatico*, Berlin, 1818.

¶ J. H. DEGNER—*Hist. Med. de Dysenteria Bilioso-contagiosa quæ* 1736 *Neomagi et in vicinis ei pagis epidemice grassata fuit.* Utrecht, 1738.

** Also written Nymwegen, Nijmwegen and Nymegen, a town in the Netherlands on the left bank of the Waal, between nine and ten miles south of Arnheim.

†† *Op. cit.*, Cap. 2, § 61-65 ‡‡ See note ‡ to p. 336, *supra*.

dysentery; nevertheless his descriptions served to direct attention to the existence of a group of dysenteric cases characterized by the prominence of the so-called bilious symptoms. This group of cases figures also in the account given by Zimmermann* of the Swiss epidemic of 1765, as the most common form of the disease during that epidemic; but Zimmermann carefully discriminated between these cases, which he supposed to owe their characters to the coexistence of a bilious fever and the other varieties of dysentery, and severely censured Degner† for his lack of discrimination.

But it was Maximilian Stoll‡ who first gave to the conception of bilious dysentery the form which it still retains. Stoll had completely emancipated himself from the belief that the bile was the agent which caused the dysenteric flux.§ He saw in the excessive discharges of bile and other evidences of hepatic disturbance merely a complication of dysentery which the hepatic disorder aggravated, but could not produce.‖ It is in this sense that bilious dysentery has also been described by Fournier and Vaidy,¶ who used the term gastric dysentery as an equivalent on account of the irritable condition of the stomach in these cases. In the same sense it has been employed by many subsequent writers, as for example Vignes, Cornuel, Haspel, Copland, Trousseau and Savignac.** Others, emphasizing the gastric disorder, make the bilious form a sub-variety of gastric dysentery, as has been done, for example, by Naumann and Hauff.††

The descriptions of bilious dysentery which these writers have given agree in all the essential points. They speak of a bitter taste in the mouth accompanied by nausea, often by bilious vomiting and purging, as ushering in the dysenteric attack. Sometimes an icteroid hue of the countenance was observed, which might even be so marked as to amount to actual jaundice; sometimes the urine contained biliary coloring matter. Uneasy sensations and tenderness in the hepatic region were observed in some of the cases, in some frontal headache, and other evidences of nervous disturbance supposed to depend upon the absorption of biliary matters attracted attention. All or a part of these symptoms are no doubt frequently observed at the commencement of dysentery, but as they occur in connection with cases of simple catarrhal dysentery as well as of the diphtheritic form of the disease, and as the severity of the hepatic disorder stands in no constant relationship to the character or intensity of the dysenteric process, it would seem more convenient to regard hepatic disorder, when it coexists, as a mere complication, than to group the cases in which it occurs as a special variety of dysentery.

These hepatic complications are especially frequent in warm climates, where the disorder of the liver often amounts to actual inflammation, culminating in the development of abscess. Accordingly abscess of the liver figures conspicuously among the com-

---

†† M. E. A. NAUMANN—*Handbuch der med. Klinik*, Bd. IV, Abth. 2, Berlin, 1835, S. 13—subdivides Die gastrische Ruhr (Dys. gastrica) into: (a) Die gallige Ruhr (D. biliosa) and (b) Die schleimige Ruhr, (D. pituitosa.) The same is done by HAUFF—*Zur Lehre von der Ruhr*, Tübingen, 1836, S. 268.

plications of dysentery in the writings of English physicians in the East and West Indies, and of the French physicians in Algeria and other French colonies. Chisholm and Annesley* employed the old term hepatic dysentery to designate cases thus complicated, but the historical associations which cluster around that phrase would appear to constitute an insuperable objection to its use in this new sense, and it seems far more convenient to speak of hepatic abscess, when it occurs in connection with dysentery, simply as a complication.

Amidst the urgent symptoms of dysentery, the comparatively insidious development of hepatic abscess is so often overlooked, that its frequency or rarity in various regions and at different times has been established by dissection rather than by clinical observation. Hence it appears convenient to postpone any discussion of the evidence relating to this subject until the post mortem appearances are under consideration. Let it suffice here to state in a general way that during the civil war hepatic abscess was far less frequent as a complication of dysentery than it is in the dysentery of the English and French tropical colonies, but yet somewhat more frequent than in the dysentery of Europe.

The symptoms to which the greatest importance attaches in diagnosticating the development of this complication are pain in the hepatic region and the physical signs of enlargement of the liver. The constitutional symptoms which often indicate the formation of uncomplicated hepatic abscess are so masked by those belonging to dysentery as to have little diagnostic value. Fever of a remittent or hectic character, night sweats, the sudden occurrence of a chill, and gradually progressing emaciation and debility are too common in uncomplicated dysentery to suggest hepatic suppuration. Of course the development of jaundice would suggest the physical exploration of the liver; but jaundice may occur without hepatic abscess, and the latter very frequently runs its course without jaundice, so that this symptom has no particular diagnostic value in this connection except so far as it may serve to suggest the desirability of physical exploration.

Pain and tenderness in the region of the liver are symptoms of much greater significance, although they are by no means invariably present. Tenderness on firm pressure is more rarely absent than pain. The pain may be acute, or dull and heavy. According to Murchison,† the former usually characterizes small multiple abscesses, the latter large single ones; because when the abscesses are multiple, inflammatory action is apt to be propagated from some one or more of them to the peritonæum, whereas the single large abscess usually commences in the interior of the liver, and therefore does not produce acute pain unless the pus approaches the surface of the organ so that the peritonæum is at length involved. This speculation has, perhaps, some foundation; at all events acuteness in the character of the pain usually indicates the existence of local peritonitis. The pain may be seated in any part of the region occupied by the liver. In some cases it is referred to the spine, and the patient describes it as though it had its seat in the vertebral column. It is

* COLIN CHISHOLM—*A Manual of the Climate and Diseases of Tropical Countries*, London, 1822, p. 58. The author was for a time Inspector General of Ordnance Hospitals in the West Indies, and his book chiefly refers to these islands. He affirms that hepatic dysentery is especially frequent in marshy situations where remittent and intermittent fevers prevail, and remarks that on dissection "The liver of all the viscera is found the most diseased—inflamed, enlarged, partially suppurated, or in some portions sphacelated, or in consistence like rotten cork," &c., &c. JAMES ANNESLEY—*Diseases of India*, London, 1828, Vol. II, p. 197—"Of Hepatic Dysentery or Dysentery complicated with Disease of the Liver." "In hepatic dysentery, therefore, we may consider the relation of morbid action as being chiefly of two kinds: *first*, that in which the dyseateric symptoms are produced by functional or organic disease of the liver; and *secondly*, that in which the diseased actions of the liver are excited by the dysenteric disease," &c., p. 199. DAVID CRAIGIE—*Elements of the Practice of Physic*, Edinburgh, Vol. I, 1837, p. 912—has used the term Hepatic flux in the same sense, which is still more objectionable.

† CHARLES MURCHISON—*Clinical Lectures on Diseases of the Liver*, Am. Ed., New York, 1868, p. 147 *et seq.* He designates the small multiple abscesses as "pyæmic abscesses," the large single ones as "tropical abscesses;" but this is surely quite arbitrary. Small multiple abscesses also occur in tropical climates, and large single ones in the temperate zone; nor is it improbable that a single large abscess may result from a single embolus obstructing a large vessel, just as multiple abscesses result from the obstruction of many smaller vessels.

often increased by taking a deep inspiration, or by the movements of the chest in sneezing, laughing, coughing, or even in speaking loudly. In some cases the patient complains also of a dull pain in the shoulder, a symptom mentioned in the Hippocratic writings.* The right shoulder is most frequently affected; and it has been suggested that this occurs when the abscess is seated in the right lobe, while if it is in the left lobe the pain affects the left shoulder.† This symptom is, however, an inconstant one, being perhaps more frequently absent than present, and sometimes arising from other causes.

The occurrence of pain in the hepatic region should lead immediately to careful physical exploration. In most cases, if there is an abscess, the area of hepatic dulness will be found to exceed its normal limits. In extreme instances the dulness may extend upward as high as the fourth rib or even higher, and downward as far as the line of the umbilicus or even lower. When there are many small abscesses the area of dulness corresponds in form to the usual outline of the liver; but in single abscesses of considerable size‡ the normal outline of the liver is often variously altered in accordance with the seat of the abscess and its size. Sometimes, where the collection of pus is large, bulging of the intercostal spaces may be observed, or the ribs may be pushed upward and outward so that the enlargement of the liver can be recognized by mensuration; in such cases fluctuation can generally be distinctly felt on careful manipulation. In a large proportion of the cases properly conducted physical examination will lead to a correct diagnosis.

The gradual enlargement of the organ from day to day can often be made out, and the rapidity with which it takes place will distinguish it from the enlargement due to echinococcus cysts or to cancer; but small multiple abscesses often exist in livers which are but slightly enlarged, and the same is also true of single abscesses of moderate size, or of the early stages of large abscesses. According to Rouis§ recognizable enlargement existed in but seventy-three of one hundred and twenty-two cases, and Frerichs|| states that cases have repeatedly come under his own notice, in which no alteration in the size and form of the organ could be recognized, there was no abnormal tenderness, and local examination furnished no data whatever for forming a diagnosis. It is not wonderful, therefore, that less skilful observers often fail to recognize hepatic abscesses during life, and first learn of their existence in the course of post mortem examination.

A short dry cough is another symptom frequently observed during the progress of hepatic abscess. It may be due merely to the mechanical interference with the respiratory functions resulting from the enlargement of the liver, or may be caused by the extension of irritation or actual inflammation to the diaphragm or pleura. For the same reasons the respiration is often hurried, and the patient sometimes complains of dyspnœa. Hæmorrhage from the bowels is another occasional symptom, and sometimes is the immediate cause of death. Finlayson¶ has recently discussed a case of hepatic abscess, uncomplicated by dysentery, in which this accident occurred. Case 92 in the last section is an example

|| F. T. FRERICHS—*Clinical Treatise on Diseases of the Liver*, Transl. of New Syd. Soc. of London, Vol. II, 1861, p. 124.

¶ JAMES FINLAYSON—*On the relationship of Abscess of the Liver to Gastro-intestinal Ulceration*, The Glasgow Medical Journal, Feb., 1873, p. 171. He shows that in this case the hæmorrhage took place into the colon. An old and apparently healing ulcer was found in the stomach, but the colon was not ulcerated. He argues that hepatic abscesses, by interfering mechanically with the portal circulation, produce congestion of the mucous membrane of the colon rather than of the small intestine, and that this favors the development either of hæmorrhage or of inflammation, and hence (inter alia) of dysentery. A similar series of results may ensue from the portal obstruction produced by cirrhosis of the liver.

of hepatic abscess complicating acute dysentery in which a profuse hæmorrhage from the bowels carried off the patient. In case 578, the patient "passed suddenly a pint or more of blood;" but in this instance the hæmorrhage did not prove immediately fatal. In both these cases the abscesses were large.

When hepatic abscess supervenes during the progress of dysentery it serves of course to aggravate the constitutional disturbance, and the patient not unfrequently perishes before the pus has had time to discharge. In other cases the patient survives long enough for the abscess to rupture, which it may do in any of the methods that occur in uncomplicated abscesses. Thus the pus may escape into the abdominal cavity, into the pleural sac, into the air passages, into the alimentary canal, or externally through the skin; or this event may be anticipated by puncture or the use of the aspirator. In any event, however, the prognosis is of course more grave than in uncomplicated abscess of the liver.

Complication with malarial fevers.—Dysentery frequently prevails simultaneously with malarial fevers, and under such circumstances the two diseases, variously combined, often coexist in the same individual. The flux may attack those whose health is more or less impaired by the influence of chronic malarial poisoning, as well as those who are suffering from intermittent and remittent fevers. Moreover, during the civil war dysentery appeared to prevail, especially in the more malarious districts. Like the malarial fevers, it was more frequent and more fatal in the Central than in the Atlantic region, and, in a general way, assumed a graver character in the Southern than in the Northern portions of each, so that the remarks, made in a previous portion of this section* on the relation between the malarial fevers and diarrhœa, are true of dysentery also. The consideration of these relations led me in former publications† to give a prominent place to malaria among the causes of dysentery; but I agree with Virchow‡ that it should be classed rather among the predisposing than the determining causes of that disease.

The malarial influence appears to favor the development of simple inflammatory or catarrhal affections of the intestinal mucous membrane. I do not think that Virchow exaggerates very much when he affirms§ that almost all the febrile conditions which occur in swampy regions during the warm months, or during the prevalence of intermittents, are accompanied by such intestinal disorders, and that these are only too readily aggravated into dysentery. But undoubtedly also intestinal catarrhs, which may or may not pass into dysentery, are very readily provoked under the same circumstances in individuals in whom no febrile condition has been developed prior to their occurrence. If periodic fevers should subsequently set in, the flux not unfrequently also manifests a periodic type; but even when uncomplicated by the fevers, the fluxes of malarial regions sometimes exhibit more or less distinct periodicity.

These circumstances did not escape the observation of the ancient physicians. In the account given by Hippocrates‖ of the diseases prevalent among those who dwell in marshy

‡ R. VIRCHOW—*Kriegstyphus und Ruhr*, Virchow's Archiv, Bd. LII, 1871, p. 30.

§ *Loc. cit.* Compare also his admirable article, *Historisches, Kritisches und Positives zur Lehre der Unterleibsaffektionen*, Virchow's Archiv, Bd. V, 1853, S. 354: "sicher ist es, dass fast alle fieberhaften Zustände, wenn sie in warmer oder wenigstens milder Jahreszeit in sumpfigen Gegenden oder unter der Herrschaft von Intermittenten auftreten, mit katarrhalischen Affektionen der Darmschleimhaut verbunden sind. Treffen diese einen mit Kothmassen viel beschwerten Darm, so sind wahrscheinlich oft die Bedingungen der Steigerung des bisher einfach katarrhalischen Processes zum dysenterischen gegeben."

‖ HIPPOCRATES—*Airs, Waters and Places*, § 7. [Ed. Littré, II, p. 29.] He attributed these diseases to drinking the water of the marshes or stagnant pools, and mentions enlarged spleens and dropsies, as well as fevers, as prevalent affections.

districts and in the vicinity of stagnant pools, he mentions that in summer they are frequently attacked with diarrhœas and dysenteries as well as by periodical fevers; and the assumption of an intermittent form by certain intestinal fluxes, as well as by other local disorders, is mentioned in the fragments which have been preserved of the writings of Archigenes.* Among the Arabian writers, periodical fluxes are spoken of by Haly-Abbas, Avicenna and Albucasis.† Mercatus (1586)‡ mentioned dysenteric stools among the dangerous symptoms which may occur in pernicious tertian fevers. I cannot, therefore, fully agree with Sprengel,§ according to whom Diomedes Cornarius (1599) was the first to describe the intermittent form of dysentery.

After the introduction of Peruvian bark into European medical practice, however, critical attention was directed afresh to the periodical fevers and their complications, among which diarrhœa and dysentery were found to occupy a conspicuous place. Thus, Richard Morton|| observed quotidian and tertian forms of dysentery during the London epidemics of 1666 to 1672, and described intermittent fevers as sometimes simulating cholera morbus, dysentery and other intestinal disorders. Torti (1709)¶ described forms of pernicious periodical fevers which were accompanied, especially during the paroxysms, by symptoms of cholera morbus, dysentery or the so-called hepatic flux, and made of this group of cases two of the seven species into which he subdivided the fevers in question; his account of dysenteric and atrabiliary tertians was substantially adopted by Burserius** and Alibert.†† Lancisius (1717)‡‡ saw dysentery prevail as a concomitant or sequel of the pernicious fever which was epidemic at Rome during the summer and autumn of 1695, and believed that it was often due to a translation or metastasis of the morbid influence which produced the fever.

---

* In the American edition of ZIEMSSEN'S *Cyclopædia* [Vol. II, p. 538] HERTZ is made to say, in his article on *Malarial Diseases*, that ARCHIGENES "makes mention of masked intermittents, especially when appearing in the form of dysentery or diabetes." I note that in the original [ZIEMSSEN'S *Handbuch der Spec. Path. u. Ther.*, Bd. II, Th. 2, Leipsic, 1874, S. 531] the passage reads: "er führt daneben auch verlarvte Wechselfieber (namentlich durch Magen- und Harnruhr) an." The statement and its phraseology appear to have been borrowed without acknowledgment from SPRENGEL—*Geschichte der Arzneykunde*, 3te Auflage, Bd. II. Halle, 1823, S. 107—whose language is: "Verlarvte Wechselfieber, besonders in Gestalt der Magenruhr, der Harnruhr, und der Katalepse, beobachtete er ebenfalls," and who verifies this statement by three references, viz: AETIUS, *Tetr.* 3, *Serm.* 1, *Cap.* 37; Ib., *Tetr.* 3, *Serm.* 3, *Cap.* 3; CAELIUS AURELIANUS, *Acut., Lib.* 2, *Cap.* 10. Looking up these references, I find that in the last the author speaks, on the authority of ARCHIGENES, of the occurrence of catalepsy with periodic type. The second reference is to the chapter in AETIUS headed, "*De his qui per circuitum quendam sanguinem mingunt: Archigenis*," which discusses not diabetes, but periodical hæmorrhage from the kidneys—"Quidam per circuitus quosdam sanguinem è renibus excernunt." The first reference is to the chapter in AETIUS headed, "*De cœliaca affectione, Archigenis*, in which the following passage occurs: "Nosse tamen oportet, quod aliquando quidem per circuitus malum hoc adfligit, temporibus quibusdam alvo restitante, quibusdam vero ordinate per certas horas fluente: aliquando vero incessanter apparet." I am obliged, therefore, to think SPRENGEL used the word "Magenruhr" in the passage cited above carelessly, since it properly means lientery rather than the cœliac flux. See, for example, in proof, the *Med. chir. Encyklopädie* of PROSCH und PLOSS, Bd. II, Leipsic, 1855, S. 588, or VOGEL—*Handb. der pract. Arzneywis*, Bd. VI, Stendal, 1816, S. 75; RICHTER, *Die spec. Therapie*, Bd. IV, Berlin, 1822, S. 146, and many other authorities might be cited. I note further that the French translator of SPRENGEL [JOURDAN, Paris, 1815, T. II, p. 77] erroneously renders the term "Magenruhr" by the expression "dyssenterie gastrique," which is properly the eqnivalent of "dysenteria gastrica." [*Vide* note †† to p. 395, *supra.*]

† HALY-ABBAS—*Lib. Totius Medicinæ*, &c., Lyons Ed., 1523, Serm. I, Pars 1, Lib. IX, Cap. 26. fol. 115—after distinguishing between intestinal and hepatic dysentery, says of the latter "nonnunquam ejus emissio sit per circuitus." AVICENNA—*Canon Med.*, Venice Ed., 1595, Lib. III, Fen. 16, Tract. 1, Cap. 2, p. 812—in a more general way mentions "fluxus ventris factus cum periodis," and ALBUCASIS—*Liber Theoricæ necnon Practicæ*, Augsburg, 1519, Tract. XVII, Sect. I, Cap. IX, fol. 78—speaks of "fluxus qui certis paroxismis insurgit."

‡ L. MERCATUS—*De Febrium Essentia, Differentia, Curatione, et de Febre Pestilentiali*, Valladolid, 1586, Lib. VI, Section on "Tertiana perniciosa;" I cite from Opera, Frankfort, T. II, 1619, p. 396—"Alvi fluxus dysentericus" is mentioned among the dangerous symptoms.

§ SPRENGEL—*Op. cit.*, Bd. III, S. 286. He cites DIOMEDES CORNARIUS—*Consil. Med.*, Leipsic, 1599, p. 28. I have not obtained access to this work. HERTZ, *loc. cit.*, borrowing this statement of SPRENGEL, makes a curious blunder in copying the citation, writing *Com. Lips.*, 1599, p. 28; but the first volume of the Leipsic Commentaries did not appear until 1752.

|| R. MORTON—*Pyretologia*, London, 1692, Appendix, p. 424 *et seq.* In Exerc. I, Cap. 4, p. 83, he speaks of intermittent fever "putting on the type of cholera morbus. griping diarrhœa, dysentery or simple vomitiug." He lauds the employment of bark in the treatment. His peculiar theory of the unity of febrile diseases, however, seems to have led him into exaggeration; for he speaks of intermittent fever as simulating scarlet fever, erysipelas, &c.

¶ FRANCISCO TORTI—*Therapeutice Specialis ad Febres Periodicas Perniciosas*, [Modena, 1709.] I cite the Venice Ed. of 1755. His species were: 1, Cholerica vel Dysenterica; 2, Subcruenta vel Atrabilaris; 3, Cardiaca; 4, Diaphoretica; 5, Syncopalis; 6, Algida; 7, Lethargica. See Lib. III, Cap. I, and Lib. IV, Cap. 1, 2 and 3.

** BURSERIUS—*Instit. Med. Pract.*, [Milan, 1781-5,] Hecker's Ed., Leipsic, 1826, T. I, p. 196. His description of Tertiana Dysenterica and of Tertiana Subcruenta vel Atrabilaris is avowedly modeled after TORTI.

†† J. L. ALIBERT—*Traité des Fièvres Pernicieuses Intermittentes*, 5me Éd., Paris, 1820. This writer, among a great variety of species, describes Fièvre pernicieuse intermittente cholérique ou dysentériqne, Ch. 1, Art. 1, and Fièvre pernicieuse intermittente hépatique ou atrabilaire, Ch. 1, Art. 2.

‡‡ J. M. LANCISIUS—*De Noxiis Paludum Effluviis*, [Rome, 1717,] Lib. II, Epidem. I, Cap. 5 and 12. I cite Opera, Venice, 1739, pp. 192 and 200.

The opinion that the poison, whatever it be, which causes the intermittent and remittent fevers is capable of acting upon the intestines under certain circumstances and of producing diarrhœa and dysentery, has been expressed by many subsequent writers upon malaria and the malarial fevers, as, for example, by Senac, Fournier and Bégin, Monfalcon, Macculloch, Mongellaz, Boudin and Barker.* Even those who, like Griesinger and Hertz,† have been unwilling to commit themselves to this theory of causation, testify to the frequency with which dysentery and other fluxes occur in malarial regions, especially during the prevalence of the periodic fevers.

It would be easy to multiply examples of the epidemic or endemic occurrence of dysentery in association with intermittent and remittent fevers in various parts of Europe. The observations of Pringle, Roederer and Wagler, Donald Monro, Harty, Cheyne, Biermann, Kicker, Boullet, Baly, Gestin, Champouillon and Chollet‡ may be cited in illustration, and several other instances are mentioned by Molo§ in his account of epidemics of intermittent fever. The testimony of these writers shows that the combinations of the malarial fevers with dysentery may occur even in the temperate zone, but it is especially among Europeans in tropical climates that they have attracted attention.

In tropical regions dysentery is not only more prevalent and more fatal than in temperate latitudes, but it is very much more frequently associated with the periodical fevers. It is, moreover, especially apt to prevail in those districts in which these fevers are endemic, and at the time of year when they are most frequent and fatal. These circumstances have not unnaturally led many of the physicians who have observed and described tropical diseases to embrace the opinion that the malaria which produces the fevers is also capable of giving rise to dysentery, and that a part at least of the tropical dysenteries are due to this cause. Without attempting to enumerate all the adherents of this doctrine, I may cite Chisholm ||

‡ PRINGLE—*Obs. on the Diseases of the Army*, 7th Ed., London, 1774, Part III, Chap. 6, § 3, p. 253—although he believed dysentery to be due to a specific contagion, was struck with the fact that during the campaigns of the English army in Flanders (1742–8) dysentery often occurred under the same circumstances as intermittent and remittent fevers, and that these fevers "sometimes ended in a bloody-flux." ROEDERER et WAGLER—*De Morbo Mucoso*, Gottingen, 1762, Sect. 1, § 6, p. 21—found the two diseases so associated during the Gottingen epidemic of 1760 that they called dysentery the daughter of intermittent fever. DONALD MONRO—*Diseases in the British Military Hospitals in Germany*, 1761–3, London, 1764, p. 63—"Oftentimes the bilious and malignant fevers terminated in the dysentery; or were accompanied with it, when it might be looked upon as a symptom of these fevers." WM. HARTY—*Obs. on the simple Dysentery and its Combinations*, London, 1805. The combinations described are with intermittent and remittent fever (Ch. 2) and with typhus, (Ch. 3.) The latter he regards as the only contagious variety of dysentery, (Ch. 4.) J. CHEYNE—*Med. Report of the Whitworth Hospital*, Dublin Hospital Reports, Vol. III, 1822, p. 1—expresses substantially the same opinion in his account of the Dublin epidemic of 1818. BIERMANN [Land- und Stadtphysikus at Peine in Hannover]—*Bemerkungen über eine in dem Bezirke meines Physikats im August und September dieses Jahrs herrschende Ruhr-Epidemie, complicirt mit Wechselfieber*, Med. Conversationsblatt, [of Hohnbaum and Jahn,] March 24, 1832, p. 88. ANTON KICKER [Kreisphysiker at Grätz]—*Bericht über die in den Bezirken Gutenhaag und Negau des Marburger Kreises in Steiermark vom 6. Sept. bis inclusive 8. Nov.* 1841 *geherrschte Ruhrepidemie*, Med. Jahrbücher des k. k. österreich. Staates, N. F., Bd. 34, 1843, S. 129. MAX. BOULLET—*Sur les causes d'une épidémie de dysenterie qui a régné dans un village de la Sologne, pendant l'automne de* 1836, Ann. d'Hygiène, T. XIX, 1838, p. 205. Most of the cases of dysentery in this epidemic either occurred as a sequel to intermittent fever or were accompanied by it in the same individuals. Sulphate of quinia was found to be a valuable remedy. This paper and the next two are worthy of special attention. WM. BALY—*Gulstonian Lectures. Lecture* 3, London Med. Gazette, Vol. IV, 1847, p. 530—"the dysentery observed in the Penitentiary at Millbank is really produced by malaria." H. GESTIN—*Épidémie de dysenterie dans le Canton de Pont-Aven, (Finistère,)* Archiv. Gén. de Méd., July, 1858, p. 5. This canton of Brittany is annually subject to intermittent fevers. The epidemic described occurred in the autumn of 1856; a large proportion of the cases were accompanied by intermittent and remittent fevers. CHAMPOUILLON—*Armée d'Italie—Diarrhée, dysenterie, fièvre intermittente en* 1859, Gazette des Hôpitaux, Nov. 8, 1859, p. 517. In the first corps of the French army, towards the end of July and the beginning of August, "la fièvre intermittente vint compliquer la plupart des cas de dyssenterie aiguë ou chronique." He derived advantage from the use of quinia in these cases. F. M. CHOLLET—*Étude sur une épidémie de dysentérie*, Paris Thesis, No. 45, 1874—in describing a little epidemic which broke out in August, 1871, at Pléchâtel, some 20–25 kilometres from Rennes, says that intermittent fever was the most frequent of the complications observed.

as having maintained it for the dysentery of the West Indies; Annesley, Grant, Hare and Cameron * for that of the East Indies; Haspel† for the dysentery of Algeria; and Sigaud‡ for that of Brazil.

But this view appears after all to have been based upon an incomplete survey of the facts. While it is true that dysentery often prevails in malarial districts along with the malarial fevers, it is also true that it occurs where these fevers are almost or quite unknown, and that in some districts in which they are endemic, dysentery is rare. Dutroulau§ has adduced examples of both kinds in his treatise on the diseases of Europeans in warm countries, and Hirsch|| has based upon these and similar cases which he has collected, a valid argument against the hypothesis that malaria stands in an immediate causal relation to dysentery. Even the English physicians in India, notably Morehead and Martin,¶ begin to abandon the opinion that malaria is an exciting, and speak of it only as a predisposing, cause.

Colin** has recently attempted to prove that it is the use for drinking purposes of the water, impregnated with decomposing organic matters, which is so often found in marshy regions, that causes the intestinal catarrhs and dysenteries which occur in these districts, while the malarial fevers are the result of ærial emanations. This suggestion, if true, would afford a solution of many facts, especially in military experience, which are now difficult of explanation; but I am not satisfied that the argument by which it is supported does more than give it a certain air of probability as an ingenious hypothesis; and this hypothesis, it must be admitted, is hardly consistent with the facts to be presently brought forward with regard to the distribution of dysentery in time of peace among the civil population of the United States.

Nevertheless, it cannot be doubted that when the causes of dysentery act either upon a civil population or an army, those individuals whose resisting powers are diminished by debilitating constitutional conditions of any kind are especially prone to become victims, and in these cases the ordinary symptoms of dysentery are often complicated by phenomena resulting from the other morbid influences, whatever they may be. When the debilitating influence is malaria, whether expressed merely by the constitutional cachexia which may be described as chronic malarial poisoning, or by the actual existence of intermittent or remittent fevers, the ordinary course of dysentery is complicated by phenomena belonging to the malarial disease. Such complicated cases have been described by many American

** LÉON COLIN—*De l'ingestion des eaux marécageuses comme cause de la dysenterie et des fièvres intermittentes*, Ann. d'Hygiène, T. 38, 1872, p. 241. I may add that N. CHAPMAN—*Remarks on chronic fluxes of the bowels*, American Journal of the Med. Sci., Vol. XIX, 1836, p. 86—mentions as a popular notion the belief that drinking the waters of the Mississippi was the cause of the chronic fluxes then of frequent occurrence in New Orleans. The opinion that drinking the waters of malarial regions may cause fluxes dates back to HIPPOCRATES; see note to p. 398, *supra*.

writers on dysentery since Sayre* reported that he had observed febrile exacerbations of a tertian type in an epidemic of dysentery at Bordentown, New Jersey, in 1792, and Currie† affirmed in 1811, that "in the Southern States of this country nothing is more common than to meet with patients with symptoms characteristic of the existence of dysentery and bilious fever at the same time."

Without attempting to enumerate all the American physicians who have published such observations, I may cite as examples the papers of Bowling, Long, H. W. Davis, Campbell, Evans, Dowell, Bemiss, N. S. Davis and Jones,‡ a list which it would be easy to enlarge. Nor is it surprising that some of these writers should have fallen into the error of believing both the dysentery, and the periodic phenomena with which it was accompanied, to be due to malaria as their common cause. H. W. Davis, Dowell, Jones, and especially Campbell,§ may be cited as having taken this view. Campbell bases upon it his strenuous advocacy of the use of quinine in the treatment, which is adopted for the same reason by H. W. Davis and Dowell. Even those who do not accept the malarial theory of causation have recognized the value of quinine in those cases of dysentery which complicate malarial conditions or are complicated by them. Of the writers referred to above, I may mention Evans and Bemiss as having taken this view, which was endorsed by several of the speakers in a recent meeting of the Central Kentucky Medical Association.‖ In time of peace, then, as well as during the civil war, the complication of dysentery with malarial fevers has frequently been observed in America.

During the war this complication was even more frequently observed than previously, because the great armies, moved suddenly from the Northern States into the malarial regions of the South, were exposed simultaneously to malarial influences and to the causes of dysentery. In the resulting compound, or hybrid forms of disease, the symptoms resulting from each cause often appeared together in the same individual from the beginning of the case to its end. Sometimes, however, dysentery, either of itself or as a sequel to diarrhœa, appeared as the primary disorder, assuming subsequently a periodic form either as to the flux itself or as to the accompanying fever; or ague or remittent fever made its appearance during convalescence from dysentery, or after it had become chronic.¶ In other cases the periodic fevers were the primary morbid condition, and dysentery alone, or preceded by diarrhœa, set in only after the health had been broken down by long con-

Jour., Evansville, Vol. I, 1854, p. 29, and *Medical Miscellanies*, Nashville Jour. of Med. and Surg., Vol. XIII, 1857, p. 377—who holds the opinion that the malaria acts by causing portal congestion, and bases on this view his recommendation of sulphate of magnesia as the most important article in the treatment. H. W. DAVIS, cited in the last note, also takes the view that the malaria acts by primarily producing portal congestion.

‖ See Abstract of Proceedings, in the Richmond and Louisville Medical Journal, Vol. XVIII, 1874, p. 664.

¶ Compare the account of the combinations of intermittent fever with dysentery given by NAUMANN—*Handbuch der med. Klinik*, Bd. IV, Abth. 2, Berlin, 1835, S. 16; also the statement made by PARKES—*Dysentery and Hepatitis of India*, London, 1846, p. 126—of the modes in which he observed the malarial fevers complicate diarrhœa and dysentery in India. "The following are the chief varieties: 1. Regular ague with dysentery; the ague being generally of the quotidian or tertian type. 2. Irregular ague (that is, ague with short irregular intervals) with dysentery. 3. Either of these forms with asthenic diarrhœa. 4. Common bilious remittent fever with diarrhœa or dysentery. 5. Malignant remittent with diarrhœa or dysentery."

tinued ague, or after remittent fever had first been developed. Lastly, in yet other cases the malarial influence manifested itself by the production of chronic malarial poisoning; the resulting cachexia, whether existing by itself or associated with the mild scorbutic taint, which was so widely spread among our troops, especially after the first year of the war, undoubtedly appeared to favor the development of dysentery, as it did of diarrhœa. The subjects of this cachexia seemed less able to resist the causes of the disease than healthy men, and once developed in them, dysentery, even in its simple catarrhal forms, was more apt to become chronic and to prove fatal.

In a general way, then, the relations of the malarial diseases to dysentery were very similar to those which existed between these diseases and diarrhœa, on which comment has already been made. A striking description of one form of malarial complication will be found in Section II of this Chapter in the account given by Surgeon W. W. Brown, of the dysentery observed by him in the 7th New Hampshire regiment at St. Augustine, Florida.* A similar form was observed by Surgeon M. R. Gage† in the 25th Wisconsin regiment at Columbus, Kentucky. A milder variety was described, under the designation malarial dysenteric diarrhœa, by Surgeon J. L. Taylor,‡ as occurring in the 3d Missouri cavalry at Little Rock, Arkansas. Surgeon David Merritt§ saw in the 55th Pennsylvania, while stationed at Beaufort, South Carolina, numerous cases of intermittent fever complicated by periodical discharges from the bowels of a dysenteric character, which quinine alone was often sufficient to cut short. Most of the cases of dysentery observed by Surgeon H. P. Strong‖ in the 11th Wisconsin regiment, while encamped near Des Arc, Arkansas, were remittent in their character. Surgeon C. A. Hunt¶ saw numerous cases of malarial fevers complicated by dysentery in the 126th Illinois regiment at Jackson, Tennessee. These fragmentary reports, however, give no just idea of the extent to which the complications under consideration were observed, or of the number of those who, like several of the reporters in Section II,** were led to believe dysentery to be of malarial origin. A similar opinion was expressed by Assistant Surgeon Coues†† with regard to an epidemic at Columbia, South Carolina, in the fall of 1868, which may be taken as a type of many of the local outbreaks of dysentery that occurred in our camps and garrisons during the war.

Complication with typhoid and typho-malarial fevers.—During the civil war dysentery constantly appeared side by side with the continued fevers in the same command and at the same time; and as large numbers of men were simultaneously exposed to the causes of the malarial fevers, of typhoid fever and of dysentery, it is not surprising that two or more of these morbid conditions often coexisted also in the same individual. The complication occurred much in the same way as the complication with the malarial fevers; that is, the continued fever and dysentery ran their course simultaneously, or either appeared as the primary disorder to which the other was subsequently superadded. Not only has the occurrence of these several combinations of dysentery with the adynamic fevers long been recognized by medical writters, but a tendency has existed in certain quarters to over-estimate their frequency, by confounding the adynamic febrile symptoms which are not unfrequently developed in connection with certain forms of dysentery, especially the diphtheritic variety, with true typhoid or even typhus fever; an error which has undoubtedly been favored by the peculiar characters assumed by dysentery during certain epidemics.

---

* Page 81, *supra*. † Page 93, *supra*. ‡ Page 86, *supra*. § Page 81, *supra*. ‖ Page 84, *supra*. ¶ Page 94, *supra*.
** See, for example, in Section II, besides the reports cited, those of VOLLUM, p. 76, GALL, p. 79, and BRETZ, p. 80. †† Page 62, *supra*.

This belief was the natural result of the teachings of Sydenham,* who had called attention to the close resemblance between the fever that accompanies dysentery, when it exists as an epidemic, and the other prevailing fevers of the same region and year. Zimmermann † enlarged upon this view, and divided acute dysentery into three genera: that which is accompanied by an inflammatory fever; that which is accompanied by a putrid or bilious fever, and that which is accompanied by a malignant fever. Harty and Cheyne ‡ especially emphasized the combinations of dysentery with typhus, which they regarded as the only contagious form of dysentery. Fournier and Vaidy § affirmed that dysentery complicated with typhus was the most common form of the dysentery of armies. They regarded it as eminently contagious, and suggested for it, though with great apparent hesitation, the designation typhous [typheuse] dysentery. Vignes || closely followed their description of this form of dysentery, which he named the typhoid variety, and endeavored to distinguish it, as they had done, from the adynamic and ataxic forms.

Subsequently, while some writers, among whom I may mention Copland,¶ continued to employ the term typhoid dysentery to designate but one of several adynamic varieties of the disease, others, like Naumann,** embraced under the head of putrid or typhous dysentery all the various adynamic and malignant forms. So intimate did the relationship between dysentery and typhus appear, indeed, that Eisenmann †† went so far as to describe dysentery in general as a mere variety of typhus, Colotyphus or Ruhrtyphus, regarding it as simply a local expression of the action of the typhous miasma or contagion. But one of the consequences of the comparison of clinical observation with the results of pathologico-anatomical investigations, which has characterized the medical researches of the present century, has been to make it quite clear that the constitutional symptoms which accompany diphtheritic dysentery often closely resemble those which were formerly regarded as sufficient proof of the complication of the disease by typhus. ‡‡

Moreover, the discovery of the peculiar lesion of Peyer's patches, which is the characteristic feature of typhoid fever, and enables it to be quite positively distinguished from spotted typhus on post mortem examination, has afforded an anatomical criterion for deciding the question of the complication of dysentery with typhoid fever—the form of typhus that most generally prevails in France and Germany as well as in the United States. The application of this anatomical criterion has so frequently shown the total

** M. E. A. NAUMANN—*Handbuch der med. Klinik*, Bd. IV, Abth. 2, Berlin, 1835, S. 20—"Die faulige Ruhr (die brandige, die Lagerruhr; Dysenteria nervosa, asthenica, typhosa, septica, putrida, colliquativa, castrensis, pestilentialis, Fluxus virulentus.") The same view is adopted by G. C. F. HAUFF—*Zur Lehre von der Ruhr*, Tübingen, 1836, S. 276—who gives nearly the same synonyms, adopting himself the designation "die typhöse Ruhr," which is also employed in the same sense by H. BRESSLER—*Die Krankheiten des Magens und Darmkanals*, Berlin, 1841, Bd. I, S. 502.

†† EISENMANN—*Die Krankheits-Familie Typhus*, Erlangen, 1835, S. 362 *et seq.*

‡‡ Even in modern times, with all our improved methods of clinical observation, cases will occasionally occur like the one recorded by H. FREY—*Klinische Mittheilungen*, Zeitschrift für Rat. Med., Bd. V, Heidelberg, 1846, S. 187—in which the symptoms so closely resembled those of typhoid fever as to give rise to the belief that this was the disease, but in which, on the autopsy, the dysenteric process was found to be present in the colon to a marked degree, while the characteristic lesions of typhoid fever were entirely absent. Such errors of diagnosis will no doubt occur to the best observers, but I fear that a great many of the instances in which typhoid fever was entered on the hospital records during the late war, although the patient was in fact suffering from dysentery, as was subsequently shown by the autopsy, were not so excusable.

absence of the characteristic lesion of Peyer's patches in cases of so-called typhoid dysentery occurring under circumstances in which the non-existence of any cases of spotted typhus quite excluded the suspicion of complication with that disease, that Rokitansky * has even expressed the opinion that dysentery does not easily enter into combinations with the true typhous process—an opinion shared by Savignac,† who has expressed his belief that the complication of dysentery with typhoid fever is excessively rare.

That this complication may, however, actually exist, was, after the anatomical characteristics of typhoid fever had been established, first anatomically shown by Trousseau and Parmentier,‡ who, in 1826, observed the coexistence of the typhoid lesions with those of dysentery in two cases. Numerous observations of the same kind have since been made by Parkes,§ in India, by Baly || at the Millbank penitentiary, by Finger ¶ during the epidemic of dysentery in the hospital at Prague, and by Lyons in the Crimea.** The latter, especially, has brought forward satisfactory evidence that in military experience, at least, the complication in question can hardly be considered a rare one. Colson †† has reported a number of similar cases observed in the French penal colony in Cayenne, and Herpain and Périer ‡‡ have also each observed the coexistence of the characteristic lesions of typhoid fever and dysentery during the epidemic prevalence of the two diseases.

Accordingly, in most modern text-books §§ typhoid fever is now enumerated among the diseases which, by combining with dysentery, may modify its symptoms and progress; but it is probable enough that this complication is far less frequent in civil life than in armies, and that in armies it is especially to be looked for in time of war. Certainly our experience in this respect during the civil war corresponded with that of Lyons during the Crimean war, and the frequent coexistence of the two diseases in the same subject was not only made probable by clinical observation, but was established by numerous post mortem examinations, from a number of which specimens have been preserved in the Army Medical Museum.

† J. D. DE SAVIGNAC—*Traité de la Dysenterie*, Paris, 1863, p. 104.

‡ A. TROUSSEAU et H. PARMENTIER—*Mém sur une épidémie de dysenterie qui a régné dans le département d'Indre-et-Loire en* 1826, Archiv. Gén. de Méd., T. XIII, 1827, p. 377, and T. XIV, 1827, p. 33. The cases referred to will be found in the second paper, Obs. XIV and XV. The authors cite from MORGAGNI—*De Sedibus et Causis*, Epist. 31, § 2—a third case, in which the symptoms of typhoid fever came on some little time after the patient had suffered from those of dysentery, and in which on the autopsy ulceration and perforation of the ileum and ulceration of the colon were observed. In commenting on these cases the authors remark that the lesions of dysentery and those of the glands of Peyer are seldom found in the same subject.

§ E. A. PARKES—*Dysentery and Hepatitis of India*, London, 1846, p. 123. "In other cases there is enlargement and ulceration both of Peyer's and of the solitary glands, and general gastroenteritis." Singularly enough he only observed this complication in the scorbutic cases.

|| BALY—*Gulstonian lectures on dysentery*, London Med. Gazette, Vol. IV, 1847, p. 470.

¶ FINGER—*Die epidemische Ruhr*, Prager Vierteljahrschrift für die prakt. Heilk., Bd. 24, 1849, S. 135—asserts that during this epidemic both spotted and abdominal typhus complicated dysentery; sometimes the two diseases occurred together, sometimes dysentery attacked the convalescents from fever. In all, 231 post mortem examinations were made; in three cases typhoid infiltration and ulceration were observed in the ileum, while the characteristic dysenteric lesions existed in the colon. In eight other dysenteric cases the typhus or typhoid fever had run its course before death, and in the typhoid cases only cicatrices or pigment deposits remained; in the typhus cases no characteristic mark of its having existed was found.

** R. D. LYONS—*Report on the Pathology of the Diseases of the Army in the East*, London, 1856, p. 53—stated that he found in a number of instances on post mortem examination that extensive changes, attributable to typhoid fever, coexisted with the lesions of dysentery, and expresses the opinion that in the majority of instances dysentery was the primary disease, and typhoid fever was developed subsequently. See also the tabulated results of post mortem examinations in dysentery, p. 30 *et seq.*

†† COLSON—*De la dysenterie typhoïde*, Gaz. des Hôpitaux, Jan. 19, 1858, p. 26—records four cases observed in Cayenne; typhoid symptoms complicated the flux during life, and after death, besides the indications of the dysenteric process in the large intestine, thickening and inflammation of the patches of Peyer were observed in the ileum. In a former report quoted by SAVIGNAC, *loc. cit.*, which I have not seen—*Rapport médical sur les maladies qui ont régné sur l'établissement pénitentiaire de l'Ilet-la-Mère, du 20 août, 1853, au 6 août*, 1854, Montpellier, 1855—COLSON reports seven deaths occurring at the same place in which similar conditions were observed. In 1847, according to H. D. ERHEL—*Étude sur la dysenterie*, Paris Thesis, No. 254, 1851, p. 43—an epidemic of typhoid fever broke out at Taïti at a time when dysentery was also raging. The two diseases are said to have complicated each other in a small number of cases, but post mortem examinations do not appear to have been made.

‡‡ HERPAIN—*Hist. de la dys. épidémique qui a régné à Saint-Hubert en* 1863, Brussels, 1863. J. PÉRIER made his observations in the camp at Chalons in 1859. I have not found either paper, and quote from A. BARRALLIER—Art. *Dysenterie* in Nouveau Dict. de Méd. et de Chir. Prat., T. XI, Paris, 1869, p. 744—who, however, holds to the opinion of SAVIGNAC that the complication in question is very rare.

§§ See, for example, HEUBNER—*Dysentery*, in ZIEMSSEN'S Cyclopædia, Amer. Edit., Vol. I, New York, 1874, p. 555, or AITKEN—*Science and Practice of Med.*, 3d Amer. Edit., Vol. II, 1872, p. 651.

It will be most convenient to analyze the observations on this subject which were collected during our civil war in a subsequent chapter, after the characteristic lesions of fever have been fully discussed. Let it suffice to remark in this place that it was so common to find the characteristic lesions of typhoid fever in the ileum in cases in which the characteristic lesions of dysentery existed in the colon, that I have been led to the opinion that the combination of these diseases is exceedingly frequent in the camps of all armies in which typhoid fever is the prevailing variety of typhus; nor do I doubt that a similar combination with spotted typhus occurs in those countries in which this is the dominant form of typhus. Similar combinations with typho-malarial fever will be discussed in the chapter in which that form of fever is described.

Complication with scurvy, or the scorbutic taint.—The complication of dysentery with openly pronounced scurvy was not very frequently observed during the late civil war; but a widespread scorbutic taint existed among the troops, especially after the first year of the war, either by itself or variously combined with chronic malarial poisoning. Both catarrhal and diphtheritic dysentery were common enough among men suffering from either or both of these cachexias, and both were then especially apt to prove fatal or to degenerate into a chronic flux. The anatomical characters of such dysenteries offered, however, no essential differences from those occurring in subjects free from these taints. Perhaps serous effusions into the cavities of the abdomen and chest and adynamic inflammations, especially of the lungs and serous membranes, are more frequent when the scorbutic complication is well marked; but these complications offer no characteristic lesion, the presence of which in the corpse is a positive proof that the scorbutic lesion existed during life. The subject of the relation of scurvy and of the scorbutic taint is an important one, but it seems most convenient to postpone its consideration to the chapter on scurvy.

Complication with inflammations of the respiratory organs.—Bronchitis and pneumonia were common complications of acute dysentery during the war, particularly of the diphtheritic form. They occurred under the circumstances mentioned in connection with acute diarrhœa, but also as intercurrent complications of the advanced stages of the disease.* The latter was especially the case with pneumonia, which involved one or both lungs, and occurred with or without accompanying pleurisy. Pleurisy sometimes, but more rarely, made its appearance without pneumonia. These affections, when developed in the course of dysentery, exhibited no peculiarities which would make any special description necessary. The pneumonia usually exhibited itself in the lobar (croupous) form, and occurred most frequently in the colder seasons of the year. It will be shown hereafter that the lesions characteristic of this form of pneumonia were found after death in about one-fifth of all the autopsies of acute diphtheritic dysentery reported during the war.† Embolic pneumonia also sometimes occurred in the course of the diphtheritic cases, but was a comparatively infrequent complication.

Complication with rheumatism.—It was common enough during the civil war for patients afflicted with diarrhœa and dysentery, in their chronic forms especially, but also in acute cases, to complain of rheumatic pains in the back and limbs. I shall endeavor to

* These intercurrent complications occur quite independently of any such suppression of the dysenteric discharge, as was supposed in the Hippocratic era to precede their occurrence.—*Prenotions of Cos*, Sect. II, § 453, [Ed. Littré, V, p. 687:] "A dysentery checked in an untimely manner produces inflammation (ἀπόστασις) in the chest, (ἐν πλευροῖσιν,) the viscera, or the joints. Does bilious dysentery produce it in the joints, and bloody dysentery in the chest or viscera?"

† I shall show hereafter that this great frequency of intercurrent pneumonia is an unusual circumstance in dysentery, resulting probably from the excessive exposures of the civil war.

show in the chapter on scurvy that in great numbers of these cases the pains were not truly rheumatic, but were phenomena of the scorbutic taint, either existing alone or combined with chronic malarial poisoning. In my treatise on Camp Diseases* I proposed the term Pseudo-rheumatism as a convenient one to designate this group of cases. I am far, however, from doubting that the exposures of the war developed numerous cases of genuine rheumatism among those predisposed to that disease; and there is evidence enough that genuine rheumatism may complicate acute dysentery either during its progress or more especially during convalescence.

Sydenham observed, during the dysentery of 1672 in London, that in many cases the patients complained of pains in the muscular parts of the body, and especially in the joints, which he compared to the pains of rheumatism.† Similar observations were made by Akenside, Zimmermann and Lépecq de La Cloture,‡ but it was especially Maximilian Stoll § who directed attention to the complication of dysentery with rheumatism. His peculiar doctrine of the rheumatic nature of dysentery has already been referred to, and it was then mentioned that his descriptions appear to indicate that he had actually observed cases in which dysentery was variously combined with rheumatism as we now understand it. The influence of his authority undoubtedly induced many of his followers to interpret pains of any kind occurring during the progress of dysentery as rheumatic, and thus, for a time, exaggerated importance was attached to the supposed relationship between rheumatism and dysentery, while the subsequent reaction against this error has caused the occasional occurrence of rheumatic complications to be too generally overlooked. The actual existence of this complication is shown not merely by the occurrence of vague pains in various parts of the body, but by the development of well marked painful rheumatoid swellings of the larger joints.

Trousseau || in modern times has directed attention anew to this accident, and has expressed the belief that these swellings affect the knees more frequently than any other joints. According to him the swelling is occasionally accompanied by effusion into the joint, sometimes so considerable as to produce a rupture of the capsule; but he admits that most generally the rheumatic fluxion, whether in the joints or elsewhere, is quite transitory and erratic, flying from one part to another. He embraces these cases under the designation "forme rhumatismale," and Savignac ¶ has described them under that of "forme rhumatoïde."

In 1854 an epidemic of dysentery occurred in the Canton of Montargis in France, in which, according to Huette, complications of this kind were unusually frequent. Huette **

† SYDENHAM—*Med. Obs.*, Sect. IV, Ch. 4, Transl. of Syd. Soc., Vol. I, London 1848, p. 179. NAUMANN—*Handb. der med. Klinik*, Bd. IV, Abth. 2, Berlin, 1835, S. 13—fell into the error of stating that this complication was observed by FORESTUS—*Obs. et Cur. Med.*, Lib. XXII, Obs. 19—but this observation, entitled "De fluxu ventris ex rheumatismo capitis vel catarrho orto," refers merely to a flux supposed to arise from the flowing down of a catarrh or rheum from the head, as explained *supra*, p. 340 *et seq.*, and not to what we now understand by rheumatism.

‡ AKENSIDE—See tract cited *supra*, on p. 342. ZIMMERMANN—*Von der Ruhr unter dem Volke im Jahr* 1765, Zurich, 1767, S. 17—compared the pains to those of a flying gout: "Andere befiel die laufende Gicht." L. LÉPECQ DE LA CLOTURE—*Coll. d'Obs. sur les Maladies et Constitutions Épidémiques*, Rouen, 1778, Part. II, p. 745—described an epidemic of dysentery at Caen and its vicinity, also in 1765, which he says often terminated in swellings of the joints similar to those of gout. Some of these suppurated, and such cases occasionally proved fatal, as he was informed by several of his fellow practitioners.

¶ SAVIGNAC—*Traité de la Dysenterie*, Paris, 1863, p. 159.

** HUETTE—*De l'Arthrite dysenterique*, Archiv. Gén. de Méd., T. XIV, 1869, p. 129. He explains his use of the term arthrite by the remark "under the designation *arthrite dysenterique* we will describe the rheumatismal accidents which may manifest themselves in the joints during the course of epidemic dysentery or a little while after its cure." He states that he has looked for this complication in a number of epidemics since 1854, but never met it again. A very interesting abstract of this paper will be found in the Boston Med. and Surg. Jour., Jan. 13, 1870, p. 47, under the head of Dysenteric Arthritis.

relates the particulars of ten cases in which he observed well marked rheumatic swellings of the larger joints. In but two of these cases was there any previous history of rheumatism. The rheumatic symptoms appeared at any time after the second week of the dysentery, and usually affected several of the joints, especially the shoulder, knee or ankle, either simultaneously or successively. He regarded this form of rheumatism as similar in its symptoms and progress to gonorrhœal rheumatism, the chief difference being that the latter is usually limited to a single joint, or at most to two, while dysenteric rheumatism attacks several either simultaneously or in succession.

This comparison of course suggested to him the opinion that the intestinal affection was the cause of the rheumatic complication, but while he affirmed this to be the case, he frankly admitted that in certain epidemics only does it possess this power. As such epidemics he regarded that of 1765, described by Lépecq de La Cloture and Zimmermann; that of 1776–1777, described by Stoll; that of 1835, described by Thomas;* and that of 1854, which served as the basis of his own description.

Whether these are properly to be regarded as the principal epidemics of the kind or not, there appears to be no doubt of the fact that the rheumatic complication under consideration occurs with unusual frequency in certain epidemics. This appears to have been the case in the vicinity of Bloomfield, Ohio, during the epidemic year 1851. During that epidemic Mendenhall† observed many instances in which rheumatic inflammation of several of the larger joints occurred as a sequel to dysentery, and gives the particulars of two of them. I must confess that my own study of the literature of this subject inclines me to believe with Barrallier,‡ that the rheumatic symptoms occasionally observed in connection with dysentery are at best but an incidental complication, and that the two diseases when they exist together exercise little influence over each other's character or progress. Rheu-

* S. THOMAS [of Tours]—*Recherches sur la dysenterie*, Archiv. Gén. de Méd., T. VII, 1835, p. 455; T. VIII, 1835, p. 157; T. IX, 1835, p. 19. HUETTE cites from the second article a case—*Obs. V*—in which during the course of a fatal dysentery, in a man 21 years old, all the joints became successively painful and some of them the seat of purulent infiltration; the right knee and left wrist were laid open by a bistoury. To these particulars I may add, from the original paper, that the right thigh and left buttock were infiltrated with pus, and that a vast purulent collection formed over the sternum. On the autopsy extensive destruction of the mucous membrane of the cæcum and colon, which laid bare the muscular coat in many places, was observed. The left pleural sac contained a large quantity of serum and was lined by soft pseudomembrane. Accumulation of purulent fluid and erosion of the cartilages were observed in the sterno-clavicular articulations, the right shoulder joint, the left wrist and the right knee, and collections of pus over the sternum and in the buttock and thigh. Surely this was not a case of mere rheumatic complication, but rather an example of extensive metastatic suppurations. BRAUN—*Beob. über Kniegelenkswassersucht*, Würtemb. med. Correspondenzblatt, Bd. VII, 1837, S. 52—reports that he observed at Stammheim, during the years 1833 and 1834, more than 40 cases of rheumatic pain and swelling of the knee, chiefly in males who were recovering from the then prevailing dysentery. He regards the joint trouble as a metastatic sequel (metastatisches Folgeübel) of the dysentery. The patients were, as a rule, poor people who had resumed work during convalescence, and the knee trouble set in after a few days' labor. WITOWSKY—*Schluss-Rapport über die Ruhr-Epidemie, welche in der 2ten Hälfte des Jahres 1846 im bunzlauer Kreise auf den Dominien: Nawarow, Semil, Jesseney, Morchenstern, Grossrohosetz und Grossskal geherrscht hat*, Prager Vierteljahrschrift, 1847, Bd. IV, S. 35—on the other hand reports (S. 44) that in the epidemic observed by him the rheumatic joint-complication frequently occurred at the beginning of the dysenteric attack, or at any time during its progress as well as during the convalescence.

† S. C. MENDENHALL—*Rheumatic inflammation as a sequel of dysentery*, Ohio Med. and Surg. Jour., Vol. IV, 1851–2, p. 376. After relating two cases somewhat briefly but clearly, he remarks: "Within the last ten months I have treated many such cases." He concludes: "Of two points I am confident—the disease is intimately connected with the antecedent intestinal disorder. It is radically different from the common forms of acute rheumatism."

‡ A. BARRALLIER—Art. *Dysenterie*, Nouv. Dict. de Méd. et Chir. Prat., T. XI, Paris, 1869, p. 749. In addition to the papers cited, I may add the contributions of RAPMUND—*Einige Fälle von Gelenkentzündung in Folge von Ruhr*, Deutsche Klinik, April, 1874, p. 132—and QUINQUAND—*Des manifestations rhumatoïdes de la dysentérie*, Gaz. des Hôpitaux, 1874, pp. 419, 442, 650 and 658. RAPMUND, during an epidemic which prevailed in the fall of 1872 in the vicinity of Minden, attacking about 400 persons, saw six cases of the rheumatic complication occurring in convalescents from dysentery. The knee-joint was always first affected, afterwards in a few instances the ankle. One patient only (a woman who had previously suffered with polyarthritis) had also both wrists involved. All the patients had suffered from colds or exposures, which might be regarded as the causes. The author regards this complication as a subacute synovitis serosa, which he thinks is not true rheumatism, differing from it in the absence of the characteristic sweats, cardiac symptoms, &c. QUINQUAND makes four sporadic cases the occasion for an elaborate article, the historical portion of which betrays ignorance of ancient medicine. He appears to imagine the word rheumatism to have been used by the Greek physicians in its modern sense, and after citing the well known definition of CÆLIUS AURELIANUS asks: "Cet auteur avait-il déjà vu ces lésions des jointures? Nous l'ignorons." Like RAPMUND, he does not regard this affection as genuine rheumatism, but as a synovitis in some way dependent on the dysentery. A somewhat similar view has been advanced by R. VOLKMANN—*Die Krankheiten der Bewegungsorgane*, in Pitha u. Billroth's Handb. der Allg. u. Spec. Chirurgie, Bd. II, Abth. 2, Erlangen, 1872, S. 502—who groups the affection in question with the intercurrent synovial inflammations occasionally observed in measles, scarlet fever, small-pox, typhus, diphtheria, mumps and puerperal fever. J. KRÄUTER—*Ueber einige Nachkrankheiten der Ruhr*, Cassel, 1871—has suggested that the rheumatic joint-inflammations and conjunctivitis, which occurred as sequelæ in 8 out of 60 cases of dysentery observed by him in the villages of Furstenhagen, Arenberu and Oedelsheim during August, 1870, were due to the absorption of fæcal material from the intestines into the blood.

matism, like dysentery, has its seasons of epidemic prevalence in certain localities, and I presume that it is only when such epidemics coincide with epidemics of dysentery that the complication in question becomes at all frequent.

Undoubtedly, genuine rheumatism was a very common affection during the civil war, and it is probable enough that a portion at least of the cases in which it was supposed to complicate dysentery were correctly interpreted; but the reports are not sufficiently explicit to serve as the basis of an intelligent opinion as to the proportion of cases in which this actually happened as compared with the multitudes of those in which pseudo-rheumatic pains of the nature indicated above were mistaken for rheumatism.

Complication with tubercular diarrhœa.—As will be explained in a subsequent part of this chapter, I have been led to the conclusion that tubercular diarrhœa, or diarrhœa dependent upon intestinal catarrh consecutive to tubercular deposits in the intestinal walls, was more frequent during the civil war than has generally been supposed; and in this place I desire to call attention to the fact that dysentery may supervene upon such intestinal catarrhs quite as readily as upon those which arise from other causes. In post mortem examinations the coexistence of the tubercular and dysenteric processes is manifested for the most part by the presence of the characteristic tubercular ulcerations in the small intestine, and of the dysenteric lesions, whether catarrhal or diphtheritic, in the large. If tubercular ulcers had previously existed in the large intestine, they are most generally masked by the more turbulent and destructive dysenteric process. Finger* observed this coexistence of dysentery with tubercular ulceration in the Prague epidemic of 1846–48, and since that time its occurrence as a complication has been generally admitted by systematic writers. Specimens Nos. 244 to 261 inclusive, Medical Section, Army Medical Museum, afford a striking illustration of the lesions found in such cases. They are a series of pieces of the small intestine showing highly characteristic tubercular ulcers, and a portion of the colon of the same patient in which the lesions of diphtheritic dysentery are well marked. A more detailed account of this case, with plates representing one of the tubercular ulcers, will be given further on in connection with the subject of tubercular diarrhœa. I may add that both intestinal catarrh and diphtheritic dysentery were of frequent occurrence in patients laboring under tubercular disease of the lungs, in whom no tubercular deposit existed in the bowels.

Complication with erysipelas.—Both Finger and Griesinger† mention erysipelas among the complications of dysentery, an observation abundantly verified during the civil war. I am not, however, inclined to regard the two diseases as very closely dependent upon each other. Erysipelas is apt to occur epidemically wherever men are crowded together, and especially in prisons and hospitals. This was so often the case in our great general hospitals during the war, that it was frequently deemed desirable to establish "erysipelas wards" for the isolation and better treatment of those affected. Without entirely sparing the healthy, epidemic erysipelas was particularly apt to attack the wounded and those suffering with almost any form of disease. In the former case the erysipelatous inflammation most generally appeared first in the injured part, in the latter, some part of the head

* Cited in next note.

† FINGER—*Die epidemische Ruhr*, Prager Vierteljahrschrift, 1849, Bd. IV, S. 142—appears to have regarded erysipelas as an epiphenomenon of dysentery, remarking that it seldom occurs before the 10th day of that disease; the face or lower extremities were most frequently affected. He mentions also the occurrence of an erythema of 3–6 days' duration, which especially attacked the front of the neck and breast, and came and went without any noteworthy symptoms. I have never observed an example of this accident. GRIESINGER—*Krankheiten von Egypten*, Abs. X, Cap. 2, Archiv für phys. Heilk., Jahrg. XIII, 1854, S. 542—observed two cases of gangrenous erysipelas of the face in patients suffering with Egyptian dysentery.

and face was most apt to be affected. The vast numbers of patients suffering under diarrhœa or dysentery, of course, afforded fit subjects for such epidemics; so also did the fever patients, and those suffering from pneumonia and other phlegmasiæ. I know of nothing to indicate that the former class was more susceptible than the latter.

Paralysis as a sequel to dysentery.—Paralysis of one or more limbs is an occasional sequel to dysentery, which was several times observed during the civil war, although it was far from attracting the attention it deserved. I note that 2,907 soldiers were reported to have been discharged the service during the war on account of paralysis, and 272 deaths were attributed to the same cause; but there are no means of ascertaining what proportion of these occurred in connection with dysentery. I find in the records but one report of a case in which acute dysentery was succeeded by paralysis, and nine in which it was consecutive to "chronic diarrhœa" so-called: two of the latter cases will be found in Section III, viz: cases 569 and 819. In case 569 the patient died of a subacute flux of about three months' duration. While under treatment for this disease, and about a month before his death, "he had an attack of paraplegia, which, after several days, confined itself to the right lower extremity." He died much emaciated. In case 819 the right arm became paralyzed about a week before death, and the right lower extremity a few days later. I subjoin the remaining cases. In case 884 the paralysis followed acute dysentery; it might seem proper to postpone the others, in which it occurred during "chronic diarrhœa," until the fluxes of that character have been treated of, but it seems more convenient to complete the discussion of the subject in this place:

CASE 884.—Private Isaac N. Cook, company I, 16th Kentucky infantry; age 26; admitted to general hospital, Quincy, Illinois, February 15, 1863, with rheumatism. This man was originally admitted to hospital No. 6, Louisville, Kentucky, August 12, 1862, suffering from intermittent fever. September 11th, he was transferred to hospital No. 7, Louisville, where the diagnosis recorded on the register was jaundice. From this hospital he was sent to Quincy. He was treated at Quincy for rheumatism and cough until March 5, 1864, when he was attacked by severe mucous dysentery with bloody, slimy stools. This lasted ten days, and then terminated in convalescence. He, however, remained unable to leave his bed, and his attending physician recognized evidences of partial paralysis of his lower extremities. He was treated with tonics, and had moxas applied to his lumbar region without benefit; and May 28th, was discharged the service on surgeon's certificate of disability.—Acting Assistant Surgeon F. K. Bailey.

CASE 885.—Private Charles Irish, company K, 6th Ohio cavalry; age 40; was admitted to 2d Division general hospital, Alexandria, Virginia, June 15, 1864. Diagnosis, chronic rheumatism. Transferred to Philadelphia, June 20th. Admitted to Summit House hospital, Philadelphia, June 21st; same diagnosis. Transferred to Satterlee hospital August 24th; same diagnosis. Transferred to Turner's Lane hospital. Admitted to Turner's Lane hospital, Surgeon R. A. Christian, U. S. V., in charge, October 20th. Diagnosis, partial paralysis of the lower extremities. The case-book of the hospital gives the following particulars: This man had typhoid fever eight or nine years ago, followed by enfeeblement of the limbs, in consequence of which he was unable to walk for months. He says his limbs were never so strong again; nevertheless, he was well enough to enlist April 4, 1864, and was sent at once to the field. Six weeks after enlistment he was attacked by dysentery, which was followed by his present trouble. He is now unable to walk, and complains of a feeling as if a rope were tied tightly around his hips; sensation is less impaired than motion; he feels a touch on the legs, but does not perceive painful impressions as distinctly on the lower as on the upper extremities. The record shows that this man was discharged the service December 21st, because of "partial paralysis of the lower extremities."

CASE 886.—Private Martin Burley, company F, 2d Pennsylvania cavalry; age 29; admitted to Douglas hospital, Washington, D. C., May 10, 1864. Diagnosis, dropsy. Transferred to Philadelphia, Pennsylvania, May 14th. Admitted to Mowe hospital, Philadelphia, May 15th. Diagnosis, general debility. Transferred, February 11, 1865. Admitted to Turner's Lane hospital, Surgeon R. A. Christian, U. S. V., in charge, February 11th. Diagnosis, partial paraplegia. The case-book of the latter hospital states that this man enlisted February 13, 1862; was first taken with diarrhœa at Occoquan creek, Virginia; it continued five months. He was furloughed for sixty days about two months after being taken ill, but was not well enough to return to his regiment when the furlough expired. While on furlough the diarrhœa ceased, but soon after his lower extremities, especially the left, became partially paralyzed. He went to Washington about six months after he received his furlough, and was admitted to Douglas hospital as above stated. At present his lower limbs are so feeble that he can only walk with crutches. Muscular contractility and sensation appear to be good in both limbs, but the left leg is feeble and three-quarters of an inch smaller round the calf than the other. His general health is apparently good. This man was discharged from the hospital by reason of expiration of term of service, March 3, 1865. His condition at that time was much improved.

CASE 887.—Private Charles L. Eastman, company K, 99th Illinois infantry; age 20; was admitted to general hospital, Quincy, Illinois, August 26, 1863, with diarrhœa. The following particulars are from the case-book of the 3d Division, Acting Assistant Surgeon F. K. Bailey in charge: The patient said he had suffered from diarrhœa from June, 1862, till very lately; is now emaciated; tongue coated, but appetite good. Ordered pills of sulphate of cinchona and sulphate of iron. September 4th: Complains of difficulty of speaking. September 10th: Complains of slight stiffness of the lower jaw and difficulty of opening the mouth. September 14th: Complains of coldness and a pricking sensation in the lower extremities. September 23d: A sense of numbness in the lower extremities, and difficulty in guiding them now supervene. October 8th: Numbness and pricking sensation continue; speech is difficult, and the voice sounds as though the mouth were full of food. Substitute for the former treatment: R. Arsenious acid and strychnia, of each 2 grains, extract of gentian q. s.; make 30 pills; take one at each meal. October 15th: Is somewhat better. He continued to improve till the 25th, when the paralytic symptoms became worse again, although it is noted on the 29th that his general health is improving. November 7th: Improvement is again noted, and continued until the patient returned to duty cured, February 16, 1864. The strychnia and arsenious acid were discontinued November 20th. This man had no looseness of the bowels after his admission to hospital.

CASE 888.—Private Abraham Mansfield, company G, 128th Ohio volunteers, was admitted to Lawson hospital, Saint Louis, Missouri, Surgeon C. T. Alexander, U. S. A., in charge, March 21, 1863. The case-book of the hospital states that he had been sick for three months with a bad cold, rheumatism and diarrhœa; was taken on board the hospital boat two weeks ago; had previously recovered from the diarrhœa, but had gradually lost the use of his lower limbs; at present, however, he complains of loss of power only from the knees down; his general health appears to be good. April 16th: The case-book reads: "Am inclined to think patient is playing old soldier; he only gets out of bed when ordered; complains that he has no use of his limbs; claims that he has been injured, but cannot tell how it was done." This suspicion, however, was erroneous, for the record concludes: Died, May 2, 1863. The cause of death given in the hospital register is chronic diarrhœa.

CASE 889.—Private Hayden Ogden, company I, 47th Indiana volunteers; age 24; admitted to the Marine hospital, New Orleans, Louisiana, September 12, 1863, with paralysis of the left lower extremity. He stated that he was attacked with a severe diarrhœa about ten months since, which lasted for four months, when he lost both sensation and motion in his left thigh and leg; the diarrhœa continued for two months longer, when typhoid fever set in, from the effects of which he is still in a very prostrate condition. Strychnia was tried without benefit, and the patient was discharged the service on surgeon's certificate of disability, October 8, 1863.—Acting Assistant Surgeon Wm. Cleary.

CASE 890.—Private Peter Harting, company E, 52d New York volunteers; age 26; was admitted to 1st Division Annapolis hospital, March 9, 1864, with partial paralysis of the legs. He stated that he was taken prisoner at Bristow Station, October 14, 1863, and confined at Belle Isle. He was then in good health, but soon began to suffer from diarrhœa, which continued, alternating with constipation, during his imprisonment. After a time his legs began to swell and he partially lost the use of them. At present he can use them much better. No treatment was employed except good diet and local frictions. April 9th, being much improved, he was transferred to the hospital at Annapolis Junction, and thence, April 26th, to Camp Parole as a convalescent.—Acting Assistant Surgeons S. J. Radcliffe and F. M. Lincoln.

CASE 891.—Corporal William H. Smith, company K, 77th New York volunteers, was admitted to McKim's Mansion hospital, Baltimore, Maryland, June 17, 1863, with paraplegia. He stated that about the first of February he was admitted to regimental hospital at White Oak Church, Virginia, suffering with chronic diarrhœa and rheumatism. About the last of February he lost the use of his lower limbs, and has been unable to walk ever since. He attributed this accident to having "taken cold," or to injuries received at one time to the left hip, at another to the left leg, prior to enlistment, from which he supposed he had recovered. He was subsequently transferred to the hospital at Potomac creek, and afterwards to Lincoln hospital, Washington, whence he came to McKim's Mansion. In this case the magneto-electric machine was used, but only with "slight benefit," and the patient was discharged the service on surgeon's certificate of disability, August 24th.—Acting Assistant Surgeon William G. Smull.

I cannot doubt that a number of similar cases occurred, the particulars of which were not reported. On this subject we have the valuable testimony of Dr. S. Weir Mitchell,* who enjoyed special opportunities for observation at the Army Hospital for Diseases of the Nervous System, in Philadelphia. He explicitly states that in the wards of that hospital he saw "many cases of palsy, chiefly paraplegia, following upon dysentery, acute or chronic."

The occasional occurrence of paralysis in connection with dysentery has long been a matter of observation. It was known to Galen,† who attributed it to the injudicious suppression of the discharges by rash medication. His statement was repeated by many

* S. WEIR MITCHELL—*Paralysis from peripheral irritation, with reports of cases*, New York Med. Jour., Feb., 1866, p. 333. He adds the following important remarks: "But in nearly every case there had been many possible causes, such as long marches, bad diet, malaria or injuries to the spine—these being so common that almost any patient long in service had some such to relate. It was thus difficult, or even impossible, to fix upon any single factor as most important or essential, where, as in the mass of cases, it was likely that several contributed to influence the final result."

† GALEN—*De venæ sectione adversus Erasistratum Liber*, Cap. 6 *ad fin.*, [Ed. Kühn, XI, p. 170.] The passage refers to the suppression of the discharges of hæmorrhoids as well as of dysentery, and the evil effects enumerated are melancholia, insanity, pleurisy, nephritis, vomiting of blood, hæmoptysis, paraplegia and dropsy.

subsequent writers;* and according to Jaccoud,† Fabricius Hildanus (1641) published the particulars of a case of paraplegia following a severe attack of acute dysentery in a young man. The first attempt at a detailed discussion of the subject, however, is the dissertation of Conrad Fabricius,‡ published in 1750. According to him paralysis is most apt to follow epidemic dysentery, generally affects one arm and the opposite leg, and is often accompanied by pains in the joints. Following the opinion of Galen, he attributed it to the premature suppression of the flux by the use of opiates and astringents. This dissertation was republished by Haller, and the form of paralysis it described was accepted by Sauvages § as a species under the designation "hemiplegia transversa." Zimmermann || observed a number of cases of paralysis following dysentery during the Swiss epidemic of 1765, but offered no explanation of their cause. John Peter Frank¶ spoke of it as an occasional accident after dysentery, compared it to the paralysis which occurs in lead colic, and believed its occurrence to be due to unusual intensity of the abdominal pains.

In more recent times a number of cases have been published in detail, among which those of Zabriskie, Moutard-Martin, Gallard, Gubler, Thomas and Leyden** may be particularly referred to. The subject has been discussed quite fully by a number of writers, especially by Gubler, Jaccoud, Mitchell, Barrallier and Leyden.†† The interpretation most generally accepted at the present day is that which explains these cases as examples of reflex paralysis;‡‡ while Leyden assumes a direct extension of the inflammatory process which exists in the rectum in dysentery to the sacro-lumbar plexus, and explains the paralysis by the resulting neuritis and consecutive lesions in the spinal cord.

Other theories have been offered,§§ but it would be foreign to my present purpose to discuss them. The cases that I have found in literature, like those collected during the civil war, which I have presented above, appear to me to be too imperfectly observed to warrant a conclusion. Jaccoud has well remarked that it would be wise to wait, before building a theory on this subject, until medical science possesses at least *one* complete observation,|||| and this implication of incompleteness applies to the cases recorded since his time as well as to those observed previously. The assumption that in these cases no lesion exists in either the brain or spinal cord because none has been observed, must be acknowledged to be a

---

* Some of these are enumerated by D. W. TRILLER—*Diss. de tumoribus subitis a dysenteria intempestive suppressa obortis*, Wittemberg, 1771; I cite Opusc. Med., Frankfort, 1766, T. III, p. 145—who mentions a number of other lesions attributed to the same cause by various authors.

† S. JACCOUD—*Les paraplégies et l'ataxie du mouvement*, Paris, 1864, p. 413. His reference is merely: "Fab. de Hilden. Obs. et cur. chir. centuriæ VI," without further particulars; and I have not been able to identify the case referred to.

‡ P. C. FABRICIUS et J. G. A. KIPPING—*De paralysi brachii unius et pedis alterius lateris dysentericis familiari*, Helmstadt, 1750; I cite from the reprint in HALLER'S *Disp. ad Morb. Hist. et Cur.*, Lausanne, 1757, T. I, p. 97.

§ SAUVAGES—*Nos. Meth.*, Amsterdam, 1768, T. I, p. 793. SAUVAGES simply adopted the description of CONRAD FABRICIUS. I cannot, therefore, agree with the remark of BARRALLIER, [*loc. cit., infra:*] "Sauvages a aussi constaté la fréquence de cette forme."

|| ZIMMERMANN—*Von der Ruhr unter dem Volke im Jahr* 1765, Zurich, 1767, S. 142 *et seq.* He observed especially paralysis of the lower limbs, and general paralysis. In the French translation of this work, Paris, 1812, p. 12, by a curious blunder the expression "ein Auschlag," (an eruption,) applied to a rash sometimes observed in the mouth, on the tongue, the abdomen, or over the whole body, Chap. 2, p. 14, is erroneously translated "une paralysie," an error perpetuated by GUBLER, (*infra*, note **,) who cites this translation.

¶ J. P. FRANK—*De Cur. Hom. Morb. Epitome*, Milan Edit., 1832, T. III, p. 437—"Tantum vero ad gradum doloris in abdomine vehementia apud hos vel illos evehitur; ut ab eo non minus, ac in *colica saturnina*, brachii aut pedis unius vel alterius paralysis sequatur."

** J. B. ZABRISKIE—*On paralysis sympathetic of visceral disorders*, Amer. Jour. of the Med. Sciences, Oct., 1841, p. 361—two cases following dysentery. MOUTARD-MARTIN—*Paraplégie, suite de dysenterie*, L'Union Médicale, Oct., 1852, pp. 492 and 504—case observed in the Hôtel-Dieu in 1849. GALLARD—*Dysenterie avec accidents cérébraux*, idem, Sept., 1859, p. 547—one case observed at the Lariboisière. A. GUBLER—*Des paralysies dans leur rapports avec les maladies aiguës*, etc., Archiv. Gén. de Méd., March, 1860, p. 267—has a section on paralysis in dysentery, in which he gives the particulars of three cases. T. GAILLARD THOMAS—*Clinical lecture on paraplegia*, Amer. Med. Monthly, June, 1862, p. 401—one case, (No. 4.) E. LEYDEN—*On reflex paralysis:* translated in Clinical Lectures, &c., New Syd. Soc., London, 1876, p. 145—one case. Paralysis has also been observed to follow other intestinal inflammations; see, for example, the cases of paraplegia consecutive upon enteritis reported by R. J. GRAVES—*Clinical Lectures*, Amer. Edit., Philadelphia, 1838, p. 76.

†† See the references to GUBLER, JACCOUD, MITCHELL and LEYDEN in previous notes; also A. BARRALLIER—Art. *Dysenterie*, Nouveau Dict. de Méd. et de Chir. Prat., T. XI, Paris, 1869, p. 747.

‡‡ The chief apostle of this view is undoubtedly BROWN-SÉQUARD—*Lectures on the physiology and pathology of the central nervous system; delivered at the Royal College of Surgeons of England in May*, 1858. Philada., 1860, p. 164—Paralysis and anæsthesia by a reflex action.

§§ As for example by GUBLER, cited above. |||| *Loc. cit.*

mere assumption, in view of the readiness with which minute structural changes might be overlooked in the absence of microscopical examination, which has not yet been resorted to in a systematic manner. In like manner the assumption by Leyden of some local lesion in the great nerve trunks proceeding to the lower extremities, lacks the support of actual anatomical observations so far as dysenteric paralysis is concerned.

The comparison made by Frank between these cases and lead colic has been repeated by Barrallier,* who affirms that in dysenteric paralysis the extensor muscles are particularly affected. I do not wish to give undue importance to the suggestion, but would remark that it has occurred to me that some, at least, of the cases reported as dysenteric paralysis may have been really due to lead poisoning. Setting aside the possibility of the accidental coexistence of lead poisoning from its usual causes, the use of the acetate of lead in the treatment of the disease may be pointed out as a probable source of this complication. Medical Inspector Mussey† reports that in 1863 he observed a case of dysentery followed by lead colic due to this cause in the hospital of the 3d New York cavalry in North Carolina. I fear the accident occurs much more frequently than is generally suspected; and of course paralysis is as prone to follow lead poisoning induced in this way as in any other.‡ I by no means, however, offer this hint as more than a possible explanation of some of the cases. I may add that while engaged in writing this paragraph, an interesting illustration of the actual occurrence of lead paralysis from the injudicious employment of acetate of lead in the treatment of dysentery, was communicated to me by my colleague, Dr. G. A. Otis. I subjoin an abstract of the case in a foot-note.§

In this instance the upper extremities only were affected, as in the majority of the cases of paralysis from lead poisoning; while in the majority of the cases of paralysis following dysentery the lower extremities only are involved, and this I presume to be a satisfactory proof, if any were needed, that the maladministration of lead cannot be held responsible for more than a part of the dysenteric cases; but it must not be forgotten that on the one hand dysenteric paralysis may affect the upper extremities as well as the lower, or, indeed, the upper extremities only, while on the other hand lead paralysis not only may affect the lower extremities as well as the upper, but has been known to manifest itself in some instances in the lower extremities alone.‖

---

* *Loc. cit.* † *Supra*, p. 79.

‡ S. EUGALENUS—*De Morbo Scorbutico, Liber*, [1588:] I cite the Amsterdam Ed. of 1720, p. 73—reports two cases of colic terminating in paralysis which he supposed to be accidents of scurvy. I think it likely enough that these were cases of lead poisoning, as has been suggested by ADAMS with regard to the paralysis supervening upon colic described by PAULUS ÆGINETA, Lib. III, Sect. 18, Transl. of Syd. Soc., Vol. I, London, 1844, p. 396. Dr. ADAMS remarks, p. 401: "The paralysis of the extremities after colic, mentioned by our author, and after him noticed by Avicenna and Haly-Abbas, was, no doubt, the same disease as the palsy after colica pictonum described by modern authors."

§ In the spring of 1865, two Catholic priests called at the Surgeon General's Office to make inquiries about a wounded man. This business concluded, Dr. OTIS, of whom the inquiries were made, remarking that one of the priests (Padre E———, aged about 50) presented a very striking example of "dropped wrists," observed: "I fear you are suffering from the effects of lead poisoning." The good man raised his eyes heavenward, and spoke of the affliction as a discipline designed by Providence for his benefit; but he asked for advice in the matter; and, on examination, it appeared that during the preceding summer, while on missionary duty in New England, he suffered, in a country village, from a severe attack of dysentery. While disapproving of "allopathy," he employed the only local practitioner; and, as appeared in the sequel, was treated, among other remedies, by pills, each containing a grain of opium and two grains of acetate of lead in some aromatic confection. A chronic flux persisted for some weeks after he had resumed his journey, and he continued for several months to have recourse to these pills, which he had found greatly to relieve his discomfort. After a time he became much emaciated, and in the winter loss of power in the extensors of the fingers, wrist and forearm appeared, and augmented until his hands were almost useless. He had been for several months prior to his visit to Washington under the care of homœopathic practitioners in Worcester and Boston, who pronounced the symptoms dependent on some centric lesion of the nervous system and probably incurable. It was thought that the affection was unmistakably due to saturnine poisoning. The padre was advised to take full doses of iodide of potassium and the sulphuric acid *limonade* of the French physicians, and also to resort to frictions and Faradization over the extensors of the forearm. He pursued this treatment, and his complete recovery ensued within three months—and was described by him as miraculous.

‖ Consult TANQUEREL DES PLANCHES—*Traité des Maladies de Plomb, ou Saturnines*, Paris, 1839—which, I regret to say, is only represented in the library of the Surgeon General's Office by the *Abridgment* of S. L. DANA, Lowell, 1848. See also C. PH. FALCK—*Die klinisch wichtigen Intoxicationen*, in Virchow's Handb. der Spec. Path. und Ther., Bd. II, Abth. I, Erlangen, 1855. According to TANQUEREL, of 113 cases of paralysis of the extremities, the lower extremities were involved in 15, and in 5 the disorder was limited to the lower extremities, the superior preserving all their motions.—*Abridgement*, p. 216; compare FALCK, *op. cit.*, S. 201.

Other complications of acute dysentery.—Various other complications of dysentery may be mentioned, such as pericarditis, endocarditis, diphtheritic exudation on the mucous membrane of the pharynx or larynx, etc. Finger and Trousseau* have observed inflammation of the parotids in the advanced stages of severe cases, a fact which should not be overlooked in attempting to diagnosticate between dysentery and fever, when the case is first seen in its latter stages, without satisfactory previous history, as so often happens in hospital practice during times of war. Cases of this complication have been reported in the United States by Minor, Strong and White.† Bedsores occasionally occur, as in case 132, but this complication is very rare, even in chronic dysentery.

Influence of Region on the prevalence of Dysentery in the United States.—In the first section of this chapter, for reasons then fully explained, the statistics of diarrhœa and dysentery were discussed together. I have, however, deemed it advisable to add in this place a few ratios deduced from the number of cases of acute dysentery separately reported. As might be expected, the distribution of these cases closely agrees with that given in Section I for the whole group. They were proportionally more numerous in the Atlantic region than in the Pacific, in the Central region than in either, and in both Atlantic and Central regions they were more numerous in the southern than in the northern portions, as is shown by the following tables:

Tabular statement of the prevalence of Acute Dysentery among the White troops, expressed in ratio per 1,000 of mean strength.

Atlantic Region.

† G. G. Minor—*A case of dysentery complicated with parotitis*, The Virginia Med. Jour., Vol. XII, 1859, p. 191. The patient was a boy 12 years old, who died on the 16th day of sporadic dysentery. The left parotid first enlarged two days before death; next day the right. The swelling was so great as to render deglutition impossible. The boy had previously had mumps. In the *Minutes of the Proceedings of the Buffalo Med. Association*, Buffalo Med. Jour., Vol. X, 1854–5, p. 405, I find several cases, viz: One reported by Dr. Strong: A lady, 30 years old, who had an apparently slight attack of dysentery and appeared to convalesce on the fifth day, when parotitis made its appearance on one side, (it is not stated which;) three or four days later the tumor discharged a thin, ichorous, purulent matter at the ear. Soon after the dysentery recommenced, was uncontrollable, and the patient died; before death the opposite parotid had begun to enlarge. Dr. White said he had witnessed three similar cases: one in 1853, the dysentery was severe, and just as it subsided the left parotid enlarged; no suppuration took place, nor did the dysentery return, but the patient died. He had seen in 1849 a young girl, and in 1852 a child of 7 years, die under similar circumstances. In all these cases the tumor is spoken of as of "a peculiar stony hardness;" all had taken acetate of lead, and Dr. White suggested that this might be the cause, as "Lead, more than any other drug, affects the secretion of saliva, checking it, and making the mouth dry." Dr. Wyckoff had seen a similar enlargement in the submaxillary gland after a mild case of dysentery in a boy who had not taken lead; he recovered.

Undoubtedly, also, in the Atlantic and Central regions the disease was more fatal in the southern than in the northern departments, although, for the reasons given in Section I,

it is impossible to give this circumstance any definite numerical expression. This geographical distribution of cases and mortality agrees substantially with the experience of the United States Army during many years of peace, and if the geographical distribution of dysentery among the civil population of the country were similar, these facts would create a strong presumption in favor of the belief that malaria plays the part of a direct cause in the development of the disease. But it has been too hastily assumed that the prevalence of particular diseases in the military garrisons of a country may be regarded as a trustworthy indication of their endemic prevalence among the civil population; and in the case under consideration it is easy to bring forward facts which contradict the inferences which have been drawn from this assumption.

Among the most eminent of the writers who have fallen into this error with regard to the occurrence of dysentery in different parts of the United States is Hirsch,* who, in his elaborate work on geographical pathology, has arrived at the conclusion that dysentery prevails endemically only in the southern and southwestern portions of our country, especially at certain points on the southern Atlantic and Gulf coasts and along the banks of the Mississippi, Arkansas and other great streams within the region in question. He based his statement in part upon the silence of American medical writers with regard to the endemic occurrence of dysentery in the northern portions of the United States; in part upon the local observations of a few writers, especially Tidyman, Evans, Little, Wright, Chalmers, Porter, Cooke and Stinnecke,† whose utterances, however, he seems to regard rather as illustrative instances confirmatory of his views than as data satisfactorily establishing them; but chiefly he relies upon the army statistics of Forry‡ and Coolidge,§ of which he speaks as affording the only comprehensive testimony on the subject, and certainly these works appear to justify his conclusions.

In appreciating their testimony, however, it must not be forgotten that they both refer to the little army of the United States only, and not to the civil population. The rank and file of that army, during the period represented, was chiefly recruited in the northern States, and to a very considerable extent from men of foreign birth, and the

* A. HIRSCH—*Handbuch der historisch-geographischen Pathologie*, Bd. II, Erlangen, 1862–4, S. 207.

† P. TIDYMAN—*Diseases of the negroes of the Southern States*, Philadelphia Jour. of the Med. and Phys. Sciences, Vol. XII, 1826, p. 306; J. P. EVANS—*Obs. on the diarrhœa of the South*, Charleston Med. Jour. and Review, Vol. VI, 1851, p. 309; R. E. LITTLE—*Climate, diseases, &c., of Middle Florida, particularly of Gadsden County*, Amer. Jour. of the Med. Sciences, Vol. X, 1845, p. 65; J. J. B. WRIGHT, Asst. Surgeon U. S. A., Amer. Med. Intelligencer, Vol. I, N. S., 1841, p. 113, in an account of the diseases at Fort Gibson, Ark.; L. CHALMERS—*Weather and diseases of South Carolina*, London, 1776, Vol. II, p. 31; J. B. PORTER, Surgeon U. S. A.—*On the climate and salubrity of Fort Moultrie and Sullivan's Island, Charleston Harbor*, Amer. Jour. of the Med. Sciences, Vol. XXXII, 1856, p. 347; J. E. COOKE—*Essay on autumnal diseases*, Transylvania Jour. of Med., Vol. I, 1828, p. 339; H. A. STINNECKE—*Med. topography and diseases of Fort Monroe*, in COOLIDGE'S Statistical Report from 1839 to 1855, [cited below,] p. 139. Of these citations it may be remarked that WRIGHT and STINNECKE were speaking of certain military garrisons, not of the civil population, so that the subsequent remarks in the text apply to their observations. I do not understand PORTER to affirm any special prevalence of dysentery among the citizens of Charleston. COOKE mentions an epidemic of dysentery in Fauquier county, Va., in 1816, and regards it as "another form of autumnal fever," *op. cit.*, p. 403–5; CHALMERS speaks of it as frequent in South Carolina; LITTLE in Florida, and TIDYMAN among the negroes of the southern States; but none of these writers bring forward any numerical facts which show that dysentery was more frequent in the region of which he wrote than in other parts of the United States, or even express a definite opinion to that effect. The most striking confirmation of the view of HIRSCH is to be found in the paper of EVANS; but a portion of the facts it contains were furnished by the military experience of the Mexican war, while the rest, for the most part, refer to the prevalence of the disease throughout the south and southwest for several years before the paper appeared [1851]—a period during which I shall presently show dysentery prevailed epidemically in all parts of the United States. To the paper of WRIGHT, cited above, on dysentery at Fort Gibson, I may add one on the same subject by L. C. MCPHAIL, U. S. A.—*Medical topography*—No. 10, American Med. Intelligencer, Vol. I, 1837–8, p. 412.

‡ S. FORRY—*The Climate of the United States and its Endemic Influences*, 2d Ed., New York, 1842, p. 298. The medical statistics of this interesting work were derived from the *Statistical Report on the Sickness and Mortality in the Army of the United States, from January*, 1819, *to January*, 1839, Washington, 1840; a work edited by Dr. FORRY himself, then an Assistant Surgeon in the army.

§ R. H. COOLIDGE—*Statistical Report on the Sickness and Mortality in the Army of the United States, from January*, 1839, *to January*, 1855, Washington, 1856; and *Statistical Report on the Sickness and Mortality in the Army of the United States, from January*, 1855, *to January*, 1860, Washington, 1860. The latter report is not cited by HIRSCH. I may add that HIRSCH frankly admits the incomplete character of the information at his disposal, and questions how far dysentery is habitually endemic in the southern States, citing in illustration the paper of J. W. HEUSTIS—*Climate, &c., of the middle section of Alabama, more especially in relation to the county of Dallas*, Amer. Jour. of the Med. Sci., Vol. VIII, 1831, p. 93—who states that in that district dysentery seldom occurs except among invalids and convalescents; and that of G. R. GRANT—*Sanitary condition, &c., of Memphis, Tenn.*, Amer. Jour. of the Med. Sci., Vol. XXVI, 1853, p. 107—who affirms that dysentery only occurs sporadically in that city; a statement which ignores the epidemics of 1846 and 1847; see the paper of J. E. STEWART—*Epidemic dysentery*, The Missouri Med. and Surg. Jour., Vol. III, 1848, p. 145.

system of changing stations every few years, which still prevails, brought constantly fresh portions of the force into the southern and southwestern regions. Under these circumstances the relations of the soldiers to the climatic conditions of the regions in question was essentially that of strangers, and it is not surprising that the army statistics represent a distribution of dysentery which approximates rather to what happened during the civil war than to its distribution among the civil population in years of peace. Neither the work of Forry, nor the army statistical report upon which it was based, give the facts with regard to dysentery separately from diarrhœa; but Forry has compiled from the statistics of the army for ten years an interesting table showing the ratio of the two diseases to strength in the posts of certain regions, an abstract of which is appended in the foot-note.*

He shows further that in the whole northern division, for the period in question, the average annual ratio of cases was 269 per 1,000 of strength; in the middle and southern, 526. In the former the annual mortality was 0.4 per 1,000 of strength, in the latter 3.7. So that the proportion of cases was about twice greater, and that of deaths about nine times greater, in the southern than in the northern portion of the United States. It is not remarkable that upon the basis of these facts Forry should have classed diarrhœa among the malarial diseases.† The more extensive and elaborate statistical reports of Coolidge indicate a distribution of diarrhœa and dysentery among the military posts of the northern and southern portions of the United States which approximates in its main features that pointed out by Forry. In these reports dysentery and diarrhœa are separated. Hirsch‡ has prepared from the first of them a table which shows the ratio of cases and deaths from dysentery to strength in each of the groups into which Coolidge distributed the several military posts; I observe that it does not contain the deaths from diarrhœa, nor does it embrace the figures of the second report of Coolidge, [1855 to 1859, inclusive.] I therefore subjoin a similar table § in which both these deficiencies are supplied.

In a general way this table shows both diarrhœa and dysentery to have been more frequent and more fatal at the military posts in the southern than at those in the northern portions of the United States. Still, even in these military statistics some striking exceptions occur. Thus, the greatest proportion of cases of dysentery occurred at the posts in the vicinity of St. Louis, Missouri, where the malarial influences must be regarded as quite mild when compared with some of the southern districts in which the ratio of cases was much smaller. The ratio of deaths at the same posts, though not the largest, is still much larger than in several of the more malarial districts. The remarkable prevalence and mortality of diarrhœa at these posts is also worthy of consideration. Indeed the mortality of diarrhœa in several of the districts is so great as to suggest the probability that a considerable proportion of the cases reported as diarrhœa were really dysentery.

If the data from which the foregoing table was compiled are grouped in such a way as to contrast the posts in the northern portion of the United States east of the Rocky Mountains with those in the middle and southern and those in the Pacific regions, the results are quite striking, as is shown in the subjoined tabular view.* According to this summary the proportion of cases of diarrhœa and dysentery in the middle and southern divisions was nearly forty-five per cent. greater than in the northern; the proportion of deaths more than three times greater; differences which, although not so considerable as those reported by Forry, are yet in the same direction. If dysentery alone be regarded, it will be observed that the proportion of cases was more than twice greater in the middle and southern divisions than in the northern; the proportion of deaths more than three times greater. So that the experience of the United States Army during many years of peace as to the frequency and mortality of these diseases in different parts of the country agrees with the experience of the army during the civil war.

But a study of the mortality tables in the census reports of the United States for 1850, 1860 and 1870 shows how unsafe it would be to assume that this military experience represents correctly the distribution of dysentery among the civil population of the United States. The incomplete character of the census returns, and the probability of numerous errors in the reported causes of death, are willingly conceded to those who may object to the conclusions suggested by these reports; but it must be admitted that the testimony of the census reports is far more valuable than the mere opinion of individuals, and more likely to give a correct view of the causes of death among the civil population than the most accurate statistics of little garrisons of strangers stationed at isolated points.

The volume of vital statistics of the census report of 1870† contains two maps which strikingly illustrate the diversity in the geographical distribution of the malarial fevers

* Average annual prevalence and mortality of *Diarrhœa* and *Dysentery* in the United States Army, 1839–59 inclusive, expressed in ratio per 1,000 of mean strength.

† *Ninth Census*, Vol. II, Washington, Government Printing Office, 1872. The maps referred to are reproduced, much more beautifully printed and on a larger scale, by F. A. Walker—*Statistical Atlas of the United States*, Washington, 1874, Plates XLII and XLV. In the following remarks I quote also from the volume of the Eighth Census, which contains the mortality statistics—Washington, Government Printing Office, 1866—and from a similar volume of the Seventh Census. The last was published separately as an executive document of the House of Representatives, viz: *Mortality Statistics of the Seventh Census of the United States*, 1850, 33d Congress, 2d Session. House of Reps. Ex. Doc., No. 98, Washington, 1855.

and the fluxes. The first represents the distribution of the deaths from intermittent and remittent fevers. The greater fatality of these diseases in the southern states, and especially along the southern Atlantic and Gulf coasts, and in the valley of the Mississippi and its tributaries, is conspicuously portrayed, and contrasted with the almost complete exemption of the New England states, New York, New Jersey, and the mountainous portions of Pennsylvania, Maryland and Virginia. The second represents the distribution of the deaths from diarrhœa, dysentery and enteritis, grouped under the general head of intestinal diseases. It not only shows no general agreement with the distribution of malarial diseases during the same year, but actually indicates in a general way, and particularly in the Central region, a greater mortality in the northern than in the southern districts. The most striking feature of this map, however, is the presence in it of a number of small patches of very dark shading representing the occurrence during the year of local epidemics. The darkest of these patches represent districts in which the mortality from the diseases in question exceeded 1,400 per 10,000 deaths from all diseases. Such a patch of some size occurs in southern Mississippi, a small one on the borders of Albemarle Sound in North Carolina, and another in the vicinity of Petersburg, Virginia; but the largest patch of the sort was in western Iowa, stretching over into Nebraska and Minnesota, and there is also a small one in northern Michigan. These maps would have been still more useful had they been drawn from the ratios of the diseases to population.

The same volume contains a table* which exhibits by states the proportion of deaths from diarrhœa, dysentery and enteritis per 100,000 living persons. An abstract of this table is subjoined,† and similar ratios, computed from the census returns of 1850 and 1860, are presented in parallel columns, in which the states are arranged in three groups corresponding as closely as possible with the Atlantic, Central and Pacific regions as employed in the tables of this work. This table indicates a very different distribution of the intestinal diseases among the civil population from that suggested by the military experience; but it may be objected that it includes the deaths reported as due to enteritis, a term so loosely used in the United States, as has already been pointed out,‡ that it undoubtedly embraces in these reports, besides a considerable number of deaths really due to dysentery and others due to diarrhœa, an indetermined number resulting from peritonitis. To avoid

this objection, the ratios for diarrhœa and dysentery separately have been computed from the three census reports and are subjoined.*

It will be seen from these ratios that neither diarrhœa nor dysentery was most prevalent in those states in which this would be anticipated on the malarial theory. If we regard the figures for dysentery alone, it will be observed that of the Atlantic states the greatest percentage of cases for 1850 occurred in Connecticut and Massachusetts, for 1860 in Massachusetts and Virginia, for 1870 in Vermont and Massachusetts. Of the states in the Central region, during 1850 the rate of mortality in Ohio and Indiana far exceeded that in any of the Gulf states. During 1860 and 1870, it is true, the rate of mortality in Louisiana was greater than that of any other state in the Central region, but Texas, which came next in 1860, was one of the states of least mortality in 1870. In both years, Wisconsin had a greater mortality than Tennessee, and Iowa than Mississippi. Arkansas, which bears such an evil reputation in the work of Hirsch, on the strength of the military experience of Wright,† had a comparatively moderate mortality in 1850 and 1860, while in 1870 its ratio was smaller than that of any other state in the Central region with the exception of Tennessee.

These considerations appear to show conclusively that dysentery prevails annually among the civil population in all parts of the United States, and that it is not most prevalent in the most malarial regions. It occurs both in the form of sporadic cases and of little local epidemics which fasten upon different districts in different years. At irregular periods these local epidemics assume larger proportions and become more numerous, and such epidemic periods are prone to extend over several successive years together. In such epidemic years, as Hirsch‡ has correctly pointed out, the epidemic prevalence of the disorder is in nowise limited by degrees of latitude or by the malarial character of the region affected; but this circumstance, instead of contradicting the experience of the civil population in ordinary years, fully agrees with it.

* No deaths reported. † State not organized.

† See note to p. 416, *supra*. ‡ *Op. cit.*, S. 209.

In the absence of a complete registration of the causes of death throughout the United States it is impossible to express numerically the facts with regard to the epidemic prevalence of dysentery, but some interesting information on the subject can be gathered from American medical literature. According to the testimony of Webster,* three periods of the epidemic prevalence of dysentery occurred during the last century: The first from 1749 to 1753; the second from 1773 to 1777; the third from 1793 to 1798.† During all three periods the violence of the disease was chiefly manifested in the New England States, though in the last two, at least, other parts of the country did not escape. The second period embraces a part of the Revolutionary War; and in the fall of 1776 dysentery was particularly prevalent and fatal among the American troops, but it was also widespread among the civil population.

During the present century, prior to the outbreak of the civil war, we have reports of numerous local epidemics in all parts of the country, but I have only been able to satisfy myself positively of the existence of one period of the widespread epidemic prevalence of the disease, viz: that which extended from 1847 to 1856. Prior to 1846 I find reports of local epidemics from various parts of Massachusetts in 1802 and 1803;‡ Chester county, Pennsylvania, in 1815;§ Fauquier county, Virginia, in 1816;‖ Charlestown, Cambridge and Boston, Massachusetts, in 1817;¶ Sandusky, Ohio, in 1818;** Washington county, New York, in 1820;†† the vicinity of Harrisburg, Pennsylvania, and Cape Ann, Massachusetts, in 1822;‡‡ Beverly, Massachusetts, in 1824;§§ Cecil and Hartford counties, Maryland, in 1825;‖‖ Chester county, Pennsylvania, in 1826;¶¶ the vicinity of the Dismal Swamp, North Carolina, in 1827;*** the town of Cortlandt, New York, in 1828;††† Greene county Alabama, in 1829;‡‡‡ Hollidaysburg, Pennsylvania, in 1832;§§§ the

† *Op. cit.*, Vol. I: "Between 1749 and 1753" dysentery "was as mortal and as general as, between 1773 and 1777," p. 264. With regard to the first period he specifies in 1749 many towns in Connecticut, p. 241; in 1750, Hartford, New Haven and other parts of Connecticut, p. 242; in 1752, the northern parts of America, p. 243. In the second period he specifies, in 1773, New Haven, Conn., and Salem, Mass., p. 260; in 1775, many places in the northern parts of America, p. 261; in 1776, all parts of the country, p. 263. In the third period he specifies, in 1793, Coventry, Conn., and Georgetown on the Potomac River, p. 300; in 1795, New Haven, Conn., p. 308; in 1796, Sheffield, Mass., and Wilmington, N. C., pp. 316 and 317; in 1797, Baltimore, Md., Westport, R. I., and Portland, Me., pp. 308, 327 and 332; and in 1798, Portsmouth, N. H., p. 346. Local epidemics during the periods in question are described or alluded to in the following papers: S. W. WILLIAMS—*Obs. on dysentery*, &c., Amer. Jour. of the Med. Sciences, Vol. III, 1842, p. 127—mentions the epidemic occurrence of dysentery at Deerfield, Mass., in 1751 and 1777; F. B. SAYRE—*Obs. on dysentery*, Philadelphia Med. Museum, Vol. I, 1804-5, p. 391—mentions its prevalence at Bordentown, N. J., in 1792; OLIVER FISKE—*Certain epidemic diseases in the county of Worcester, Mass.*, Med. Communications, of the Mass. Med. Society, Vol. II, 1813, p. 318—mentions its epidemic prevalence in that county in 1796; WM. BUEL—*The bilious fever and dysentery which prevailed in Sheffield, Mass., in the year* 1796, The Med. Repository, Vol. I, 1798, p. 453; J. BARKER—*On the febrifuge virtues of lime, magnesia and alkaline salts in dysentery*, &c., The Med. Repository, Vol. II, 1799, p. 147—mentions the epidemic prevalence of dysentery in 1797 at Portland, Me., and several neighboring towns; WM. HARRIS—*Facts relative to the black vomit, dysentery*, &c., *as they occurred in Mifflin county, Pennsylvania, during the hot weather of* 1797, 98 *and* 99, The Med. Repository, Vol. IV, 1801, p. 105. It appears from this paper that dysentery was prevalent in Mifflin county a year after the epidemic period indicated in the text.

1812	37	1820	243	1828	155	1836	116

Dr. WM. H. FORD, secretary of the Board of Health of Philadelphia, kindly furnished the following figures in a letter received from him January 13, 1877. Deaths from dysentery in Philadelphia:

Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.
1807	70	1816	30	1825	87	1833	44
1808	40	1817	33	1826	72	1834	70
1809	20	1818	31	1827	58	1835	114
1810	27	1819	37	1828	50	1836	95
1811	48	1820	127	1829	53	1837	119
1812	24	1821	124	1830	49	1838	141
1813	69	1822	191	1831	121	1839	120
1814	66	1823	187	1832	78	1840	118
1815	44	1824	69				

These figures from 1831 to 1840 inclusive, are identical with those published in the last of the three papers by G. EMERSON—*Vital Statistics of Philadelphia*, Amer. Jour. of the Med. Sciences, Vol. I, 1827, p. 116; Vol. IX, 1831, p. 17; and Vol. XVI, 1848, p. 13. In the first two of these papers the statistics of diarrhœa and dysentery are given together.

With regard to the great epidemic period from 1847 to 1856, we possess exceedingly interesting data. The committees on epidemics of the American Medical Association collected much information, and undoubtedly stimulated the preparation of many of the numerous reports which appear in the journals. Moreover, we possess some statistics which, although far from complete, give an excellent notion of the resulting mortality. From these various sources of information I gather that during the period in question the epidemic influence was by no means uniformly distributed, but was manifested in the form of a multiplication of the local epidemics that occur in ordinary years.

These local epidemics were not limited by the northern boundaries of the United States, for we have reports of their occurrence in Canada, especially in 1849.* With regard to the New England states the most satisfactory information is from Massachusetts. The registration reports of that state show that for six years prior to 1847 the deaths from dysentery had averaged 236 annually.† In 1847 the number suddenly increased to 1,074; in 1848 to 2,135; in 1849 it was 2,455. After this it averaged above a thousand deaths a year until 1856, when it fell to 930, and subsequently steadily decreased till 1860, in which year the number of deaths was 441. The population of Massachusetts was 994,514 in 1850, and 1,231,066 in 1860. No such definite information exists with regard to the rest of the New England states, but a committee of the American Medical Association reports the general prevalence of dysentery throughout these states in 1848.‡ We have information of its unusual frequency at Hartford, Connecticut, from 1848 to 1852,§ and the registration reports of the state of Rhode Island show it to have been more frequent than usual in that state during 1853, 1854 and 1855.‖ From the state of New York we have reports referring to or describing local epidemics in 1847, 1848, 1849, 1851, 1853,

* E. STIMSON—*Remarks on the epidemic bowel complaint of* 1849, *commonly called epidemic dysentery*, Buffalo Med. Jour., Dec., 1849, p. 377; and T. MACK—*Epidemic bowel complaint during the latter portion of the summer* 1849 *at St. Catharines, Canada West*, British American Jour. of Med. and Phys. Science, Jan., 1850, p. 225.

† See the registration reports of the State of Massachusetts, from which I have abstracted the number of deaths from dysentery annually as follows:

Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.
1841	268	1846	410	1851	1,674	1856	930
1842	294	1847	1,074	1852	1,018	1857	715
1843	120	1848	2,135	1853	1,046	1858	752
1844	200	1849	2,455	1854	1,159	1859	612
1845	122	1850	1,188	1855	1,131	1860	441

In these registration reports from 1841 to 1848 the year commences May 1st, and includes the first four months of the following year. The report for 1848 is for eight months only, from May 1st to Dec. 31st; the subsequent years begin Jan. 1st and end Dec. 31st. See especially the remarks in the 8th registration report, Boston, 1851, p. 114, and the 10th, Boston, 1852, p. 96. See also J. M. NYE—*Epidemic dysentery in Lynn*, [Mass.,] 1848, Boston Med. and Surg. Jour., Vol. XLIII, 1851, p. 212; the report of MORRILL WYMAN—Trans. Amer. Med. Ass., Vol. II, 1849, p. 197, on its prevalence at Cambridge, Mass., during 1847-8; and J. REYNOLDS—*Typhoid fever and dysentery in the epidemic form during the last four seasons on Cape Ann*, Trans. Amer. Med. Ass., Vol. III, 1850, p. 137.

‡ D. F. CONDIE—*Report of Committee on Pract. Medicine*, Trans. Amer. Med. Ass., Vol. II, 1849, p. 152.

§ Proc. of 63d annual convention of the Connecticut Med. Soc., 1855, p. 43. The number of deaths from dysentery in Hartford is given as follows:

Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.
1847	5	1849	53	1851	68	1853	11
1848	13	1850	19	1852	46	1854	10

‖ The registration reports of the state of Rhode Island commence in 1853; from that time to 1860 the number of deaths from dysentery is given as follows:

Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.
1853	67	1855	71	1857	65	1859	53
1854	118	1856	51	1858	61	1860	49

1854 and 1855.* From the state of New Jersey we have such reports for 1848 and 1851.† In the state of Pennsylvania local epidemics began to prevail during 1847, but they appear to have been most general and severe during the years 1851, 1852 and 1853, to the first of which most of the accounts refer.‡ The mortuary reports of the city of Philadelphia, on the other hand, represent the years 1849, 1851 and 1852 as those of greatest mortality. In Maryland it would appear from the statistics of the city of Baltimore, published by Joynes and Frick, that the epidemic prevalence of the disease began in 1849 and reached its height in 1854. It prevailed to the same extent in 1855, and then slowly declined, but was still unusually prevalent in 1857, and can hardly be said to have returned to its usual figure before 1860.§ The reports from Virginia show that dysentery was epidemic

* CONDIE—*loc. cit.*—reports dysentery as epidemic in New York in 1848. I find also the following special reports: DE WITT C. VAN SLYCK—*Endemic dysentery at Lyons, New York, during the summer and autumn of* 1847, New York Jour. of Med., Vol. X, 1848, p. 204; A. WILLARD—*Dysentery in the village of Greene, Chenango county, New York, during the past summer*, The Annalist, Vol. III, 1849, p. 151; S. B. HUNT—*Mercurials in dysentery*, Buffalo Med. Jour., Vol. VIII, 1852-3, pp. 232 and 327—mentions an epidemic in Livingston county in 1848; T. G. MEACHEM—*Dysentery as it prevailed in East Bloomfield, New York, during the autumn of* 1848, Buffalo Med. Jour., Vol. IV, 1848, p. 395; A. WILLARD—*Epidemic dysentery*, New York Jour. of Med., Vol. IV, 1850, p. 77, in Greene, New York, 1849; E. R. MAXSON—*Malignant dysentery*, Buffalo Med. Jour., Vol. VIII, 1852-3, p. 354; H. TAYLOR and J. H. BEECH—*Report on dysentery*, Trans. Amer. Med. Ass., Vol. VIII, 1855, p. 545—speak of dysentery as epidemic at Lima and in Wyoming county, New York, in 1853; M. C. HASBROUCK—*Remarks on dysentery*, New York Jour. of Med., Vol. XI, 1853, p. 49—speaks of dysentery as often epidemic in Rockland county, New York, but without giving dates; F. D. LENTE—*Epidemic dysentery in the village of Cold Spring during the years* 1854-5, New York Jour. of Med., Vol. XVI, 1856, p. 171.

† J. F. GARRISON, in Trans. Amer. Med. Ass., Vol. II, 1849, p. 191; and J. PARRISH—*op. cit.*, Vol. V, 1852, p. 295.

‡ JAMES BRYAN—*Epidemic dysentery*, New York Jour. of Med., Vol. X, 1848, p. 49—speaks of the disease as epidemic in Philadelphia in 1847; and A. P. DUTCHER—*Epidemic dysentery*, Cincinnati Med. Observer, Vol. II, 1857, p. 535—describes it as prevailing in the vicinity of Enon Valley, Pennsylvania, during the same year. The extent to which it prevailed throughout the state in 1851 is well indicated in the several county reports in the Transactions of the Med. Society of Pennsylvania, Session of 1852. It was also epidemic in Philadelphia during the same year. See HOLLINGSWORTH—*Epidemic dysentery among the orphans at Girard College*, Trans. of the College of Physicians, Vol. I, 1853, p. 166; and the remarks of Dr. CONDIE on its general prevalence throughout the city at the time. See also the account given of epidemics in various parts of the state during 1851 in the report on Pennsylvania, Trans. Amer. Med. Ass., Vol. V, 1852, pp. 305-339. Note also B. F. LINDLY—*An epidemic disease of Washington County, Pennsylvania, during the summer and autumn of* 1851, The Western Lancet, Vol. XIII, 1852, p. 82. According to DUTCHER—*loc. cit.*—it was again epidemic in Enon Valley in 1852. For accounts of other local epidemics during that year and 1853, see the Transactions of the Medical Society of Pennsylvania, Sessions of 1853 and 1854. In the volume for the session of 1856, p. 96, note particularly the account given by D. LEASURE of the epidemic in Lawrence county in 1851, in which the author shows clearly that the distribution of the disease in the county did not coincide with that of intermittent fever. Dr. WM. H. FORD, secretary of the Philadelphia Board of Health, has kindly furnished the following statement with regard to that city. Annual number of deaths from dysentery in Philadelphia from 1840 to 1860, inclusive:

Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.
1840	118	1846	69	1852	552	1858	240
1841	130	1847	171	1853	370	1859	129
1842	100	1848	315	1854	447	1860	178
1843	93	1849	578	1855	266		
1844	57	1850	412	1856	301		
1845	65	1851	501	1857	197		

§ L. S. JOYNES—*Statistics of the mortality of Baltimore from* 1836 *to* 1849, Amer. Jour. of the Med. Sciences, Vol. XX, 1850, p. 297; and CHARLES FRICK—*Vital statistics of the city of Baltimore*, op. cit., Vol. XXX, 1855, p. 312; also by the same—*Pathology of epidemic dysentery*, op. cit., Vol. XXII, 1851, p. 305. According to these authorities the annual number of deaths from dysentery in Baltimore was as follows:

Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.
1836	25	1841	22	1846	7	1851	161
1837	39	1842	25	1847	42	1852	222
1838	25	1843	22	1848	46	1853	242
1839	16	1844	13	1849	148	1854	252
1840	27	1845	13	1850	237		

These papers refer only to the city of Baltimore. We also hear of it in 1851 in Kent county: See Report on *Epidemic diseases of Maryland*, Trans. of the Amer. Med. Ass., Vol. V, 1852, pp. 341-351. J. W. MOHLER, secretary of the Health Department of Baltimore, has furnished me the number of deaths from dysentery in that city since the report of FRICK, from which I abstract the following:

Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.
1855	252	1857	202	1859	141
1856	213	1858	137	1860	59

I may add, on the authority of the same gentleman, that from 1866 to 1876, inclusive, in spite of the increased population, the largest number of deaths from dysentery for any one year was 85 during 1869, the smallest 52 for 1876.

in Henry county during the summer of 1853, and throughout the part of the state which now constitutes West Virginia, in 1851, 1852 and 1853.* The only report I find from North Carolina refers to 1851 and 1852.† The reports from South Carolina refer to the years 1851, 1852, 1853, 1854 and 1855;‡ those from Georgia to 1847, 1848, 1851, 1852, 1853 and 1854.§ So far as these reports give numerical statements with regard to the prevalence of the disease in any particular cities or districts, they are in accord with the Census of 1850, which shows a greater mortality from dysentery in the northern than in the southern portion of the Atlantic region.

Still more numerous are the accounts of the epidemic prevalence of dysentery during the period under consideration in various parts of the great Central region of the continent. The earliest report from Ohio is for 1847, the latest for 1853; the reports referring to 1851 are more numerous than those for any other of these years.‖ The same is true of Indiana, the reports from which extend from 1848 to 1853.¶ The few reports from Illinois refer to 1853, 1854 and 1855.** From Michigan the reports are fuller and represent the epidemic prevalence of the disease in various parts of the state from 1847 to 1855.†† They are still more complete from Kentucky and Tennessee; in the case of the former

* P. R. REAMEY—*The epidemic dysentery of Henry county, Virginia, as it prevailed during the summer of* 1853, The Stethoscope, Vol. III, 1853, p. 557. J. E. REEVES—*The Health and Wealth of the city of Wheeling*, Baltimore, 1871, p. 150.

† THOMAS HINES—*Epidemic typhoid dysentery*, The Stethoscope, Vol. V, 1855, p. 7. The district referred to borders on the Dismal Swamp.

‡ W. T. WRAGG—*Epidemic dysentery on Ashepoo river in* 1851, *afterwards spreading to Combahee river*, Charleston Med. Jour. and Rev., Vol. VI, 1851, p. 757. SALLEY—Trans. of South Carolina Med. Ass., same Jour., Vol. XI, 1856, p. 184—states that dysentery was epidemic at Orangeburg during the summers of 1852-3-4-5. See also MOBLEY—*Epidemic dysentery as it appeared in the districts of Chester and Lancaster in* 1853-4, Proc. of the South Carolina Med. Ass., 1855, Appendix F, p. 62.

§ SMITH and MARTIN—*Notice of an epidemic dysentery*, Southern Med. and Surg. Jour., Vol. IV, 1848, p. 30. This account refers to the vicinity of Atlanta, Georgia, in 1847. J. J. M. GOSS—*Epidemic dysentery*, same Jour., Vol. X, 1854, p. 459—states that the disease was epidemic in 1847-8 in Oglethorpe and Madison counties; in 1852 in Walton and Gwinnett counties. J. S. WEATHERBY—*Dysentery in Gordon and Cass counties*, [Georgia, 1851,] same Jour., Vol. VII, 1851, p. 725. H. F. CAMPBELL—*Cases of an unusual form of fever and dysentery*, [Georgia, 1851,] same Vol., p. 567. According to the *Reports on epidemics*, Trans. Amer. Med. Ass., Vol. V, 1852, p. 367, it was also epidemic in Houston and Hancock counties, Georgia, during 1851. E. M. PENDLETON—*Epidemic dysentery in Hancock county, Georgia, during the years* 1851-2-3, Charleston Med. Jour. and Review, Vol. IX, 1854, p. 168. D. C. O'KEEFFE—*Epidemic dysentery*, [vicinity of Greensboro', Georgia, 1852-53,] Southern Med. and Surg. Jour., Vol. X, 1854, p. 325. H. A. RAMSAY—*Bloody Flux*, [vicinity of Thompson, Georgia, 1853,] Nashville Jour. of Med. and Surg., Vol. V, 1853, p. 257. B. R. RIVES—*Cases of dysentery*, Southern Med. and Surg. Jour., Vol. XV, 1854, p. 650—speaks of dysentery as epidemic in Baker county, Georgia, in 1853-4.

‖ I. A. COONS—*Dysentery in Montgomery county, Ohio*, Western Lancet, Vol. XV, 1854, p. 195—states that the disease prevailed annually for six years, 1847-52, inclusive, but especially in 1849 and 1852. L. SLUSSER—*Nitrate of silver in epidemic dysentery*, Medical Examiner, Vol. VI, 1850, p. 450, vicinity of Canal Fulton, Ohio, 1849. J. A. MURPHY—*Epidemic dysentery of* 1849-50, Western Lancet, Vol. XII, 1851, p. 69, Cincinnati, Ohio. S. P. HILDRETH—*Epidemic dysentery as it appeared in Marietta, Ohio, in* 1851, same Jour., Vol. XIII, 1852, p. 166. B. STANTON—*Dysentery as it appeared in Salem* [Ohio] *and vicinity during the summer of* 1851, same Vol. p. 509. C. W. PRATHER—*Dysentery complicated with gastritis*, same Vol., p. 227—states that the disease was epidemic in Butler county during the summers of 1849-50-51. J. W. TULLIS—*Treatment of dysentery*, Ohio Med. and Surg. Jour., Vol. III, 1851, p. 323, epidemic at Troy, Ohio, 1850. T. W. GORDON—*Remarks on dysentery*, same Jour., Vol. V, 1853, p. 208, vicinity of Georgetown, Ohio, 1851. D. A. HOFFMAN—*Opium in a case of epidemic dysentery*, same Jour., Vol. IV, 1852, p. 383—states that it was epidemic in the vicinity of Jackson C. H., Ohio, 1851. S. C. MENDENHALL—*Rheumatic inflammation as a sequel of dysentery*, same Vol., p. 376—states that it was epidemic in many parts of Ohio during 1851. J. B. EVANS—*Epidemic dysentery*, North-Western Med. and Surg. Jour., Vol. IX, 1852-3, p. 493, Ross county, Ohio, 1852. S. C. ROBERTS—*Dysentery as it appeared at Bainbridge, Ohio, and vicinity during the summer and autumn of* 1852, Western Lancet, Vol. XIV, 1853, p. 597. S. C. MENDENHALL—*Note-book gleanings*, Ohio Med. and Surg. Jour., Vol. VI, 1853-4, p. 30—mentions that dysentery was epidemic in the vicinity of Sunbury, Delaware county, Ohio, during the summer and autumn of 1852. For other accounts of epidemic dysentery in Ohio, especially during 1849, 1851, 1852 and 1853, see the reports on the epidemics of Ohio in the Trans. of the Amer. Med. Ass., Vol. V, 1852, pp. 438-485, and Vol. VII, 1854, pp. 288-356.

¶ I. CASSELBERRY—*Epidemic dysentery*, Western Lancet, Vol. VIII, 1848, p. 143, Evansville, Ind., and vicinity, 1848. The same—*Diseases of Southern Indiana*, same Jour., Vol. XIII, 1852, p. 781—says dysentery was epidemic in this region during the summers of 1848-49-50-51. WM. MATHEWS—*Epidemic dysentery of the West*, Nelson's Northern Lancet, Vol. IV, 1851-2, p. 127—says dysentery was epidemic in Western Indiana in 1851. W. DICKEY—*Dysentery as it prevailed in the town and vicinity of Dalton, Wayne county, Ind., in the summer and autumn of* 1851, Western Lancet, Vol. XIII, 1852, p. 526. J. S. DU HATE—*Muco-gastro-enteritis, as it prevailed in Southern Indiana as an epidemic*, [1851,] same Jour., Vol. XII, 1851, p. 719. E. READ—*Dysentery and its treatment*, Indiana Med. Jour., Vol. I, 1854, p. 29—states that dysentery was epidemic in the region about Terre Haute, Ind., during 1852-3. For further accounts of the prevalence of dysentery in Indiana during 1849 and 1851, see W. T. S. CORNETT—*Report of committee on Practice of Med.*, Proceedings of 3d annual meeting of the Indiana State Med. Society, May, 1852, p. 33; and for its prevalence during 1851-3 see the reports of the committees on the epidemics of Indiana, Trans. of the Amer. Med. Ass., Vol. V, 1852, pp. 485-503, and Vol. VII, 1854, pp. 356-390.

** W. S. LINN—*A word on dysentery*, Iowa Med. Jour., Vol. I, 1854, p. 161—mentions its prevalence at Chili, Illinois, in 1853. S. W. THOMPSON—*Ileo-colitis as it prevailed in and around Fairfield, Wayne county, Ills., during the summer of* 1854, North-Western Med. and Surg. Jour., Vol. III, 1854, p. 529. H. W. DAVIS—*Dysenteria intermittens*, same Jour., Vol. V, 1856, p. 295—states that dysentery was epidemic in the eastern portion of Illinois during the summer and autumn of 1855.

†† H. TAYLOR and J. H. BEECH—*Report on dysentery*, Trans. of the Amer. Med. Ass., Vol. VIII, 1855, p. 547—mention its prevalence in various parts of Michigan in 1847-48-49-50-51 and 1854. See also the same Transactions, Vol. V, 1852, pp. 526-528, for further particulars with regard to its prevalence in 1851, and Vol. VII, 1854, pp. 390-418 as to its prevalence in 1852-3; also the following papers: F. K. BAILEY—*Dysentery*, North-Western Med. and Surg. Jour., Vol. I, 1853, p. 385, in which its epidemic occurrence in the vicinity of Almont, Mich., in 1852 is mentioned; J. AVERY—*Epidemic dysentery as it prevailed in the Grand River Valley* [Michigan] *during the autumn of* 1855, The Med. Independent, Vol. I, 1856, p. 332.

state they extend from 1849 to 1853,* in the case of the latter from 1846 to 1856.† The reports from Alabama extend from 1849 to 1856, and are particularly full with regard to 1851.‡ From other states in the Central region the reports are either fragmentary or altogether wanting. There is a report from Mississippi for 1852;§ one from Louisiana for 1854 and 1855;‖ several from Texas for 1853, 1855 and 1856;¶ and one from Arkansas for 1853–4.**

Here, too, I may mention the reports of Stillman and Blake, which have been cited by Hirsch,†† as evidence of the endemic prevalence of dysentery in California, but which refer to years, 1849–50, belonging to the great epidemic period under discussion, a circumstance which may account for the unusual frequency of the disease at the time referred to, if indeed it were not entirely due to the errors of diet and the exposed life of the emigrants who, at the period in question, were swarming into the state in search for gold. Certainly no unusual prevalence of dysentery in California is indicated by the Census Reports of 1860 and 1870, in both of which it has a percentage of mortality less than the average for the states of the Atlantic or Central regions.

---

* WM. C. SNEED—*Epidemic dysentery in Frankfort and Franklin county, Kentucky, during the summer and fall of* 1849, Western Jour. of Med. and Surg., Vol. V, 1850, p. 1. J. HARDIN—*Treatment of dysentery.* same Jour., Vol. VIII, 1851, p. 1—states that it was epidemic at Louisville during 1849–50. Its prevalence in that city during 1850 and 1853 is also mentioned by L. P. YANDELL—*Trans. of the College of Phys. and Surgs. of Louisville*, American Practitioner, Vol. II, 1870, pp. 279 and 286. W. W. FRITTS—*On dysentery*, Western Jour. of Med. and Surg., Vol. XII, 1853, p. 1, Nicholas county, Ky., 1851. See also *Report on the epidemics of Tennessee and Kentucky*, Trans. of the Amer. Med. Ass., Vol. V, 1852, p. 557, for some further account of its prevalence in Kentucky during 1851, and two subsequent reports in the same Transactions, Vol. VI, 1853, p. 340, and Vol. VII, 1854, pp. 111 and 114, for its prevalence in 1852 and 1853. The table on p. 111 reports 1,019 deaths from dysentery during 1852 in forty-nine counties of Kentucky.

† J. E. STEWART—*Epidemic dysentery*, Missouri Med. and Surg. Jour., Vol. III, 1847, p. 145—mentions its prevalence at Jackson and Memphis, Tenn., during the summer and fall of 1846 and 1847. J. HARRIS—*Dysentery*, Nashville Jour. of Med. and Surg., Vol. V, 1853, p. 337, at Cagewell, Tenn., 1851–2–3. R. THOMPSON—*Dysentery*, same Jour., Vol. IV, 1853, p. 143, at Salisbury and Lancaster, Tenn., 1852. See also, for further particulars with regard to its prevalence in Tennessee in 1851–2–3, the reports on the epidemics of Tennessee and Kentucky cited in the last note. T. L. MADDIN—*Dysentery*, Nashville Jour. of Med. and Surg., Vol. V, 1853, p. 198—says that during the summer of 1853 dysentery prevailed extensively not only in Tennessee, but throughout the whole Mississippi Valley, and in many places with alarming fatality. WM. P. MOORE—*Opium in dysentery*, same Vol., p. 204—mentions that in 1853 dysentery was epidemic throughout the valley of Green river, Kentucky, and particularly in Simpson county. ISAAC TAYLOR—*Dysentery*, same Vol., p. 205, East Tennessee, 1853. J. T. MARABLE—*Dysentery or bloody flux*, same Jour., Vol. VI, 1854, p. 1, Montgomery county, Tenn., 1853. M. RANSOM—*Epidemic dysentery near Salem, Rutherford county, Tenn., during the summer of* 1855, Southern Jour. of the Med. and Phys. Sciences, Vol. IV, 1856, p. 87. R. O. CURREY—*Epidemic dysentery in Knox county* [Tenn.] *in July and August*, 1856, same Jour., Vol. V, 1857, p. 100. I. TAYLOR—*Epidemics of Blount county* [Tenn.] *during* 1856, Nashville Jour. of Med. and Surg., Vol. XII, 1857, p. 502—dysentery was epidemic from July to October. B. FRAZIER—*Epidemic dysentery in the Sequatchee Valley* [Tenn.] *in* 1856, Southern Jour. of the Med. and Phys. Sciences, Vol. V, 1857, p. 231.

‡ W. B. WELCH—*Dysentery in Morgan county, North Alabama*, 1849–50, The Western Lancet, Vol. XIII, 1852, p. 19. A. A. J. RIDDELL—*Epidemic bloody flux*, New Orleans Med. and Surg. Jour., Vol. VII, 1850, p. 99, Prairie Bluff, Ala., 1850. F. E. GORDON—*Salines and opiates in dysentery*, same Jour., Vol. IX, 1852, p. 188—states that dysentery was epidemic throughout Alabama in 1851. WM. TAYLOR—*Epidemic dysentery at Talladega, Ala., in the autumn of* 1851, same Jour., Vol. VIII, 1852, p. 592. For further particulars as to the prevalence of the disease in various parts of Alabama during 1851, see Proc. of the Med. Ass. of the State of Alabama, Session of December, 1851. W. TAYLOR, in the same Transactions for 1855, states that dysentery was also epidemic in Alabama in 1852 and 1853. See also, for further particulars with regard to epidemic dysentery in Alabama in 1851, the *Reports on Epidemics*, Trans. Amer. Med. Ass., Vol. V, 1852, p. 380. F. E. H. STEGER—*Dysentery*, Nashville Med. Record, Vol. II, 1859–60, p. 270—affirms that dysentery was rare in northern Alabama until 1852, after which it recurred annually for several years. J. TURRENTINE—*Epidemic dysentery*, Charleston Med. Jour., Vol. XII, 1857, p. 145—states that dysentery had been present in northern Alabama for several years prior to the date of his paper. According to S. A. CARTWRIGHT—*Dysentery among negroes*, New Orleans Med. and Surg. Jour., Vol. XI, 1854–5, p. 145—local epidemics occurred on certain plantations in south Alabama in 1851–52 and 1854.

§ R. R. GRESHAM—*Dysentery*, &c., Western Jour. of Med. and Surg., Vol. XII, 1853, p. 302—mentions that dysentery was epidemic in the vicinity of Ebenezer, Miss., in 1852.

‖ J. B. PAYNE—*Epidemic dysentery*, New Orleans Med. and Surg. Jour., Vol. XV, 1858, p. 87, Claiborne parish, Louisiana, 1854–5.

¶ J. P. CUNLIFFE—*Malignant epidemic dysentery*, Southern Jour. of Med. and Phys. Sciences, Vol. I, 1853, p. 320, Titus county, Texas, 1853. W. A. RAWLINGS—*Treatment of dysentery*, Nashville Jour. of Med. and Surg., Vol. X, 1856, p. 28, epidemic about Huntsville, Texas, 1855. W. L. GAMMAGE—*Dysentery*, New Orleans Med. and Surg. Jour., Vol. XIII, 1856–7, p. 451, epidemic in Cherokee county, Texas, 1856.

** G. W. LAWRENCE—*Report on Climatology, &c., of Arkansas*, Trans. Amer. Med. Ass., Vol. XXIII, 1872, p. 419—states that during 1853–4 dysentery was epidemic in several counties of Arkansas.

†† J. D. B. STILLMAN—*Obs. on the med. topography and diseases (especially diarrhœa) of the Sacramento Valley, California, during the years* 1849–50, New York Jour. of Med., Vol. VII, 1851, p. 289: "The number who arrived in California during the six months from the first July, 1849, to first of January, 1850, was over 90,000; of these nearly 30,000 performed a voyage by sea of 17,000 miles, more than 60,000 crossed a wilderness of greater extent than the entire distance from the mouth of the Tagus to the eastern confines of Russia, over arid plains and rugged mountains. Of this number, it was roughly estimated that one-fifth had found graves within the first six months after their arrival." Here were all the conditions which usually accompany the dysentery of armies. Scurvy was common, but STILLMAN thinks that the scorbutic subjects were no more disposed to the fatal dysenteries and diarrhœas which prevailed than the others, and affirms, "those who died from scurvy had neither dysentery nor diarrhœa." He insists that the diarrhœa and dysentery of California are endemic and "of malarious origin, in common with intermittent and remittent fevers," p. 307. JAMES BLAKE—*Climate and diseases of California*, Amer. Jour. of the Med. Sci., Vol. XXIV, 1852, p. 53—says that during October and November, 1850, the principal diseases were diarrhœa and dysentery. They were very fatal, and occurred chiefly among emigrants who had just crossed the plains. Compare the remarks of A. HIRSCH—Prager Vierteljahrschrift für die Prakt. Heilk., Bd. XLVII, 1855, S. 68, paper cited *supra* in note to p. 401.

The mortality report of the Census of 1850 gives valuable information with regard to the actual severity of the great dysenteric epidemic which has just been sketched. So many of the reports cited refer to 1851 that it seems probable that this year, rather than 1850, was that during which the disease was at its height; nevertheless the number of deaths from dysentery reported in 1850 was 20,556, while, in spite of the constantly increasing population of the country, the total number reported in 1860 was but 10,468, and in 1870 only 7,912. I append in a foot-note * a table which gives a summary view of the total number of deaths from diarrhœa, dysentery and enteritis in the whole United States, according to each of the three census reports, together with ratios expressing the mortality per 100,000 living persons. These ratios indicate that the percentage of mortality from dysentery during the year represented by the Census Report of 1850 was more than four times as great as in 1870; and it is in every way probable that during 1851 the mortality was still greater than this. It has already been shown † that according to the Report of 1850 the mortality from dysentery was greater in the northern and central than in the southern states of the Central region; and the remark already made with regard to the Atlantic region, that nothing in the special reports I have collected is in disaccord with this testimony, may be repeated here. So that the interesting evidence that has been presented with regard to the epidemic period under discussion affords no substantial support to the malarial theory of the causation of dysentery.

In concluding this branch of the subject it may be added, that from 1856 to 1861 I find but few reports of local epidemics of dysentery, viz: one from Fort Gaines, Georgia, in 1857; one from Le-Roy, Illinois, in 1858; and one from North Carolina, in which the disease is affirmed to occur more or less extensively in that state every summer,‡ and to prevail at times in the mountainous districts in which the periodic fevers do not originate.

Influence of Season on the prevalence of Dysentery in the United States.—The comparative monthly frequency of acute dysentery in each of the three regions during the war, and the year subsequent to it, is represented in the following tables for white and colored troops separately. Curves constructed from the ratios given in these tables would closely approximate in their form the curves presented in Section I, which represent the total number of cases of diarrhœa and dysentery, both acute and chronic. It appears from these ratios that acute dysentery was most frequent during the summer and autumn, but certain irregularities in the curves in individual years and regions plainly indicate that other influences, connected undoubtedly with the movements and exposures of the great armies, may materially modify the effect of season alone.

The influence of season indicated by these ratios is corroborated by the experience of the United States Army in time of peace. The reports of both Forry and Coolidge* give the number of cases by quarters instead of by months. In these reports, the first quarter terminates March 31st, the second June 30th, the third September 30th, and the fourth December 31st. In both reports the greatest number of cases of both diarrhœa and dysentery is shown to have occurred during the third quarter.† The report of Coolidge gives the number of cases of diarrhœa and dysentery separately, and it is seen that their relation to season was very similar.

The relation of season to the mortality of dysentery among the civil population of the United States is well shown by the several census reports.‡ In the Census Reports of 1860 and 1870 the mortality is given by months, and in both years August was the month of the greatest mortality of dysentery.§ It will be seen that in both years the minimum occurred during the winter, the month of least mortality being February, in 1860, and January, in 1870. From the point of minimum the mortality steadily increases until May, when a very great increase takes place, and it then rapidly rises to the maximum in August, after which, diminishing considerably during September and October, it suddenly experiences a great fall in November, and then gradually diminishes to the month of min-

* See note to p. 416, *supra*.

† Frequency of *Diarrhœa* and *Dysentery* in the United States Army in time of peace in each quarter of the year, expressed in ratio per 1,000 of mean strength: The ratios from the report of COOLIDGE have been computed from a consolidation of his tables.

	First quarter.	Second quarter.	Third quarter.	Fourth quarter.
Report of Forry, Diarrhœa and Dysentery	54	107	166	75
Report of Coolidge, Diarrhœa	51	84	139	78
Report of Coolidge, Dysentery	14	26	37	22

‡ In the mortality report of the Census of 1850 the figures are given by quarters, as in the army reports just cited. The quarters, however, unfortunately do not exactly correspond. "Spring" embraces February, March and April; "summer," May, June and July; "autumn," August, September and October; and "winter," November, December and January. The number of deaths from diarrhœa and dysentery was as follows:

	Spring.	Summer.	Autumn.	Winter.
Diarrhœa	652	1,766	3,176	686
Dysentery	1,009	3,570	14,254	1,554

§ Monthly number of deaths from *Dysentery*, according to the Census Reports of 1860 and 1870:

YEAR.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.
1860	273	233	254	336	829	899	1,473	2,519	1,970	1,009	333	264
1870	209	221	228	275	452	486	1,171	1,870	1,593	869	305	232

imum. The number of deaths from diarrhœa during the same years is added for comparison.* It will be seen that the fluctuations are very similar, and that the month of August is that of greatest mortality for both years.

These results with regard to the relation of dysentery to season are in close agreement with those collected by Hirsch† with regard to its endemic prevalence in Europe and other temperate regions in the northern hemisphere, and indeed with its epidemic occurrence in the same regions. Thus of 496 European epidemics, the period of greatest prevalence was during the spring in 11, spring and summer in 4, summer in 158, summer and autumn in 203, autumn in 103, autumn and winter in 6, and winter in 11. In the tropical regions of the northern hemisphere the period of maximum appears to be somewhat later—September to November; while in the southern hemisphere the maximum falls most frequently in the months of March or April. In all cases, the period of greatest prevalence appears to be either the latter portion of the hot season or the time of its gradual transition into colder weather.

Comparative frequency of Dysentery among the White and Colored troops.—The statistics of diarrhœa and dysentery discussed in Section I, and those relating to acute dysentery, presented a few pages above, show that dysentery during the civil war was both more frequent and more fatal among the colored troops than among the white. Some reasons have already been offered in explanation of this circumstance.‡ In confirmation of the opinion then advanced, a tabular view of the comparative mortality of dysentery among the white and colored civil population of the United States, according to the Census Reports for 1850 and 1870, is subjoined,§ and the figures for diarrhœa and enteritis have been added for comparison. The Census of 1860 is not available for this comparison, as the mortality of the white and colored races was not printed separately in it.

It will be seen from the table that the proportionate mortality of diarrhœa and enteritis, according to both Census Reports, was nearly the same for both races. The same is true for dysentery according to the Census of 1870, while in that of 1850 dysentery appears to have been more than three times as fatal among the whites. It must be remembered, however, that the Census of 1850 represents one of the years of epidemic dysentery in which, as has been shown, the epidemic influence was most extensively felt in the northern states; that is, just those states in which the negro population was very

* Monthly number of deaths from *Diarrhœa*, according to the Census Reports of 1860 and 1870:

Year.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.
1860	227	195	231	296	703	791	1,300	1,744	1,161	651	303	222
1870	443	418	459	488	894	1,077	2,467	3,139	2,482	1,288	588	447

† Bd. II, S. 224 of work cited on p. 416, *supra*.

‡ See p. 8, *supra*.

§ Ratios of deaths from *Diarrhœa* *Dysentery* and *Enteritis* per 100,000 living persons, for white and colored separately:

	1850.		1870.	
	White.	Colored.	White.	Colored.
Dysentery	99	31	20	20
Diarrhœa	27	27	36	38
Enteritis	12	13	24	20

small. If this circumstance is not admitted to account for the difference, it may be observed that this difference is in the opposite direction to that observed during the civil war, and that neither Census Report supports the opinion which has been drawn from the papers of Tidyman and Cartwright,* that dysentery is especially frequent and fatal among the negro race in the United States. For myself, I have been led to the conclusion that whatever differences may exist in the extent to which diarrhœa and dysentery prevail among the white and colored races in particular localities or at particular times, depend rather upon differences in the circumstances to which they are exposed than upon difference of race.

RELATION OF DYSENTERY TO AGE AND SEX.—The military statistics of the civil war afford no convenient data for inquiring into the comparative frequency of dysentery among soldiers of different ages and different lengths of service. The Census Reports, already cited, show that while no age is exempt, as is indicated by the subjoined summary, children, especially those under five years of age, are peculiarly liable.† As to the sexes, a rather larger number of males would appear from the same Reports to die from the disease.‡

SECOND ATTACKS.—Van Geuns§ declared that in his large experience he never saw any one who had once had dysentery again attacked by it, and brings forward the fact that those districts in Holland which suffered by the epidemic of 1779 were spared by that of 1783, in support of the opinion that, as by small-pox and scarlatina, the constitution of the patient is so modified by an attack of dysentery as to exempt him from a repetition of the disease. On the other hand, Catteloup|| states that in the military hospital of Tlemcen about one in ten of the dysenteric patients admitted had suffered from dysentery previously,

* P. TIDYMAN—*A sketch of the most remarkable diseases of the Negroes of the Southern States*, Philadelphia Jour. of Med. and Phys. Sciences, Vol. XII, 1826, p. 329: "There is no disease in the autumnal season which prevails more commonly among the blacks than dysentery, and it is frequently very fatal, unless arrested by seasonable attention." S. A. CARTWRIGHT—*Remarks on dysentery among negroes*, The New Orleans Med. and Surg. Jour., Vol. II, 1854, p. 145. This paper refers to local epidemics on certain plantations in south Alabama during 1851–52 and 1854, which the author did not witness himself. The paper is a curious one on account of the vigor with which the writer combats what he evidently regards as a most fatal error, that the "negro is a black white man," resembling the superior race in every quality "except that of having white skins." H. V. WOOTEN [of Lowndesboro', Alabama]—*Dysentery among negroes*, same Volume, Jan., 1855, p. 448—replies to Dr. CARTWRIGHT'S article, and denies "that the epidemic dysentery of south Alabama is confined to, or particularly fatal amongst, the negro population."

† Ages of those who died of *Dysentery*, according to the Census Reports of 1850, 1860 and 1870:

YEAR.	Under 5 years.	5 and under 10.	10 and under 20.	20 and under 50.	Over 50.
1850	11,475	2,172	1,439	3,207	2,218
1860	7,151	718	439	1,244	906
1870	5,004	431	326	1,013	1,133

Mr. E. B. ELLIOTT, the well known statistician, has furnished me the following table, which shows the probable proportion of living persons of the ages specified in the table: Number of persons living at certain ages of life in a constant population supplied by 1,000,000 annual births, according to Mr. E. B. ELLIOTT'S *United States Life-Table* for the year 1870:

Under age of 5	4,009,240	From 10 to 20	6,776,490	Over age of 50	8,677,640
From 5 to 10	3,575,640	From 20 to 50	16,215,410	Total population (all ages)	39,254,420

If this distribution of population be compared with the figures given in the table for 1870, it will be seen that the proportion of deaths to population steadily diminishes up to the period from 20 to 50, during which it is somewhat increased, while after 50 it is very decidedly greater than between 20 and 50. The figures for the other years indicate a similar distribution, except that in 1850 the increase between 20 and 50 is not noted.

‡ Sexes of those who died of *Dysentery*, according to the Census Reports of 1850, 1860 and 1870:

YEAR.	Males.	Females.
1850	10,928	9,628
1860	5,630	4,838
1870	4,270	3,642

§ M. VAN GEUNS—*Abhandlung über die epidemische Ruhr, besonders des Jahrs 1783, aus dem Holländischen übersetzt*, Dusseldorf, 1790, S. 134 *et seq.*

|| CATTELOUP—*Rech. sur la dyssenterie du nord de l'Afrique*, Recueil de Mém. de Méd., de Chir. et de Pharm. Militaires, T. VII, 1851, p. 99: "Dyssenteries de première invasion 989, dyssenteries récidivées 112, total 1101." These were all acute attacks. CATTELOUP, however, seemed inclined to admit that the first attack exercises a modifying influence, for he adds the further statistical facts that of the 989 first attacks 110 died, while of the 112 second attacks but 8 died.

and asserted that in the course of three years' service he had seen several soldiers have each as many as five attacks. In our military experience, second and third attacks were of very common occurrence; the first attack, even when the patient appeared to have completely recovered, leaving the bowels very susceptible to disturbing influences of every kind, so that relapses were readily provoked. I think it probable that in very many of these cases the disease was at first merely of the catarrhal variety, and that very often the intestine did not fully regain its normal condition between the attacks; but I have no doubt whatever of the possibility of second attacks of diphtheritic dysentery, even after years of health have elapsed, and should always expect, when dysentery began to prevail at the commencement of a campaign, that the officers and men who might have suffered from it in former wars would be among the first victims.

POST MORTEM APPEARANCES IN ACUTE DYSENTERY.—The anatomical lesions of dysentery have been so well described by some of the Greek physicians, especially Aretæus and Archigenes, as to make it quite certain that their knowledge must have been drawn either directly or indirectly from the post mortem examination of subjects dead of that disease. Such examinations were probably not infrequently made by the Alexandrian Greeks after Herophilus and Erasistratus had been permitted to dissect human bodies by the first Ptolemy; but the advanced condition to which these celebrated men appear to have brought human anatomy seems to render it very unlikely that they could have been, as some think, the first to dissect human bodies intelligently.

From several independent sources we are informed that such dissections had long before been made by the ancient Egyptians,* whose custom of embalming the dead was

* The author of the treatise *Introductio seu Medicus*, which has been ascribed to GALEN, [Ed. Kühn, XIV, p. 675,] while recording that such dissections were made by the Egyptians, seems to have regarded the results as chiefly valuable to surgery, remarking: "Porro ex cadaverum dissectione, quam in condiendis iis habere moris erat, multa etiam, quæ manu administrantur, apud primos medicos inventa esse videntur." PLINY, however, declared that the Egyptian kings dissected the bodies of the dead for the purpose of investigating diseases. In speaking of the medical virtues of the juice of the radish he remarks: "Tradunt et præcordiis necessarium hunc succum: quando phthisin (phthiriasin?) cordi intus inhærentem non alio potuisse depelli compertum sit in Ægypto regibus corpora mortuorum ad scrutandos morbos insectantibus," *Nat. Hist.*, Lib. XIX, Cap. 26, [Valpy's Ed., London, 1826, Vol. VI, p. 3015.] His nephew, C. PLINIUS SECUNDUS—*De Re Medica*, Lib. IV, Cap. 1, in Med. Antiqui, etc., Venice, 1547, fol. 201—has given the following paraphrase of this passage: "Contra phthiriasim succus ejus adhibetur, qui solus potest tenuitate subtili adimi corporis liniamenta, cor penetrare. Aegyptii enim reges, quibus erat studium scrutari corpora mortuorum, et causas valetudinum, occulta fide recognoscere, in corde ipso nasci ejusmodi vitium, prodiderunt." The Egyptian historian MANETHOS, who lived in the reign of Ptolemy Philadelphus, declared, if we may believe EUSEBIUS—Lib. I, *Chronicorum*, Cap. XX, § 4, Opera, T. I, Columna 184, Edit. Migne, Paris, 1857–66—that ATHOTIS, (also Athostis, Athothis, Athot, Thot, &c.,) king of Egypt, was both physician and anatomist, and that he wrote books on anatomy, ("καὶ βίβλους ἀνατομικὰς συνέγραψε.") This king was the successor of MENES, and began to reign, according to the compilation of Count J. POTOCKI—*Chronologie des deux premiers Livres de Manethon*, St. Petersburg, 1805, p. 1—in the year 3609 B. C. According to D. M. J. HENRY—*L'Égypte Pharaonique*, Paris, 1846, T. I, p. 132—in the year 5241 B. C. Various other estimates of the date of this king have been made, which, however, are of no importance to our present purpose, since all place him many centuries before the time of the Ptolemies. According to CLEMENT of ALEXANDRIA—*Stromata*, Lib. VI, Cap. 4, Opera, Potter's Ed., Oxford, 1715, p. 758—the ancient Egyptians possessed six Hermetic Books of Medicine treating severally of Anatomy, of Diseases, of Surgical instruments, of Pharmacy, of the Eye and of Diseases of Women. HENRY—*op. cit.*, T. II, p. 113—believed that of these Hermetic Books, that treating of Anatomy was the work which MANETHOS ascribed to ATHOSTIS. It is probable that the culmination of Egyptian medical knowledge was reached long before the time of ARISTOTLE; for he refers to the existence of an Egyptian law which compelled physicians to practice according to written rules for the first four days of sickness: "Et in Ægypto post diem quartum movere licet medicis: quodsi ante id tempus facere conentur, suo periculo faciunt," *Politica*, Lib. III, Cap. 10, (15,) Paris Ed., 1848–54, T. I, p. 535. DIODORUS SICULUS—*Bibliothecæ Historicæ* Lib. I, Cap. 82, C. Müller's Ed., Paris, 1843, T. I, p. 66—gives the same law in more detail, though he does not refer to the permission to deviate from the written code after a four days' trial: "Medici enim annonam ex publico accipiunt, et medicinam ex lege scripta, per multos ab antiquo medicos illustres concinnatam, applicant. Si leges, quas sacri codicis lectio tradit, secuti ægroto sanitatem reddere nequeant, culpa vacant, et indemnes abeunt; sin contra præscriptum agant, capitis judicium subeunt. Nam medendi rationem longi temporis usu observatam et ab optimis artificibus ordinatam paucos ingenio et sollertia superaturos legislator censuit." After such a custom had once been established the progress of medical science must soon have been checked, and a demand would be created for authoritative compilations, such as those enumerated by CLEMENT of ALEXANDRIA. As mentioned in the text, many medical historians have been inclined, nevertheless, to believe that the anatomical notions acquired by the Egyptians were of the rudest kind. This was the opinion of HERMAN CONRING—*De Hermetica Ægyptiorum veteri et nova Paracelsicorum medicina*, Helmstadt, 1648, [I cite the Ed. of 1669]—as may be seen, especially in Lib. I, Cap. 10, p. 89, which is headed, "Physiologiam et Pathologiam Ægyptiacam humani corporis, partim rudem fuisse, partim ineptam: parûm certé habuisse veræ scientiæ." Similar views were entertained by LE CLERC—*Hist. de la Méd.*, 1696, I cite the English transl., London, 1699, p. 18; by J. H. SCHULZE—*Hist. med.*, Leipsic, 1728, Period I, Sect. I, Cap. 3, p. 23; D. P. GERIKE—*Programma de Athotis Tosorthri et antiquissimorum Ægyptiorum anatomia fabulosa*, etc., Helmstadt, 1739; HALLER—*Bibl. Anat.*, 1774, T. I, p. 7; and SPRENGEL—*Geschichte der Arzneykunde*, 3te Aufl., Bd. I, Halle, 1821, S. 61 *et seq.* Even J. HYRTL—*Antiquitates anat. rariores*, Vienna, 1835, p. 47 *et seq.*—who seems disposed to take a more favorable view, and who states, among other circumstances, that mummies have been discovered whose parts were sewed together, showing that the interior of the body was not inaccessible to the curious in those ancient times, expresses his belief (p. 57) that no one of sound mind will contend that bodies were dissected by the ancient Egyptians with much art.

favorable to the pursuit of anatomy; and although many writers on medical history have inclined to the opinion that the anatomical notions thus acquired were of the rudest kind, yet it must be confessed that the additions to our knowledge of Egyptian culture made during the present century have been of a character to increase our respect for ancient Egyptian medicine, and to favor the opinion of those who hold that the anatomical knowledge possessed by the Egyptians before the Greek conquest was at least fairly comparable with that which they had acquired in other sciences of observation.

Nor does it seem unlikely, when we consider the circumstances under which the wonderful intellectual development of the Alexandrine Greeks took place, that they were largely indebted in the matter of anatomy as well as in so many other directions, to the learned men of the conquered nation; or that Herophilus and Erasistratus * were fortunate not merely in receiving from a Greek prince permission to dissect human bodies, but also in obtaining that permission at such a time and place that it was possible for them to enjoy the instruction of the Egyptian anatomists. How much knowledge of pathological anatomy was acquired by the Alexandrine School, either from the Egyptians or independently from Greek investigation, is a matter of uncertainty, since only a few fragments of its medical writings have been handed down to us; but if, as seems probable, the descriptions of the dysenteric lesions found in the writings of Aretæus and Archigenes † were derived from that source, its acquaintance with pathological anatomy must have compared favorably with the knowledge of normal anatomy for which it enjoys a well deserved reputation.

On the other hand, a higher estimate of Egyptian anatomy has been entertained by several writers, among the more modern of whom I may particularly mention HENRY—*op cit., supra*, T. II, p. 107 *et seq.*, and M. S. HOUDART—*Hist. de la Méd. Grecque*, Paris, 1856, p. 45—whose posthumous work, published under the auspices of CH. DAREMBERG, contains a very interesting essay on Egyptian medicine—Livre II, De la médecine chez les Egyptiens. Quite recently the publication, under the auspices of the German government, of a fac-simile of the very perfect papyrus discovered a few years since by GEORG EBERS—*Papyros Ebers das hermetische Buch über die Arzeneimittel der alten Ägypter in hieratischer Schrift*, Leipsic, 1875—has thrown new light on Egyptian medicine. A calendar on the back of the scroll would seem to show that it must have been written about the year 1552 before Christ, and its contents appear to indicate that it is in fact the Hermetic book on Pharmacy. This remarkable work is evidently a compilation from various sources which were already ancient when it was written. If the opinions formed of its age are correct, it shows that, more than a thousand years before HIPPOCRATES, Egyptian medicine had made most respectable progress. It is full of prescriptions in which the medicaments are set down in order, with the quantities of the liquids indicated by measure, that of the solids by weight. They are grouped in accordance with an anatomical classification of diseases. Among them are a number (on Taf. 30–35) for heat, burning and pain in the lower bowel and anus, from which we may infer that dysentery had already attracted considerable attention. The names of the medicines and of the diseases mentioned are, it is true, as yet for the most part untranslated, but enough has been made out to increase materially our respect for old Egyptian medicine, and to make us regret more than ever that we do not possess the other Hermetic books, especially those on anatomy and diseases, which would probably throw a flood of light on the sources of many of the pathological doctrines of the Greek physicians, who undoubtedly drew a considerable part of their medical knowledge from Egypt.

* The first PTOLEMY (P. Lagus, or Soter) gave permission to HEROPHILUS, and probably to ERASISTRATUS, to dissect human bodies. (Compare HALLER, cited in last note, T. I, p. 56, with SPRENGEL, cited in last note, Bd. I, S. 533 *et seq.*, for summary accounts of the various opinions with regard to the date and place in which the latter practiced anatomy.) They made good use of their opportunities, and their anatomical writings obtained great credit among the Greeks. CELSUS—Lib. I, *Prefatio*, Lee's Ed., Vol. I, London, 1831, p. 8—has accused them of having obtained by royal edict criminals out of prison for dissection alive, and TERTULLIAN—*De anima Liber*, Cap. IX, "Anima et spiritus, vivere et spirare, unum atque idem est," Opera, Paris Ed., 1658, T. I, p. 9—with malignant exaggeration sets down the number of victims thus butchered by HEROPHILUS at six hundred. But it may well be doubted whether these accusations have any foundation in facts; they are not even alluded to by GALEN, PLINY, RUFUS THE EPHESIAN or CÆLIUS AURELIANUS, all of whom have preserved fragments of the observations and opinions of these anatomists. The Alexandrine School of Medicine, of which they may be regarded as the founders, prospered for a long time. More than six hundred years later AMMIANUS MARCELLINUS— Lib. XXII, Cap. 16, § 18, Tauchnitz Ed., Leipsic, 1867, p. 275—declared that it was sufficient to secure credit to a physician anywhere to have it known that he had studied in Alexandria. Several of the earlier physicians of this school wrote on anatomical subjects, (compare HALLER and SPRENGEL, cited above,) but as their writings have perished it is not possible to say how far they cultivated pathological anatomy.

† ARETÆUS—*De Causis et Signis Morb. Diut.*, Lib. II, Cap. 9, Boerhaave's Ed., 1731, p. 59; ARCHIGENES—In *Ætius*, Tetrab. III, Serm. 1, Cap. 43, Lyons Ed., 1549, p. 599. The descriptions of the lesions of dysentery given by these authors are so nature-true that it is impossible to believe them to be conjectural or speculative. Directly or indirectly they must have been derived from actual observation. Note particularly the account given by ARETÆUS of the sloughing of considerable portions of the internal tunic of the colon in certain cases of dysentery, and the comparison drawn by ARCHIGENES between the lesions of the dysenteric intestine and the papules and ulcers of certain skin diseases; a comparison which has been repeated with approval by one of the most acute observers of pathologico-anatomical processes of the present century, ROKITANSKY—*loc. cit.*, note ‡ to p. 370, *supra*. We know so little of the history of these men that the sources of their knowledge of the dysenteric lesions must remain uncertain. The most probable conjecture is that it was drawn from Alexandria. I cannot, therefore, agree with the learned C. G. ACKERMANN—*De Dysenteriæ Antiquitatibus*, Leipsic, 1777—that the Greek physicians understood by the expression ulceration of the intestines something different from what we now mean by that phrase. This writer has correctly pointed out that in the so-called bloody, hepatic and atrabiliary forms of dysentery (see note ‡ to p. 336, *supra*) the idea of intestinal ulceration was not involved; nay, that even in dysenteria propria (d. ulcerosa of the Greeks) the first grade or stage of GALEN (see p. 345, *supra*) existed without ulceration, and he inferred, therefore, that the Greeks believed rather that ulceration resulted from dysentery than that it caused it, [pp. 45 and 72.] Indeed he was so thoroughly convinced (as others of his times also were) that intestinal ulceration is a rare complication in dysentery, that he admits with the greatest reluctance that the Greek physicians, whom he warmly admired, believed it to be a frequent accident. He offered two explanations of their language on the subject. On the one hand, he suggested that modern therapeutics had advanced so far in his day that dysentery

Both Aretæus and Archigenes included in their conception of dysentery forms corresponding to what we now call typhoid fever, and accordingly they gave a prominence to ulceration of the small intestine in dysentery which does not accord with our modern limitation of the disease.* In this and other particulars their descriptions of the dysenteric lesions were long pretty closely followed by medical writers, who were unable to improve or modify them because they made no dissections.

The enlightened views of the Alexandrine school with regard to human dissections, resisted everywhere else by superstition, took no root beyond the soil of Egypt. Neither Galen, Celsus nor any of the subsequent Greek or Roman physicians appear to have dissected human bodies, and the same remark applies to the Arabians.† Human anatomy,

---

was generally cut short before it progressed to ulceration; whereas the Greek physicians, not enjoying these modern advantages, were unable to prevent this from happening, (p. 71.) On the other hand, he asserts that the word ulceration was used in a much broader sense by the ancients than in modern times; and that, hence, when they spoke of ulceration of the intestines they really meant only in a general way that the intestines were diseased; "veteres medici sub hac voce nihil aliud intellexerint, quam ipsum generale id, quod intestina ab humore ea affluente male afficerentur," (p. 36.) In support of this ingenious speculation he appeals to the doctrine of GALEN with regard to the form of lassitude called ulcerous, which he thinks conclusive evidence in his favor. I do not believe, however, that this doctrine had any practical influence on the use made by the Greeks of the name ulcer, (ἕλκος,) which I find everywhere employed in the very same sense as at the present day. GALEN expressly tells us that an ulcer is a solution of continuity; compare *De Inaequali Intemperie*, Cap. 6, [Ed. Kühn, VII, p. 745,] and *De Morb. Causis*, Cap. 11, [*op. cit.*, p. 38;] and his descriptions of the dysenteric process, taken in connection with those of ARCHIGENES and ARETÆUS, leave no doubt that intestinal ulceration, as understood in those days, was actual ulceration with loss of substance. At the same time it must be admitted that the Greeks used the adjective ulcerous (ἑλκώδης) in a more extended sense than we do. They saw that ulcers vary in extent from great chasms to almost imperceptibly minute losses of substance, and they had no microscope to follow the process after it escaped the vision of the unaided eye. What more reasonable to them than the speculation that ulcers, too minute to be seen, might account for many of the phenomena of disease, especially for pain, even when no solution of continuity could be detected by the eye? In this sense I understand the language of HIPPOCRATES in the treatise *De Fracturis*, § 31, [Ed. Littré, III, p. 527.] He has just said that on the third or fourth day after a fracture, whether simple or compound, the pressure of bandages and other interference should be avoided, because, at about this time after an injury, an inflammatory condition in the injured part is apt to occur, which tends to produce fever, and nothing should be done to aggravate this natural tendency. The passage which follows reads in the accepted Latin version: "Quid enim est præcipui in re medica usus non in ulceribus modo, verum etiam multis in aliis morbis, cum quo communionem non habeat? Nisi si quis alios quoque morbos ulcera esse dixerit. Quæ sane oratio quandam habet probabilitatem. Multis enim modis alii cum aliis cognationem habent," [Kühn's Edition of HIPPOCRATES, T. III, Leipsic, 1827, p. 116.] Now the Greek word, (ἕλκεα,) which is here translated ulcers, is translated wounds both by LITTRÉ *(loc. cit.)* and ADAMS, [Transl. of Sydenham Society, Vol. II, p. 540.] The English version of the latter reads as follows: "And if any piece of information be particularly valuable this is; to which of the most important cases in medicine does it not apply? and that not only in wounds but in many other diseases, unless one should call all other diseases wounds. And this doctrine is not devoid of a certain degree of plausibility, for they are allied to one another in many respects." GALEN, however, seems to have understood HIPPOCRATES to refer to ulcers, as plainly appears from his commentary on this passage, *Comm. III in Hippoc. de Fract. Lib.*, § 34, [Ed. Kühn, XVIII, B, p. 586,] in which he himself arrives at the conclusion that painful diseases, at least, may be classified with ulcers, since a solution of continuity, which is characteristic of ulceration, is known to give rise to pain. See also *De Inaequali Intemperie Liber*, Cap. 6, [*op. cit.*, VII, p. 745,] where he remarks, "ut alicubi et Hippocrates ait, proferens omnes morbos esse ulcera." Similar notions underlie the doctrine of ulcerous lassitude referred to by ACKERMANN. It would take more space than can be spared here to discuss the general doctrine of lassitude and its varieties as understood by the Greeks. The reader may consult GALEN—*De Sanitate tuenda*, Lib. III, Cap. 5–8, [Ed. Kühn, VI, p. 190 *et seq.*,] where the subject is treated of at length, very probably after the teachings of THEOPHRASTUS, who, according to GALEN, wrote a special treatise on this subject. See also ÆTIUS, Tetrab. I, Sermo IV, Cap. 35–44. The lassitude which follows excessive gymnastic exercises, or the fatigue of journeys, is taken as the type of spontaneous lassitude, such as that which precedes fevers, and each is similarly subdivided; ulcerous lassitude is so called because the sensation in the skin and beneath it, which immediately precedes the horror or rigor, was supposed to resemble the sensations which accompany ordinary ulcers, partly because the actual, though invisible, solutions of continuity which produced these sensations were supposed to be caused by the vellicating or vulnerating action of irritating humors in the skin or the tender flesh beneath it. I regard this doctrine merely as the result of an effort to explain certain ill-understood morbid conditions by comparing them with other coarser and more readily comprehended lesions. And I do not think that ACKERMANN could have been induced to suppose that this use of the word ulcerous had anything to do with Greek opinion as to dysentery, had he not himself believed that ulceration was much rarer in dysentery than it really is.

* ARETÆUS says *(loc. cit.)* that if the ulcers of the small intestine become excavated and phagedenic (κοῖλα καὶ ἀνεσθίοντα) acute fevers set in, which in some cases are latent and smoulder in the intestines; in other cases ardent fevers (καυσώδεες) occur accompanied by prostration of strength, thirst, anxiety, dry tongue and small feeble pulse. ARCHIGENES also *(loc. cit.)* asserts that those who suffer from ulcerations of the small intestine are tormented by thirst, and that sometimes malignant fevers arise; "dolor quoque vehemens supra umbilicum considet, quandoque et febres malignæ oboriuntur." LIEBERMEISTER—*Ziemssen's Cyclop.*, Amer. Ed., Vol. I, New York, 1874, p. 42—has recently expressed doubts "whether any of the different forms of dysentery and intestinal ulcers described by Aretæus belong to typhoid fever," remarking that "The intestinal lesions in typhoid fever are not so striking, to those who make no autopsies and only observe symptoms, as to be considered an essential feature." But I must believe the descriptions of ARETÆUS to have been drawn not merely from observation of symptoms, but from ocular examination of the intestines either by himself or by those from whom he obtained his knowledge. I may add that the custom of inspecting the entrails, which formed a part of the ceremony of embalming, must have given to the ancient Egyptians ample opportunities for observing intestinal ulcers, and that typhoid ulcers are quite as conspicuous as the ulcers of dysentery. The knowledge thus acquired would probably have been enlarged and extended by the Alexandrine school, and we shall see that the view which regarded these ulcers of the small intestine as a variety of dyseatery, continued to find favor until the time of MORGAGNI and even later.

† Compare, on this subject, the opinions of HALLER and SPRENGEL in the works cited above. Rude attempts at dissection were undoubtedly made at various times during this period, which bore little fruit on account of the imperfect training of those who made them. Thus, according to GALEN, the physicians who accompanied the Roman army in the German war, though they found occasion to dissect the dead bodies of the slain barbarians, learned no more by their efforts than is understood by cooks.—*De Comp. Med.*, Lib. III, Cap. 2, [Ed. Kühn, XIII, p. 604.] PROCOPIUS—*De Bello Persico*, Lib. II, Cap. 23, Bonn, 1833, T. I, p. 254—relates that during the plague which devastated Constantinople in the year 543, the physicians dissected some of those who died in hopes of getting a better understanding of the disease; but in this case the investigation appears to have been limited to a mere incision into the buboes: "Medici quidam, cum in his cæcutirent accessionibus morbi, ejusque caput in bubonibus residere secretum rati, defunctorum cadavera scrutari decrevissent; dissectis tuberibus aliquot, enatos ibi carbunculos teterrimos deprehenderunt." An interesting account of this plague is given by GIBBON—*Decline and Fall of the Roman Empire*, Chap. 43. See also J. FREIND—*History of Physick*, 3d Ed., London, 1726, Part I, p. 156.

long neglected, was first again revived by Mundinus of Bologna* at the commencement of the fourteenth century, and it was nearly two hundred years later that the earliest autopsies of individual cases of dysentery, which have been preserved to the present day, were published in the posthumous work of Antonio Benivieni,† (1506–7.) Several additional autopsies of dysenteric subjects were made by Hollerius,‡ who died in 1562, and these were the only ones besides those of Benivieni which Schenckius § was able to collect for his encyclopedic work, (1584–97.) After this, observations began to multiply, so that Bonetus ‖ obtained for his Sepulchretum (1679) a number of additional autopsies, among which, in spite of the imperfect character of the descriptions, it is possible to recognize the more important varieties of the dysenteric lesions. Morgagni ¶ (1762) found still richer material at his disposal, and being an agreeable writer, exercised a greater influence on the formation of modern opinion than his less gifted but laborious predecessor.

Like Aretæus and Archigenes, both Bonetus and Morgagni embraced the ulcerations of typhoid fever in their conception of dysentery. The discovery by Peyer of the closed glands, which still bear his name, at first only appeared to strengthen this opinion. Peyer** himself (1677) regarded the glandular plexuses of the ileum as favorite seats for the dysenteric ulcers, especially in epidemic dysentery, and Bonetus †† quoted this opinion with approval.

---

* MUNDINUS dissected the body of a human female in the year 1306; afterwards in 1315 he publicly dissected two others, and, continuing his researches, published a work on human anatomy based on his own observations; [HALLER, T. I, p. 146, *op. cit.*, note * p. 432.] There are in the library of the Surgeon General's Office two black-letter copies of the *Anatomy* of MUNDINUS; one published in Pavia, 1507, the other without date. After his time public dissections of human subjects came into vogue in all the universities, at least as an occasional practice; (SPRENGEL, *op. cit.*, S. 611.) Among those who distinguished themselves by their anatomical pursuits in these early days I may particularly mention BARTHOLOMÆUS MONTAGNANA, who died at Padua about 1460—*Selectiorum Operum Lib. unus et alter*, Frankfort, 1604, p. 582—and who states, in speaking of the circumstance that fæcal matters are not found in the jejunum, that he himself had personally observed this fact in fourteen dissections of human bodies; "ut in XIV corporibus humanis anatomice sectis oculus meus testificatus est."

† ANTONIO BENIVIENI—*De abditis nonnullis ac mirandis morborum ac sanationum causis*, Florence, 1506–7. I cite the Paris Ed. of 1529, bound up with CELSUS, SCRIBONIUS LARGUS, &c. He died in the year 1502. The cases referred to in the text are two in number, of which the second clearly represents an actual autopsy, but I doubt greatly whether this is true of the first. As they are the earliest examples of this class of observations I append a translation of them, (*op. cit.*, fol. 18–19:) "XCV. *The villi, by which the retaining power (of the bowel) is sustained, eroded by a preceding dysentery.* Tormina of the intestines, which the Greeks call dysentery, usually ulcerate the intestines internally, and thence bloody and mucous excrements descend; and when that disease lasts long it either carries off the patient, or, which perchance is worse, it remains incurable. We knew a certain Julian who was troubled with this disease for forty days, at the end of which his pains and desire of going to stool ceased. His bowels remained in a very loose condition, and were moved exceedingly often. He could not be cured by any means; nor was he ever able as long as he lived to restrain the violence of his bowels, but in whatever place the desire of going to stool seized him, he there relieved himself. This condition was doubtless produced by the preceding tormina ulcerating and consuming the villi, on which the retaining power itself depends. XCVI. *The viscera eroded by a similar dysentery.* We have also seen another man, a native of Aretium, who was troubled even still longer with these tormina, which finally caused eroding ulcers of the intestines themselves, afterwards a tabes, and at last death. The viscera (intestines) displayed internal erosion, from which sanies was continually discharged while it remained thus affected, which did not exceed three years."

‡ JAC. HOLLERIUS—*De Morbis Internis*, Lib. I, Cap. 43, *Scholia;* this work was published posthumously, Paris, 1565, its author having died in 1562; I cite Opera, Geneva, 1623, p. 353—published three autopsies of dysenteries. In the first, a child 12 years old, the rectum was found ulcerated, the interior of the œsophagus and the epiploon "corrupted," the lungs "altered"; in the second an ulcer had penetrated all the coats of the stomach near the pylorus; in the third a great quantity of pus was found in the intestines.

§ J. SCHENCKIUS—*Obs. Med., Rar.*, Lib. VII, 1584–97; I cite the Frankfort Ed., 1609, p. 387 *et seq.*

‖ THEOPHILUS BONETUS—*Sepulchretum*, Geneva, 1679—tells us in his preface that PETER CASTELLI (who died about 1656–8) collected, under the title "Sepulchretum," accounts of about two hundred autopsies: "*Pet. Castellum*, Medicum Romanum, necrotirises amplissime professum, ac justo hus volumine complexum notat *Marcus Aur. Severinus* lib. de Abscessibus pag. m. 187. Eundem ducentorum cadaverum evisceratorum historias collegisse, titulo *Sepulchreti* emittendas, asserit Clar *Velschius* [George J. Welsch] initio Sylloges Observationum." The loss of this work, which was never published, must be regretted. In the *Sepulchretum* of BONETUS the principal lesions of dysentery are very fairly illustrated. Cases are related, for example, in which the large intestine was tumid and inflamed, (Obs. 8;) the intestines were inflated and their internal tunics abraded, (Obs, 6;) ulcers and abscesses were found from the beginning of the colon to the end of the rectum, (Obs. 2;) ulcers and cavities the size of half a pea (follicular ulcers?) were found in the rectum, (Obs. 12;) the intestines were gangrenous, (diphtheritic dysentery?) (Obs. 9;) extreme tenuity of the intestine was observed in chronic fluxes, (Obs. 20;) abscess of the liver complicated dysentery, (Obs. 18, 19, 23 and 25;) the spleen was enlarged, (Obs. 24,) &c., &c.

¶ J. B. MORGAGNI—*De Sedibus et Causis Morborum per Anatomen Indagatis*, Veniec, 1762, Epist. XXXI. Here, too, should be mentioned the autopsies of dysenteric subjects collected by J. LIEUTAUD—*Historia Anatomico-Medica, etc.*, Paris, 1767, Lib. I, Sect. 4, T. I, p. 80 *et seq.*

** J. C. PEYER—*Exerc. anat. med. de glandulis intestinorum*, Pars II, Cap. 8 and 9, 1677; I cite the reprint in the *Bibl. Anat.* of MANGETUS, Geneva, 1685, T. I, p. 125 *et seq.*—believed that the cause of diarrhœa, lientery, the cœliac passion, dysentery, colic, the iliac passion and tenesmus was very often at least to be found in disease of these glands. Especially did he think this was the case in epidemic dysenteries, (Cap. 9.)

†† BONETUS *(loc. cit.)* gives in Obs. 3 an undoubted case of typhoid fever in which the small intestine was found here and there sphacelated, its tunic eroded and in four places perforated. In the scholia he cites the opinion of WEDEL that similar gangrenous cases are sometimes accompanied by mental hebetude: "Mentem simul laborare interdum, et doloris lancinantis faces non sentiri in phrenitide alibique conspicuum est." In Obs. 4 he cites a possible case from BARTHOLINUS of a woman dead of dysentery in whose intestines purulent tubercles abounded, and in the scholia makes a long extract from Cap. 9 of the essay of PEYER, quoted in the last note. I have examined the original of this case, BARTHOLINUS—*Hist. anat. et med. rar.*, Cent. VI, Hist. 2, Copenhagen, 1661, p. 201—but without finding any additional particulars. The report leaves it uncertain whether the "tubercles" were in the small intestine or the large.

Brunner,* who not long after contributed additional information with regard to the intestinal glands, describes a case of protracted flux in which the intestinal ulcers were, in his opinion, undoubtedly seated in the glandular plexuses of Peyer. Morgagni,† who willingly accepted the same view, cites this case in connection with several others of a similar tenor. Among them is one recorded by Bassius‡ (1731) of ulceration of the ileum consecutive to dysentery, which is illustrated by an etching on copper sufficiently well executed to remove all doubt as to the character of the ulcers. That Morgagni, with this plate before him, regarded the case as one of dysentery, shows clearly the nature of his own views as to this point. In what manner correct notions of the relation between the characteristic lesions of Peyer's patches and a specific form of continued fever were subsequently attained, will be shown hereafter in the chapter on camp fevers. Let it suffice at present to mention the names of Petit and Serres§ among the pioneers in this reform.

I have already indicated that Morgagni, while freely admitting that ulceration of the intestine is frequently found in the bodies of subjects dead of dysentery,‖ showed more fully than his predecessors that dysentery may prove fatal without intestinal ulceration,¶

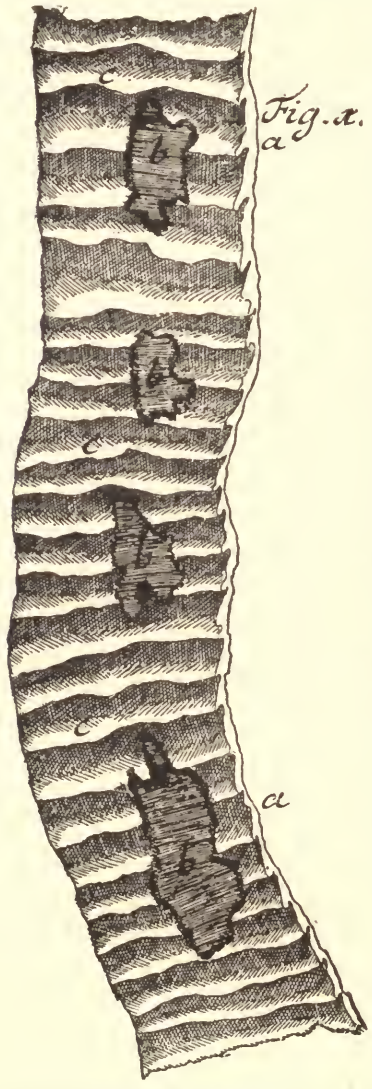

Fig. x.

* BRUNNER: I have not had access to the original of this case, which is cited by MORGAGNI—*op. cit.*, Epist. XXXI, § 13 and 15.

† MORGAGNI—*Op. cit.*, Epist. XXXI, § 15. I note that the case of VALSALVA, described in § 2 and 3, and spoken of in § 13 as a "young man, in whom a diarrhœa, without tormina, succeeding to a dysentery, he found the latter part of the ileum and the first part of the colon ulcerated," which is often cited as a case of typhoid fever, was really an example of what I call typho-malarial fever; "a simple tertian" intermittent fever of a month's duration being followed by a typhoid stage which proved fatal about the 14th day.

‡ H. BASSIUS—*Obs. Anat. Chir. Med.*, Halle, 1731, Decad. III, Obs. 7, also Tab. XI, Fig. 1, "Ilei exulceratio notabilis dysenteriæ pedissequa." The patient was a woman 42 years old, who is said to have been attacked with dysentery in the autumn of 1726, after partial recovery from which she continued to have two or three mucous stools daily, together with a constant gnawing pain about the umbilicus. These symptoms continued till the following spring, when a slow fever set in, which by and by changed into a hectic, and the patient died in a state of extreme emaciation. The autopsy was made April 20, 1727. The abdomen only was opened, in which most of the viscera were found in a normal condition. The liver was infarcted and wonderfully distended. The exterior of the intestines displayed a number of blackish spots and striæ, scattered here and there, which were supposed to indicate the existence of gangrene. The capacity of the intestinal canal was quite irregular, especially in the ileum, where, in different places, it was alternately contracted and dilated. The contents of the ileum being propelled downward, two ligatures were tightly applied, and a piece about half an ell long was dissected out. This being opened, was found to present a number of ulcers, which lay in a continuous series like the links of a chain, at the distance of about a finger's breadth, or sometimes of a joint of the thumb, from each other. "The glandular plexuses of Peyer, in other cases sufficiently conspicuous, were wanting in this case; hence it seems not unwarranted to suspect, especially since the ulcerous erosions were found at about the same distance from each other and in the same situation in which the aforesaid glands are located, that they were eaten up and consumed by the ulceration, and that the erosion of the ileum was chiefly due to the lesions of these glands." The copper etching with which the case is illustrated is here reproduced of full size by the photo-relief process. The following is the original description of this figure: "Tab. XI, Fig. 1. Intestini ilei portionem ostendit hinc inde erosi. *a*, *a*, Ilei portio. *b*, *b*, *b*, *b*, Erosiones ejus notabiles ac profunda. *c*, *c*, *c*, *c*, Juga, s. valvulæ conniventes." MORGAGNI *(loc. cit.)* has suggested that this plate represents a portion of the jejunum rather than of the ileum, basing this view upon the character of the valvulæ conniventes. But the account given by BASSIUS of the manner in which the piece was removed is not favorable to the supposition that he was mistaken. I may add that valvulæ conniventes similar to those represented in this piece sometimes extend almost to the ileo-cæcal valve, and that the character of the ulcers represented is favorable to the opinion that BASSIUS was right in calling it a piece of the ileum. I do not care to discuss the question whether the case was one of typhoid fever from the first, or whether that disease first set in during the following spring, (as the "febris lenta" of which our author speaks.) This last supposition is perhaps most probable, but as the condition of the large intestine is not recorded, the matter must remain unsettled.

§ M. A. PETIT et E. R. A. SERRES—*Traité de La Fièvre Entéro-Mésentérique*, &c., *(avec Figures Coloriées,)* Paris, 1813.

‖ MORGAGNI—*Op. cit.*, Epist. XXXI, § 13 to 17. See also p. 361–2, *supra*.

¶ *Ib.*, Epist. XXXI, § 17 to 28. WILLIS and SYDENHAM are often cited *(e. g.* by FOURNIER et VAIDY—*Dict. des Sci. Méd.*, T. X, Paris, 1814, p. 319) as the first to have recognized that dysentery might exist without ulceration, (consult the passages cited in note † to p. 347, *supra*;) but their utterances were based rather on the consideration of symptoms than on anatomical observations. I may add that SYDENHAM mentions the possibility of the "corrosion of some of the larger vessels that spread over the intestines" (which implies ulceration) to explain the intestinal hæmorrhages of certain cases, and adds that "at times the intestines, from the force of the inflammation," "have been struck with incurable gangrene." *Med. Obs.*, Sect. IV, Chap. 3, Sydenham Society's Transl., Vol. I, London, 1848, p. 167.

and hence inferred ulceration to be still more frequently absent in non-fatal cases. I have also related how Stoll,* on the basis of his own autopsies, was led to the conclusion that ulceration of the intestine was very rare in dysentery, and have alluded to the great influence which his opinions exerted. Stoll appears in these autopsies to have encountered chiefly the catarrhal forms of the disease. The severer diphtheritic variety had in the meantime been seen and described by various observers, among whom may be particularly mentioned several English military surgeons, Cleghorn, Sir John Pringle and Donald Monro,† while others seem to have encountered chiefly some of the forms of follicular disease, to be described hereafter in connection with the chronic fluxes; at least this is a reasonable interpretation to put upon some of the imperfectly described observations of Dolæus, Hewson, Wollaston and John Hunter.‡ These diversities in the phenomena recorded

* See p. 342, *supra*. Compare also the suggestion of ACKERMANN, note †, p. 433, *supra*.

† G. CLEGHORN—*Obs. on the Epidemical Diseases in Minorca from* 1744 *to* 1749, London, 1751; I cite 4th Ed., London, 1779, p. 246—"constantly found the great guts either entirely mortified, or partly inflamed, partly mortified, the rectum being generally most affected." CLEGHORN went to Minorca as surgeon to the 22d regiment of foot. J. PRINGLE—*Obs. on the Diseases of the Army*, London, 1752, Part III, Ch. 6, p. 260—under the head "Of the Dissections," reported but four autopsies made on soldiers during his service in Flanders, remarking, "These were the only dissections made of those who died of the dysentery, or soon after it. For, tho' I wanted not opportunity of opening more bodies, yet finding these cases agree so well with the observations of those authors collected by BONETUS, I thought it unnecessary to pursue the enquiry farther." In case 1 "the larger intestines" were "black and putrid, the coats præternaturally thick, and on the inside much ulcerated, especially in the rectum and lower part of the colon. The villous coat was either wholly abraded, or changed into a corrupted slimy substance, of a greenish colour; not only in the part described, but also in the cæcum and its appendix." In case 2 "The rectum was extremely putrid; and from thence the gangrene seemed to have spread to the colon, which was entirely mortified, but chiefly towards its lower end. The villous coat was partly consumed, and what remained was blackish, tender, and easily separated." In case 4 "the intestines were wholly mortified, and the stomach partly so." There were several abscesses in the liver, and "the spleen was likewise corrupted." On the other hand, in case 3, "the ligaments" of the colon "were either destroyed, or so relaxed, that the divisions of the cells were obliterated, but no part of the intestines were either mortified or inflamed. The liver was of an extraordinary bulk, reaching almost to the navel and spleen, and weighed about ten pounds. Its substance was tender, and in the posterior part next the diaphragm, was found a large abscess." DONALD MONRO—*An account of the Diseases which were most frequent in the British Military Hospitals in Germany from January*, 1761, *to the return of the Troops to England in March*, 1763, London, 1764, p. 63—found "after death in the bodies of some patients, who died of old fluxes at Bremen," that "in all of them the rectum was inflamed, and partly gangrened, especially the internal coat" Sixteen years later, reprinting this account—*Obs. on the Means of Preserving the Health of Soldiers; and of Conducting Military Hospitals, and on the Diseases incident to Soldiers*, &c., London, 1780, Vol. I, p. 326—he modified the language so that it reads: "In all of them the rectum was inflamed, and partly livid and black, and eroded, especially the internal coat." He adds that after his return from Germany he had examined the bodies "of many who died of old dysenteries," and found in all of them "a number of livid, black, gangrenous-like spots, in both the colon and the rectum, but which were most frequent in the rectum."

‡ J. DOLÆUS—*Encycl. Med. Dogmat.*, Lib. III, Cap. 5 (in Opera, Frankfort, 1703, T. I, p. 234)—made six autopsies, of which he says: "Sex enim cadavera dysentericorum à nobis secta probarunt æquè tenuia ac crassa purulentis scatuisse tuberculis, quæ inde nigra et sphacelata reperimus." In one of these cases he also found the pylorus gangrenous, ("planè sphacelatum, et corrosum.") DONALD MONRO (Vol. I, p. 332 of the second work cited in the previous note) translates this passage as follows: "In the bodies of six people who had died of the dysentery, which he opened, he found the small as well as the great guts black and sphacelated, and full of purulent tubercles;" but I feel somewhat uncertain whether DOLÆUS did not mean that the tubercles were black and sphacelated, rather than the general surface of the intestine. On the latter supposition the cases may have been examples of diphtheritic dysentery, like two others mentioned by DOLÆUS himself further on in the same chapter, of which he says: "Duos tamen exenteravi dysenteria defunctos, in quorum cadaveribus non ulcus, sed totum intestinum rectum sphacelatum inveni," (*op. cit.*, p. 236.) On the former supposition I must think the cases were probably examples of typhoid fever, like the case observed by BARTHOLINUS, cited above, as recorded by BONETUS, (Obs. 4, see note †† to p. 435, *supra*,) in which also purulent tubercles are said to have abounded in the intestines. Mr. HEWSON'S cases were published in the 4th edition of PRINGLE'S *Observations* (London, 1764, p. 251) and in subsequent editions of that work. The first was a man 45 years old, who died after an illness of several weeks. The autopsy was made by Mr. HEWSON in the presence of Dr. HUCK and Sir JOHN PRINGLE. "The dissecter having cleared away the blood and mucus from the inside of the cæcum, the colon, and upper part of the rectum, made us take notice of certain excrescences of a lighter colour than the rest of the surface. They were of a roundish figure, nearly equal in their height (which was about a twelfth part of an inch) but of unequal breadth. We all agreed that we had never seen any thing so nearly resemble the small-pox, of a flat sort, at the height of the disease. These excrescences stood as thick on this tract of the intestines, as variolous pustules, when numerous, do upon the skin; but differed from them in this, that as far as we examined them they were of a firm consistence, without any cavity." These eminences were observed "only in the larger intestines." Mr. HEWSON stated that a few days before he had opened another person dead of dysentery in whom he had found similar appearances; and afterwards showed a portion of the colon, "which he had cut out of the other body and had preserved in spirits," to Sir JOHN, who remarks: "He said, that to the best of his remembrance he had taken it from the lower part of the gut. I could easily trace the resemblance between this preparation, and that which I had seen in the recent subject; though the tubercles were here more numerous, and generally higher than in the other." CHARLTON WOLLASTON'S two cases are related in a letter to Sir GEORGE BAKER—*De Catarrho et de Dysenteria Londinensi*, London, 1764, p. 43. In the first case he found evidences of inflammation in the lower part of the ileum; and the colon and rectum having been removed and cleansed with a sponge, he observed lesions which he described as follows; "in tunica villosa non leves morbi notas invenimus: tota enim referta fuit tuberculis; hinc rotundis, parvulis, rubris; inde latis, fungosis, eminentibus; quæ visa sunt conflari ex tuberculis quamplurimis parvulis, in eminentiam unam fungosam cõeuntibus." In the second case the small intestine presented no marks of inflammation. The transverse colon was in a sloughing condition, and presented four or five perforations by which the intestinal contents had escaped into the abdominal cavity. In the rest of the colon and the rectum tubercles were found similar to those in the first case, but smaller and less numerous. "Tubercula fungosa visa sunt; at non adeo crebra, neque adeo lata, aut ulta, ac in altero cadavere." The first of these cases is illustrated by two etched plates, which will be referred to in a subsequent note. JOHN HUNTER—*Observations on the Diseases of the Army in Jamaica*, London, 1788, p. 229 *et seq.*—after citing the observations of HEWSON and WOLLASTON, declared that similar tubercles were found in all the dysenteric subjects he had examined, although he admits that the number of these cases was not considerable. He described them as follows: "There are to be seen small tubercles, like pustules, sometimes in a smaller, sometimes in a greater number; and they are to be found in different stages, so that their progress can only be collected from several observations combined. The same subject will frequently furnish, in different portions of the gut, examples of the several stages. Their progress appears to be nearly as follows: there is first a small round tubercle of a reddish colour, and not more than one tenth of an inch in diameter; it increases gradually till it be near a quarter of an inch in diameter, and becomes paler as it grows larger. In this stage

by equally sincere observers, which naturally resulted from the fact that the personal experience of each represented but a small number of more or less similar cases, became at once intelligible so soon as large numbers of post mortem examinations were made by single pathologists, whose experience soon established the fact that various pathological processes might be observed in the intestines after the death of those who during life had presented the general clinical history of dysentery.

It would require more space than can be given in this work to trace in detail the subsequent progress of investigation into the pathological anatomy of dysentery. Some of the salient points in this progress have been already sketched.* Others will be referred to in connection with the discussion of particular points in subsequent parts of this section. I shall therefore merely subjoin in a foot-note† a list of the more important essays and

there appears a small crack on the top with a slight depression, which gradually increase; and on examining the contents of the little tumour, I have generally found them to be a cheese-like substance. The pustule, for though it contain no pus, I do not know any name more expressive of its appearance, is seated under the villous coat, between that and the muscular coat. As the opening enlarges, the edges become prominent, and the base grows rough and scabrous, from which matter oozes out, that is sometimes tinged with blood. Such is the progress of one, but they are often in clusters, and become confluent, so as to form a rough unequal ulcerated surface, with an hard and thickened base. Sometimes they appear like a small eating ulcer in the gut, in which the prominence of the edges give an appearance of a loss of substance, or as if the villous coat were intirely removed." "The tubercles are most frequently found in the great guts, but they are also sometimes to be met with in the ileum; and there is an appearance of more or less of inflammation in their neighbourhood." What was the nature of the tubercles described by these writers? It would be difficult at the present time to be positive. HUNTER'S description corresponds in many respects to the tumefaction of the solitary follicles of the colon and the formation of follicular ulcers which occurs in intestinal catarrh. Perhaps, too, the cystic formations, which will be described hereafter in connection with the chronic fluxes, were observed in some of the cases. Nor can the possibility of the presence of the typhoid lesion be excluded in all these cases, and even it may have happened in others that small patches of pseudomembrane, such as sometimes occur in diphtheritic cases, may have been described as tubercles. This latter possibility was first suggested by ALEXANDER MONRO, JR.—*Morbid Anatomy of the Human Gullet, Stomach, and Intestines*, Edinburgh, 1811, p. 119—who remarked that the "coagulable lymph," effused when "the villous coat" of the intestine is inflamed, sometimes "takes on the form of small tubercles, of a conical figure, which have been minutely described by my uncle, DR. DONALD MONRO, by SIR JOHN PRINGLE, and SIR GEORGE BAKER, as having been often found in the bodies of persons who have died from dysentery." [I note, however, that DONALD MONRO did not himself see any of these tubercles, but simply mentions the observations of this kind made by his predecessors.] Consult also the observations on this subject by DAVIS and CHISHOLM, cited in the next note.

* See p. 343 *et seq.*, *supra*.

† In the following list, which makes no pretensions to completeness, and names only important treatises, I shall not include the iconographic works, which will be discussed in a foot-note a few pages further on, or those chiefly devoted to the microscopical anatomy of the dysenteric intestine, which will be referred to when that subject is under consideration. The following are the more important works by German observers: P. F. HOFFENGÄRTNER—*Beytraege zur anat. Geschichte einiger Krankheiten*, Hufeland's Jour., Bd. VI, St. 3, 1798, S. 523—details of three autopsies of acute dysentery and four in cases of chronic flux, (chronische Bauchflüsse.) H. LICHTENSTEIN—*Über die Ruhrepidemie unter den holländischen Truppen am Vorgebirge der guten Hoffnung, in den Sommermonaten*, 1804–5, Hufeland's Jour., Bd. XXVII, St. 2, 1808, S. 48—an interesting account of an epidemic of dysentery combined with an epidemic catarrh of the respiratory organs. In all there were 637 patients and 133 deaths. A number of autopsies was made, and a sketch of the conditions observed is given. The colon was found spasmodically contracted, its inner surface ulcerated, covered with little pustules in some places, excoriated in others; peritonitis, hepatic abscesses and pneumonia were the common complications. G. F. JÄGER—*Ueber die im Jahre* 1811 *in Stuttgart herrschende Ruhr*, Rheinische Jahrb., Bd. I, Heft 1, 1819, S. 21 *et seq.* Interesting pathologico-anatomical observations on dysentery are contained in the following essays on the Napoleonic campaign of 1812 against Russia: J. ARNOLD—*Diss. de dysenteria in exercitum regium bavaricum bello Moscovitico anno* 1812 *epidemice grassata*, Landshut, 1817; SCHERER—*Hist. morborum, qui in expeditione contra Russiam anno* 1812 *facta legiones württembergicas invaserunt, præsertim eorum, qui frigore orti sunt*, Tubingen, 1820, [in Weber's Sammlung med.-prakt., Dissertationen von Tubingen, Stück V, 1823, S. 21;] DILLENIUS—*Beob. über die Ruhr, welche in dem. russ. Feldzuge* 1812 *unter den vereinigten Armeen herrschte*, Ludwigsburg, 1819; I have not seen this essay, and cite from HAUFF—*Zur Lehre von der Ruhr*, Tubingen, 1833, S. 196—whose work contains an excellent bibliography of previous observations. Worthy of note as a careful study from nature is the paper of JOHANN WAGNER—*Einige Formen von Darmgeschwüren:* III, *Die dysenterische Darmverschwärung*, Med. Jahrb. des k. k. österreich. Staates, Bd. XI, 1832, S. 268. Special interest attaches to the often quoted works of C. ROKITANSKY—*Der dysenterische Prozess auf dem Dickdarme*, etc., Med. Jahrb. der k. k. österreich. Staates, Bd. XX, 1839, S. 81; Id., *Handbuch der Path. Anat.*, Vienna, 1841–46; also English transl. of Sydenham Society, London, 1849 to 1854; Id., *Lehrbuch der Path. Anat.*, 3te Aufl., Vienna, 1855–61. This great pathologist compared the dysenteric lesions to those which are produced in the œsophagus in consequence of swallowing corrosive acids. In his original monograph, and the first two editions of his *Handbuch*, he described "four natural degrees or forms" of the process. In the *Lehrbuch* of 1855 the description is somewhat compressed, but three degrees or "grades" are admitted, and the whole subject of dysentery is discussed as a subheading, under the caption: "3. Diphtheritische Entzündung," (*op. cit.*, Bd. III, S. 206.) The older accounts of this author have been so generally cited that I have thought it desirable to subjoin the following extract which represents his latest views: "a) In dem *leichtesten* Grade erscheint die Schleimhaut trübe, hie und da geröthet, injicirt, von einer dünnen Lage eines blassgelblichen, grauröthlichen, eiterigen Exsudates bekleidet. Zugleich bemerkt man, indem man sich dieses durch Abstreifen mit dem Skalpellrücken darstellt, dass die Schleimhaut sofort selbst in Form eines graulichen, grauröthlichen, blutigen Breies herabgeht. Hie und da finden sich kleinere oder grössere Strecken, wo die Schleimhaut augenscheinlich zu einem ganz dünnen, florähnlichen Überzuge des submucösen Bindegewebes reducirt ist oder das letztere wirklich blossliegt. Die Solitärdrüsen sind geschwellt. Das submucöse Bindegewebe ist etwas infiltrirt, der Darm gemeinhin erweitert. Hie und da sieht man namentlich an den Falten der Schleimhaut Erscheinungen, welche die höheren Grade characterisiren. b) In den *höheren* Graden erscheint die Schleimhaut von einem schmutzig-weissen kleienartigen Stratum necrosirten Epithels, von einem dicklichen röthlich-graulichen, mit zarten weisslichen, madenartigen Flocken,—dem ausgestossenen Epithel der Drüsenschläuche,—untermischten, eiterigen Exsudate bekleidet, darunter in verschiedenem Grade geröthet und injicirt, gewulstet und dabei in demselben vorbemerkten Schmelzungszustande begriffen, morsch, hie und da abgängig. Die submucösen Gewebe, besonders das submucöse Bindegewebe, sind in hohem Grade infiltrirt, wobei das letztere an den besonders intensiv erkrankten Stellen zu Buckeln gewulstet erscheint (Gely's Hypertrophie mamelonnée du tissu sousmuqueux). Ausserdem ist die Schleimhaut hie und da, besonders im Colon desc. und Rectum, von croupösen Exsudatmembranen bekleidet, sehr häufig, besonders auf der Höhe der vorgedachten Buckel und Wülste, zu einem grünlich-braunen, blutig suffundirten Schorfe verwandelt, unter welchem das submucöse Bindegewebe ecchymosirt erscheint. An zahlreichen Stellen ist die Schleimhaut gleichsam siebförmig excidirt, wobei der Substanzverlust nur eine Schichte der Schleimhaut betrifft oder durchgreift; im letzteren Falle sind die feinen Nadelstich-, Mohnkorn-grossen Excisionen von einem schmutzig-gelben necrosirenden Schleimhautsaume umgeben. Überdiess wird man bei genauer Besichtigung der Schleimhaut Mohnkorn- bis Hirsekorngrosse Grübchen in

works containing original observations on this subject which have been published since those last mentioned, and proceed at once to give an account of the lesions observed in cases of acute dysentery during the civil war, which will be based upon the autopsies reported in Section II and the specimens preserved in the Army Medical Museum.

---

verschiedener Menge gewahr, welche die Schleimhaut perforiren und in das submucöse Bindegewebe verdringen; sie rühren von der theilweisen oder völligen Destruction eben so vieler Solitärdrüsen her, welche in einem acuten Vereiterungsprocesse untergingen (S. Fig. 23). Das Colon ist contrahirt, in seinen Häuten gewulstet, starr, später erweitert, und enthält nebst Gas das oben bemerkte röthlich-granliche, dickliche, eiterige, oder ein schmutzig-braunes, jauchiges, stinkendes, flockig-krümliches Fluidum. Die Lymphdrüsen in den Mesocolis sind angeschwollen, blutreich, gelockert. c) In dem *höchsten* Grade ist die Schleimhaut in grossen zusammenhängenden Strecken zu einem grünlich-braunen, festsitzenden, oder schwarzen, morschen, losen Schorfe verwandelt, welcher nicht selten in Form röhriger Lappen ausgeführt wird. Das submucöse Bindegewebe ist serös infiltrirt, blass, von schwarzen, eine pulverige, schlammige Blutmasse enthaltenden Gefässramificationen durchsetzt, späterhin eiterig infiltrirt, morsch, zerreisslich, häufig von kleineren und grösseren Heerden durchsetzt, in welchen es von der Schleimhaut her zu einer schwarzen zottigen Pulpe necrosirt.—Hiebei ist der Darm erweitert, häufig collabirt und enthält schwarzbraune, kaffeesatzähnliche, sphacelös riechende Materien, die Mesenterialvenen führen nicht selten vom Darme her eine schwarze, schlammige, necrosirende Blutmasse." Worthy of note are also the observations of FINGER—*Die epidemische Ruhr*, Prager Vierteljahr-schrift, Bd. XXIV, 1849, S. 125—see p. 405, *supra*. W. GRIESINGER—*Beob. über die Krankheiten von Egypten*, Archiv für Physiologische Heilk., 1851, S. 528. O. HEUBNER—*Beitraege zur internen Kriegsmedicin*, Archiv der Heilk., 1871, S. 412, Dysenterie. FRANZ SEITZ—*Aerztliche Beobachtungen aus dem deutsch-französischen Kriege im Jahre* 1870–71 *besonders über die herrschende Ruhr*, Aerztliches Intelligenz-Blatt, December, 1871, S. 637 and 649, 1872, S. 10, 26, 43, 58, 68 and 82. Among the French works I may particularly name the following: F. J. V. BROUSSAIS—*Hist. des Phlegmasies*, Paris, 1808; I cite the 3me Éd., Paris, 1822, T. II. p. 517 *et seq.*—who, however, appears chiefly to have observed chronic catarrhal cases. In these he found the mucous membrane thickened, and presenting little ulcers, which he compared to chancres (ulcères vénériéns) and believed to originate in the solitary glands. "L'examen attentif de ceux de ces ulcères qui ne sont encore que commençans m'a fait croire qu'ils prenaient naissance dans les cryptes ou glandules qui fournissent la mucosité." *Op. cit.*, T. III, p. 78. A. TROUSSEAU et H. PARMENTIER—*Mém. sur une épidémie de dysenterie qui a régné dans le département d'Indre et Loire en* 1826, Arch. Gén. de Méd., T. XIII. 1827, p. 377, and T. XIV. p. 33. J. GUÉRETIN—*Mém. sur la dysenterie épidémique de Maine-et-Loire en* 1834, Arch. Gén. de Méd., T. VII, 1835, p. 51. S. THOMAS (de Tours)—*Recherches sur la dysenterie*, same Jour., T. VII, p. 455, T. VIII, p. 157, T. IX. p. 19. GÉLY—*Essai sur les altérations anatomiques qui constituent spécialement l'état dysentérique*, Journal de la Section de Médecine de la Soc. Académ. de la Loire-Inférieure, T. XIV, 1838, p. 193. MASSELOT et FOLLET—*Mém. sur l'épidémie dysentérique qui a régné a Versailles dans les mois d'Aout, Septembre et Octobre*, 1842, Arch. Gén. de Méd., T. I, 1843, p. 434, T. II, pp. 51 and 147. CATTELOUP—*Recherches sur la Dysenterie du Nord de l'Afrique*, Paris, 1851. GUSTAVE SACHER—*De la dysenterie*, Paris Thesis, No. 283, 1853, a paper important because its pathological descriptions are avowedly borrowed from an unpublished essay of CHARCOT, (p. 10.) The following are among the more important English works: THOMAS CAWLEY—*An account of the dysentery as it appeared among his Majesty's troops in Jamaica during the late war; with dissections explaining the proximate cause of that disease*, &c., The London Med. Jour., Vol. VII, 1786, p. 337—reports fourteen autopsies. He takes the ground that the "prevalence and fatality of the dysentery were caused by the scurvy," p. 341. J. B. DAVIS—*A Scientific and Popular View of the Fever of Walcheren*, &c., London, 1810, p. 155 *et seq.*—reports forty-two autopsies on subjects dead at Ipswich of the Walcheren diseases, among whom was a number of dysenterics. He found in the slighter cases "certain marks of vascular derangement." In those cases which followed the fever "the coats of the large intestines were preternaturally thick and hard," and in places "there were small eminences of the size of a pin's head or eminences of the magnitude of a grain of wheat, cut in halves, rougher at their apex, than their sides and bases; or small round bodies with an ulcer at their point, or little ragged ulcers excavated in the middle, resembling chancres; or one large, or a succession of small ulcers spreading wide upon and deep into the coats of the intestine." He speaks of these eminences elsewhere as "tubercles," and says that they "had their origin underneath the villous coat of the intestine." The gut was generally inflamed around the ulcers, and, "in advanced stages of the disease, gangrenous." Moreover, "the ileum and jejunum were frequently interspersed with tubercles, inflamed, and ulcerated in different parts," pp. 190–2. Undoubtedly in some of these cases the lesions of typhoid fever existed. GEORGE BALLINGALL—*Pract. Obs. on Fever, Dysentery, and Liver Complaints*, &c., Edinburgh, 1818—tabulates thirty-five autopsies with the remark: "I have dissected not less than a hundred subjects dead of this disease, and have witnessed the dissection of many more," p. 58. He observed inflammation, abrasion, ulceration, and in a few instances "the tuberculated appearance which has been so aptly compared to small pox." COLIN CHISHOLM—*A Manual of the Climate and Diseases of Tropical Countries*, &c., London, 1822, p. 55—says that in the dysentery he saw in the West Indies the large intestines were always in a state of inflammation. "The effects of this state are gangrenous blotches, but oftener tubercular excrescences on the internal surface of the large intestines.—These excrescences are the result of exudation of lymph. The rectum is more especially the seat of these—the whole length of this intestine being often covered with a dark bloody slime, and a number of excrescences which resemble very much the pustules of small-pox of a flat kind, at the height of the disease." J. CHEYNE—*Med. report of the Whitworth Hospital, House of Industry; containing an account of dysentery, as it appeared in the latter end of* 1818, Dublin Hospl. Reports, Vol. III, 1822, p. 1—thirty autopsies. O'BRIEN—*Observations on the Acute and Chronic Dysentery of Ireland*, Dublin, 1822, (see p. 343, *supra.*) JOHN ABERCROMBIE—*Path. and Pract. Researches on the Diseases of the Stomach, the Intestinal Canal*, &c., Edinburgh, 1828, p. 206 *et seq.* His descriptions, like those of O'BRIEN, represent distinctly both the catarrhal and diphtheritic forms. On p. 211 he gives a good description of follicular ulcers, and remarks, "the cases in which these occur are generally chronic." P. M. LATHAM—*An Account of the Disease lately prevalent at the General Penitentiary*, London, 1825. This "disease" at Milbank is described as "Sea Scurvy," conjoined with diarrhœa or dysentery, p. 5. In those who died of the fluxes the principal lesions observed in the intestinal canal were "ecchymosis, congestion of the small blood vessels, and ulceration," p. 44. Sometimes the ulcers "did not exceed in diameter the size of a pea, and were of a circular shape. Sometimes they were large and irregular, occupying in diameter a space of one or two inches," p. 47. E. A. PARKES—*Remarks on the Dysentery and Hepatitis of India*, London, 1846. This observer appears to have encountered a preponderance of catarrhal cases, and arrived at the conclusion that inflammation and ulceration of the solitary glands of the colon "are the earliest morbid changes in dysentery," p. 6. WM. BALY—*Gulstonian Lectures*, London Med. Gaz., Vol. IV, 1847, p. 441 *et seq.*—on the other hand, encountered both the catarrhal and diphtheritic forms. In his 1st degree, he describes follicular enlargement and sloughing (not ulceration) of the apices of the swollen follicles. In his 2d degree, in some cases, "the glands lose their vitality, and are converted into small sloughs, but the mucous membrane in which they are imbedded is inflamed and thickened, and is likewise altered on its surface." In other cases "the solitary glands have not apparently suffered more nor perished sooner than the surrounding mucous membrane; consequently no small round ulcers have been formed. But the entire mucous membrane, in larger or smaller tracts, where the inflammation has reached a certain height, has fallen into the state of gangrene, and these gangrenous portions, which are generally seated on the prominent folds of the membrane, subsequently becoming detached, leave larger ulcer-like excavations." Lastly, in his 3d, or most severe degree, "the inflammation affecting a large extent of the mucous membrane reduces it with extreme rapidity to the state of sphacelus." JOHN MACPHERSON—*On Bengal Dysentery*, Calcutta, 1850—tabulates 160 autopsies of acute and 55 of chronic dysentery. R. D. LYONS—*Report on the Pathology of the Diseases of the Army in the East*, London, 1856—tabulates 51 autopsies of subjects dead during the Crimean war, and classifies the dysenteric lesion as (a) exudative, (b) pustular dysentery, or follicular colitis. (This is a most conscientious work, and worthy of all praise.) CHARLES MOREHEAD—*Clinical Researches on Disease in India*, 2d Ed., London, 1860, p. 238 *et seq.*—gives the details of a considerable number of interesting autopsies; the same remark applies to the paper of S. G. CHUCKERBUTTY—*Cases illustrative of the pathology of dysentery, with remarks*, Indian Annals of Med. Sci., No. XIX, 1865, p. 90 *et seq.*—which contains the details of 39 autopsies. T. S. CLOUSTON—*Sewage exhalations the cause of dysentery*, Med. Times and Gazette, June, 1865, pp. 567 and 597—gives a description of the pathological anatomy based on 16 autopsies.

The lesions found in the intestinal canal in these cases may be briefly summarized as follows: either the mucous membrane of the large intestine presented the anatomical characteristics of simple inflammation without ulceration, or follicular ulceration existed, or some form of pseudomembranous inflammation was present. Lesions belonging to the first two categories occurred in simple inflammatory dysentery; those belonging to the last were characteristic of the diphtheritic variety of the disease. In either case the inflammatory process sometimes extended with more or less severity to the small intestine.

Simple inflammation without ulceration.—A condition of simple catarrhal inflammation involving the mucous membrane of the large intestine alone, or extending for a variable distance into the small intestine, was, I presume, much more frequently the only intestinal lesion existing in acute dysentery than would be inferred from the comparative rarity with which this accident only was found in the post mortem examination of fatal cases. Such cases are very apt to terminate in recovery, and probably seldom prove fatal unless the health of the patient is already broken down by some chronic cachexia, or he is carried off by some intercurrent disease. Under the last named circumstances especially, the intestinal lesion found may be very slight in its character, as, for example, in case 499, a lad of 19 years of age suffering from acute dysentery, who shortly after his admission to general hospital was attacked by pneumonia, and died on the eleventh day after admission. Gray hepatization of the lower lobe of his right lung was found after death, but "the intestines presented no evidences of serious disease."*

The description already offered of the inflammatory process in the intestinal canal, in that portion of this section which treats of the post mortem appearances in acute diarrhœa,† so precisely corresponds to what was observed in simple catarrhal dysentery when the inflammatory process did not go on to ulceration, that a detailed account of the pathological conditions observable in these cases would lead to needless repetition. The reader is therefore referred to that portion of the section for particulars. The reasons for the development, in these cases of intestinal catarrh, of the characteristic clinical features of dysentery rather than of diarrhœa are to be sought in the more acute character of the process, its greater severity, its extension further down the large intestine so as to involve the peripheral nerves of the expulsive apparatus, the greater sensibility of the individual attacked, or in the simultaneous action of two or more of these circumstances.

The number of autopsies recorded in Section III of cases of recognized dysentery in which these comparatively slight lesions were observed is quite small, viz: Cases 121, 185, 562, 590, 780, 783 and 805; but I doubt not that others, especially of those enumerated on page 310, were really of this nature. The history of many of those cases is so imperfect that it is impossible to be sure whether the patients died of diarrhœa or of catarrhal dysentery; frequently the only testimony is the very fallible evidence of the diagnosis recorded on the hospital register. Of the cases just enumerated, case 185 was one of Bright's disease of the kidneys; five days before death uræmic convulsions occurred; next day the patient was attacked by acute dysentery, which was the immediate cause of death, and was probably

* Page 197, *supra*.

† That the intestines might be found free from recognizable disease in the cadavers of subjects dead of dysentery, and other severe forms of flux, was especially remarked by G. C. CONRADI—*Handbuch der Path. Anat.*, Hannover, 1796, S. 148—who explains this circumstance by the remark that the local lesions are the consequence, not the cause, of the disease, and that many patients die of the fever or from other causes before the disease has reached the stage in which the local processes become evident. So also HUFELAND—*Bemerk. über die im Herbst 1795 in und bey Jena ausgebrochne Ruhrepidemie, und den ausgezeichneten Nutzen der Nux Vomica in derselben*, Hufeland's Jour., Bd. I, St. 1, 1795, S. 87—reported that during the Jena epidemic of 1795 he found no serious lesions of the intestinal mucous membrane in those cases in which death took place from exhaustion during the first violence of the attack, but simply observed that the colon was spasmodically contracted.

induced by the elimination of urea from the intestinal mucous membrane. The colon and rectum were greatly "inflamed and thickened." In case 590 there is a history of acute dysentery, but the patient died of intercurrent pneumonia. "A considerable portion of both lungs was hepatized," but the only lesion observed in the intestinal canal was that "the mucous membrane of the rectum was inflamed." In four of the other cases acute dysentery alone appears to have been the cause of death; in a fifth, case 805, it was complicated, according to the report, by "remittent fever." The lesions observed in the intestinal mucous membrane in these cases were as follows: Case 121, the mucous membrane of the ileum near the ileo-cæcal valve was highly congested, in places appeared to be "denuded of epithelium," that of the colon was thickened and congested; case 562, "both large and small intestine were inflamed throughout, especially from the middle of the ileum downward, but no marked ulceration was observed;" case 780, "the mucous membrane of the lower portion of the ileum was red and thickened," that of the colon "dark purple and thickened," a condition which "diminished in degree towards the sigmoid flexure, where the mucous membrane again became healthy;" case 783, "the small intestine was normal, the colon was highly inflamed throughout the greater portion of its length;" case 805, the mucous membrane of the "small intestine was inflamed, thickened and softened in places; that of the large intestine was very much inflamed and thickened."

Follicular ulceration.—But acute dysentery does not usually prove fatal until more serious lesions than these have been developed in the intestinal mucous membrane. The inflammation in fatal cases is often so intense as to favor the early development of ulceration, commencing especially in the solitary follicles, though often affecting also other portions of the mucous membrane. The best modern authorities recognize these lesions as of frequent occurrence in simple catarrhal dysentery, and I have no doubts as to the accuracy of this opinion. All that I have been able to observe myself, or collect of the observations of others, during the civil war, has however impressed me with the belief that the number of cases of fatal acute dysentery in which follicular ulceration of the large intestine was the characteristic lesion, was quite small when compared with those in which the diphtheritic process existed in some stage of its progress.

Follicular ulceration, attended by the well known concomitant thickening of the submucosa, was indeed an exceedingly frequent lesion in the bodies of those who died of flux; but when a complete history of the case could be obtained, it usually proved that the patient had suffered from looseness of the bowels, either continuously or at intervals, for several months. Sometimes the illness began as an acute catarrhal dysentery and passed gradually into a chronic flux of variable duration; sometimes it commenced as acute diarrhœa which persisted with various fluctuations often for a long time, and not unfrequently assumed the dysenteric form only during the last few days or weeks of life. Where the history is incomplete these cases were almost always recorded as chronic diarrhœa. I have, therefore, been led to the conclusion that during our civil war, at least, follicular ulceration was rather one of the common and characteristic lesions of chronic flux than of acute dysentery, and for this reason I propose to postpone its detailed description to a subsequent portion of this section in which I shall treat of the lesions found in the chronic fluxes.

Nevertheless, follicular ulceration stands closely related to acute dysentery in several ways. Thus, in a considerable number of cases, after a chronic flux had persisted with varying severity for a longer or shorter time, intense symptoms of acute dysentery set in,

tormina, tenesmus and the characteristic discharges of diphtheritic dysentery, and death soon followed. On the autopsy, in such cases, thickening of the submucosa and follicular ulceration were very generally found in the colon; but between the follicular ulcers the mucous membrane was the seat of a more or less intense diphtheritic process, usually indeed still in its earlier stages, because in these cases, which are to be interpreted as acute diphtheritic dysentery supervening upon a chronic ulcerative catarrh of the colon, the development of the diphtheritic process generally proves speedily fatal.

The lesions found in cases of this class will be most conveniently discussed after I shall have treated in detail of follicular ulceration, and I shall postpone their consideration to that place. Meanwhile it must be borne in mind that soldiers suffering under mild chronic fluxes not unfrequently persist in carrying the musket for a considerable time; medical aid is afforded by the regimental surgeon; the flux is arrested for a while, and again bursts out afresh; months often elapse before the patient finally is sent to general hospital. Now when, in such cases, acute diphtheritic dysentery supervenes, the patient at once breaks down and is sent to hospital, where he presents the characteristic phenomena of the consecutive disease and his previous history is too apt to be overlooked. Even where the diphtheritic process is not developed toward the close, chronic ulcerative catarrh of the colon in its later stages often gives rise to symptoms resembling those of the advanced stages of acute dysentery, so that if the case is only seen at this period it is easy to underestimate the significance of the earlier stages and the actual duration of the disease. I am quite sure that a portion at least of the instances, in which follicular ulceration of the colon has been found after death from dysentery by the European observers, also belong really to one or the other of the two categories just indicated; certainly the majority of the cases of follicular ulceration of the colon which are figured in the pathological plates are avowedly from chronic cases.*

I do not doubt that under other circumstances follicular ulceration of the colon may be more frequently found after death from acute dysentery than it was during the civil war; and even during the civil war I do not doubt that in cases of catarrhal dysentery follicular ulceration was often developed at a very early period, or that such cases were still more apt to prove fatal than those of simple inflammation without ulceration. It is reasonable to suppose that the intense forms of catarrhal inflammation of the intestinal mucous membrane, which especially produce the symptoms of dysentery, would develop follicular ulceration and thickening of the submucosa much earlier than the less severe, more subacute process, which more generally gives rise to symptoms of diarrhœa rather than of dysentery. While, therefore, I point out that the number of fatal cases with a clear history of acute dysentery, in which follicular ulceration was the principal lesion of the colon, found on the autopsy was not large, I am far from supposing that this condition was not of frequent occurrence both in the cases that recovered and still more frequently in those which, commencing as acute catarrhal dysentery, subsequently assumed a chronic form. In the majority of the fatal cases of acute dysentery in which autopsies were made during the war, however, diphtheritic inflammation of the large intestine was undoubtedly the characteristic morbid process.

* See note to p. 444, *infra*. The cases observed by HEUBNER—*Beiträge zur internen Kriegsmedicin*, Archiv der Heilkunde, Jahrg. XII, 1871, S. 412—in the reserve hospital at Leipsic during the Franco-German war, appeared to have been of the character described in the text. There were but five deaths, and the author himself describes three of these as chronic cases. His statement that none of these cases presented evidences of the diphtheritic process, but manifested simply suppurative inflammation (eitrige Entzündung) of the intestine, while no doubt strictly accurate, can hardly, therefore, from the small number of observations, be of any value in indicating the prevalent form of dysentery even in the Franco-German war.

Diphtheritic inflammation.—This form of inflammation was usually found coexisting with more or less highly developed catarrhal inflammation of other portions of the intestinal tract, and in the acute cases, especially, with a catarrhal inflammation which had not yet resulted in the formation of follicular ulcers. The catarrhal inflammation, manifesting itself by all the characters described above,* was sometimes limited to the colon, but more frequently involved also the lower part of the ileum, or extended, usually in the form of detached inflammatory patches of variable dimensions, high up the small intestine. The diphtheritic process, which in most cases must be regarded as having supervened upon the previously developed catarrhal inflammation, varied greatly both as to its extent, the firmness or tenacity of the exuded material, and the stage of the process in which death occurred. Sometimes the exudation was limited to the descending colon and rectum, or to the latter alone; sometimes it involved other portions of the large intestine or the whole of it; sometimes it extended for a variable distance into the small intestine; sometimes the exudation, or at least some part of it, was quite superficial, lying as a separable layer upon the surface of the mucous membrane, involving only its superficial epithelium and filling the interiors of the follicles of Lieberkühn. Usually, however, in a portion at least of the affected area, the adenoid tissue of the mucosa, and often a part or even the whole of the submucosa, were also involved.

The exudation consists essentially of a fibrin-like substance, which under the microscope presents usually a finely granular or indistinctly fibrillated appearance; which coagulates with various degrees of firmness and entangles in the coagulum a variable number of migrated white corpuscles. The parts embraced in the coagulated exudation promptly lose their vitality and slough, the depth of the slough being coequal with the depth of the previous exudation. The extent to which sloughing is found to have occurred in any particular case depends partly upon the original extent of the diphtheritic process, partly upon the period that has elapsed between its development and the death of the patient. The exudation and the resulting sloughs were primarily whitish or yellowish in color, but they were often reddened by hæmorrhage, or colored greenish or blackish by subsequent changes in the transuded blood. Often, also, they were superficially stained greenish-brown or blackish by the intestinal contents. All the diverse appearances observed in the diphtheritic cases resulted from mere variations in the manner in which the several processes thus briefly enumerated were combined. Here may be mentioned the fact pointed out by Virchow, that the portions of the mucous membrane involved in the diphtheritic layer no longer secrete,† at least until the sloughs begin to separate, when a certain amount of pus is formed; so that the mucus and muco-pus of the dysenteric discharges proceed chiefly from those parts of the mucous membrane affected by catarrhal inflammation.

The chromo-plate which faces page 442 illustrates one of the forms in which the diphtheritic process manifests itself in acute dysentery of an intense character. The patient was admitted to Douglas Hospital, Washington, D. C., during September, 1864, from the army of the Potomac, suffering with acute dysentery, and expired shortly after admission. On the autopsy the whole colon was found in a condition similar to that exhibited by the specimen, and patches of redness existed throughout the ileum. No other abnormity of importance was observed. The specimen represented by the plate was brought to the

---

* *Supra*, p. 296 *et seq.*

† *Kriegstyphus u. Ruhr*, Virchow's Archiv, Bd. LII, S. 26: "Die diphtheritischen Stellen als solche sondern gar nichts ab."

Army Medical Museum immediately after the autopsy, by Assistant Surgeon Wm. Thomson, U. S. A., and a water-color drawing made by Mr. Hermann Faber. It is a portion of the descending colon, spread out to exhibit its mucous surface. This is irregularly plastered over with a thick curd-like pseudomembrane of a greenish-yellow color, which, in numerous small patches, is either so thin as to be transparent or is altogether absent, permitting the livid red of the inflamed mucous membrane to appear on the surface. Perpendicular sections showed the mucosa and submucosa to be thickened and infiltrated with an exudation resembling that upon the surface. The specimen is preserved in the Army Medical Museum, [No. 360, Medical Section.] This plate, and the following ones representing various stages of the diphtheritic process in the intestine, should be compared with the plates illustrative of the pathological anatomy of dysentery published by the museum at Chatham, by Annesley, Cruveilhier, Albers, Gluge* and others.

Another form in which the diphtheritic process manifests itself is well displayed in the photo-plate facing this page. This is a reproduction of a nature-size photograph of No.

---

* *Anat. Drawings from Preparations in the Museum of the Army Medical Department at Chatham*, Fasc. I, London, 1824—Plate IX, Fig. 1, and Fasc. II, London, 1834—Plate VIII, Figs. 1, 2, 4 and 5. These figures are executed in the coarse lithography of the time at which they appeared, and are uncolored; it is therefore difficult, if not impossible, to determine the lesions represented. The cæcum, from a case of acute dysentery, represented in Plate VIII, Fig. 2, is undoubtedly a specimen of diphtheritic sloughing, and the dependent sloughs are pretty well indicated. I judge the perforations in Figs. 4 and 5 of the same plate, and the ulcerations represented in Fig. 1, Plate VIII, and Fig. 1, Plate IX, to be also results of the diphtheritic process, but cannot feel positive on account of the imperfect character of the representation. JAMES ANNESLEY—*Diseases of India*, London, 1828. The costly colored plates of this splendid work cannot always be satisfactorily interpreted. Those that represent hepatic abscesses, as well as those which represent displacements, constrictions and dilatations of the colon in dysentery, or general and partial peritonitis, are quite intelligible; but those that represent the mucous surface of the intestine are so deficient in detail that it is difficult to decide what pathological conditions existed in the original specimens. Fig. 1, Plate 33 and Plate 35 certainly represent the diphtheritic process. I judge Plate 32 to represent acute catarrhal dysentery with small follicular ulcers, and Plate 38 to represent a characteristic thickened colon with follicular ulcers, from a case of chronic flux. The other pictures of morbid conditions of the mucous surface in dysentery, viz: Plate 21, Fig. 3; Plate 25, Fig. 3; Plate 28, Figs. 3 and 4; Plate 31, Fig. 2; Plate 34, Figs. 1 and 2; Plate 36, Fig. 2; Plate 39; and Plate 40, Figs. 1 and 2, I confess myself unable to interpret on account of the peculiar manner in which they are executed. J. CRUVEILHIER—*Anat. Path. du Corps Humain*, 1829–42. In this great work several varieties of the diphtheritic process are very satisfactorily represented by three colored lithographs, viz: Livraison 31, Plate 3, which represents diphtheritic eschars in patches on the mucous surface of the colon, from a case described by the author as "entérite par plaques gangréneuses;" Liv. 38, Plate 3, Figs. 1 and 2, represent portions of colon thinly coated with pseudomembrane, from cases of acute dysentery, and Liv. 40, Plate 5, is a strikingly effective though somewhat rough representation of the commencement of sloughing in diphtheritic dysentery, from a soldier dead of the acute form of that disease. Follicular ulceration of the colon is not figured in this work. J. F. H. ALBERS—*Atlas der Path. Anat.*, Bonn, 1832–62. This work is not equal to that of CRUVEILHIER in the execution of its lithographic plates. Tab. 17 and 18, Abth. IV, contain four figures, two of them colored, which are readily recognized as representations of the diphtheritic process. G. GLUGE—*Atlas der Path. Anat.*, Jena, Bd. II, 1850. Lief. 18, *Die Dysenterie*, Taf. 1 and 2, are colored lithographs which are recognizable as representations of the diphtheritic process, but which, in execution, are inferior even to those of ALBERS. In Taf. 3, which is devoted chiefly to the microscopical appearances, Figure 4 is a rather rude representation of follicular ulceration. The account of the case given in the text describes it as one of "ulcerous dysentery," but does not indicate how long the patient had been sick. Besides the foregoing works, I may mention the following as containing representations of the lesions in dysentery: G. BAKER—*De catarrho et de dysenteria Londinensi*, &c., London, 1764—gives two copperplates: Tab. I representing a portion of the rectum, and Tab. II a portion of the colon, from a sailor who had suffered from diarrhœa and dysentery for seven months. The autopsies were made by C. WOLLASTON, who describes both as covered with "tubercles," some round and small, others broad and fungus-like. The plates, which are but rudely executed, nevertheless give probability to the opinion of ALEXANDER MONRO, that these were really effusions of coagulable lymph—see note to p. 437, *supra*—if so, these plates are the earliest representations of diphtheritic dysentery with which I am acquainted, and represent a diphtheritic process which supervened after the patient had suffered for some time from catarrhal diarrhœa, as indeed is indicated by the history of the case; WM. STARK—*Spec. med. inaug. septem historias et dissectiones dysentericorum exhibens*, &c., Leyden, 1766—published two etchings on copper, admirably executed, which represent some of the lesions characteristic of chronic fluxes. I shall refer again to these excellent plates in connection with cysts and follicular ulceration of the colon, and will only remark here that but one of the seven histories analyzed in this dissertation was a case of acute dysentery, viz: Hist. VI, and that the lesions of this case are not represented in the plates; MATT. BAILLIE—*The Morbid Anatomy of some of the most important parts of the Human Body*, 2d Edit., London, 1812, Fasc. IV, Plate II, Fig. 4, and Plate III, Figs. 1, 2 and 3. This work contains four figures, (copperplates, uncolored,) of which the first cited represents follicular ulceration of the colon; no history. The figures on Plate III, we are told, are intended "to illustrate the morbid appearances observable in the great intestines of persons who have been carried off by that fatal species of dysentery which too often arises in camps." Two of these figures are possibly intended to represent the diphtheritic process. In Fig. 3 the mucous surface appears to be healthy. I must say, however, that these laboriously executed plates do not indicate the pathological details of the specimens in such a manner as to justify a positive opinion. J. HOPE—*Principles and Illustrations of Morbid Anatomy*, London, 1834—Figs. 125 and 126, both said to represent gangrene of the mucous membrane of the colon; 126 is said to have been taken from a case of "acute dysentery of extreme severity and rapidity." ROBERT CARSWELL—*Illustrations of the Elementary Forms of Disease*, London, 1838—gives no illustrations of the diphtheritic process, but two colored lithographs representing follicular ulceration, viz: Plate II, Fig. 4, in the section on Softening, and Plate IV, Fig. 3, in the section on Melanoma. The latter was a chronic case; whether the former was or was not, is not stated. In the same way in the splendid work of H. LEBERT—*Traité d'Anat. Path.*, Paris, 1857–61—4 vols. folio, illustrated by copperplates colored by hand, the diphtheritic process is not figured. There are, however, on Plates 116, 117 and 118 six figures of follicular ulceration of the colon, four of which are from chronic cases; in the other two the duration is not specified. In a general way, then, the plates representing the lesions of dysentery hitherto published may be divided into three groups: (1) those which evidently represent the diphtheritic process; (2) those which represent follicular ulceration of the colon; and (3) those which are so imperfectly executed that it is now impossible to determine just what the nature of the process represented really was. From the latter group of course no valuable inferences can be drawn, and even in the case of the two former groups several of the plates are unaccompanied by definite histories; but so far as the facts are given with regard to these groups, the first always represents the lesions of acute dysentery and the second those of a chronic flux, the only exception being ANNESLEY'S Plate 32, described above. This result certainly affords additional support to the opinion I have formed on the basis of my own observations. See p. 442, *supra*.

TRANSVERSE COLON WITH PSEUDO-MEMBRANOUS PATCHES.

No. 124. MEDICAL SECTION.

124, Medical Section. The following history of the case was furnished by Surgeon George F. French, U. S. V., hospital No. 3, Vicksburg, Miss.*

CASE 892.—Private Benjamin F. Lemon, company G, 93d Indiana volunteers; age 20; admitted October 12, 1863. Chronic diarrhœa. Says he had lung fever five years ago, and that whenever he takes cold he has a very severe pain in the left side after a full inspiration; has been subject to a dry cough for some time. Nevertheless he enlisted in August, 1862, and is reported on the rolls of his company as present for duty until October 10, 1863. He states, however, that August 1, 1863, he had a mild attack of diarrhœa, which in about two weeks gradually changed into dysentery, with tenesmus and bloody stools. When the dysentery was at its height the stools varied in number from twenty to forty, soon diminishing, however, to eight or ten daily; in appearance they were sometimes gelatinous, sometimes mucous and white. About the middle of October his appetite, which up to that time had been excellent, failed. November 1st: Pulse 84; tongue pale in the centre, red on the edges, with slight white fur at its base; stools small and variably white, flocculent, gelatinous or shreddy. Treatment: He never had any injections until he entered this hospital, and says he had no other diet than the ordinary ration. After October 10th he was treated with opiate and turpentine injections; being very anæmic, he was also put upon tincture of the chloride of iron. Tarragona wine and stimulants were given freely. His diet consisted of boiled milk, rice, farina and occasionally rare broiled beef. Died November 21st. *Autopsy* ten hours after death: There were strong pleuritic adhesions investing the whole anterior surface of the left lung. The heart was normal. The liver was normal. The spleen was about the size of a kidney, and had an abnormal congenital fissure in its upper end. The stomach was normal. There were a few spots and tracts of inflammation with moderate softening here and there in the small intestine. About the same degree of inflammation and softening in the cæcum, but no ulcerations in the cæcum or ascending colon. The transverse colon was dark and livid; the descending colon and rectum were bright red. For about sixteen inches above the anus the bowel was almost bared of its mucous coat by ulceration, [sloughing?] and there was only a slight glaze over the muscular coat, which presented a whitish appearance. At the lower end of the rectum livid, yellowish-gray, warty granulations adhered to the surface. The upper portion of the rectum was slightly roughened with a superficial exudation; still higher up some of the ulcerations are ragged, others round or oval, all limited to the mucous coat, and some of them filled with a dirty white adherent lymph, causing them to appear raised above the surface. [Nos. 124 and 125, Medical Section, Army Medical Museum, are from this case. The ulcers "still higher up" than the upper part of the rectum, filled with lymph so as "to appear raised above the surface," were the patches of pseudomembrane described below.]

No. 124, Medical Section, the specimen represented in the plate, is a portion of the transverse colon from this case. The upper part of the specimen displays the smooth unbroken surface of the mucous membrane, and this surface appears in places as far as to the bottom of the piece; but commencing in the upper third and increasing in frequency and size towards the lower part of the piece, its surface is occupied with patches of a pretty firm curd-like pseudomembrane. The smallest of these patches is not larger than a pin's head, the largest, in the lower part of the piece, covers an irregular area several inches in length. No. 125, Medical Section, is a portion of the descending colon from the same case. It is even more continuously plastered with pseudomembrane than the lower part of No. 124. In places where the pseudomembrane is very thin or absent a few minute follicular ulcers can be recognized. From the account given by Surgeon French, it would appear that still nearer the rectum a large part of the mucous membrane had been destroyed by the sloughing of the diphtheritic exudation.

This case appears to have been one of catarrhal diarrhœa running into catarrhal dysentery about the middle of August, and subsequently subsiding into a chronic flux, with eight or ten stools a day. Diphtheritic dysentery probably supervened after the first of November, perhaps not long before death. On this point the history is imperfect; the diphtheritic process did not extend above the transverse colon, and the diphtheritic sloughing was limited to the rectum. The catarrhal inflammation which preceded the diphtheritic exudation was most intense in the descending colon and rectum, for no follicular ulcers were found in the transverse colon or higher up. The diphtheritic inflammation was evidently extending at the time of death, and the plate, which represents its superior limit, may therefore be regarded as representing an early stage of the process.

The two foregoing plates represent examples of that variety of the diphtheritic process in which a firm exudation accumulates on the surface of the mucous membrane, involving

* See p. 254, *supra*, for other cases observed by Surgeon French.

also generally that membrane itself and a portion of the submucous connective tissue, before sloughing takes place; but in other cases the exudation was less rich in fibrin, or the fibrin itself was less coagulable, so that the mucous membrane, together with more or less of the submucous layer, speedily sloughed, having first become more or less swollen by an infiltration of feebly coagulating fibrin, the portions of which, that reached the mucous surface, were so readily swept away by the intestinal discharges that often they did not adhere to the surface at all, or adhered in but limited areas. Representations of this form of the diphtheritic process will be found in parts of the plates reproducing Nos. 970 and 1060, Medical Section, and between these extreme cases in the one direction and those of the firm, tough pseudomembrane already described in the other, every possible transition form existed.

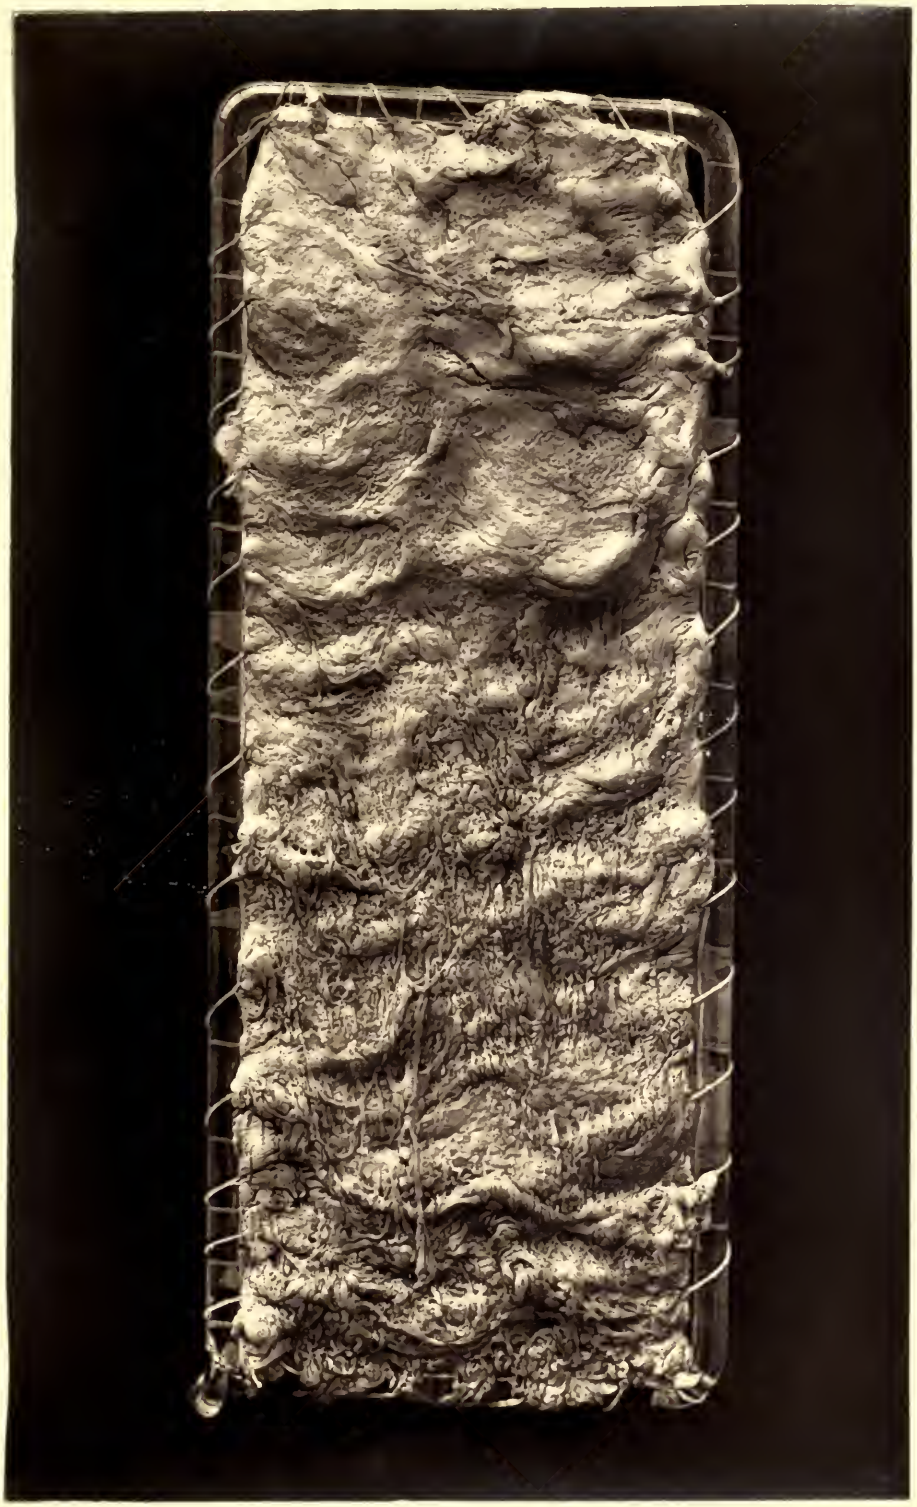
The sloughing which attacks the parts entangled in the diphtheritic exudation may be a gradual process, in which the necrosed tissue separates in little shreds; or portions of the surface of considerable size may be thrown off. The plate facing this page, which is a reproduction of a nature-size photograph of No. 703, Medical Section, illustrates one variety of the former of these processes. The following is a brief history of the case:

CASE 893.—Private Wm. Brooks, company H, 2d United States colored troops; enlisted March 11, 1865. From this time till December 31, 1865, he appears on the muster-rolls of his company as present for duty, except during September and October, when he was on detached service. With the exception of these two months he served in Florida, and was under treatment by the regimental surgeon in June for constipation, and in July and August for jaundice. About the middle of December he was taken sick with dysentery, and in January was sent north for treatment. He was admitted to Harewood hospital, Washington, D. C., January 12, 1866, having at that time been sick four weeks. He had the usual symptoms of acute dysentery, and died January 20th. Was not much emaciated at the time of death. The treatment consisted of astringents, opiates and supporting measures. *Autopsy:* The small intestine appeared to be quite normal. The colon was thickened and ulcerated in many places throughout. The rectum as in the specimen. The condition of the other organs is not recorded.—Surgeon R. B. Bontecou, U. S. V. [No. 703, Medical Section, Army Medical Museum, is from this case.]

The specimen represented by the plate is from the rectum of this patient. In the upper part of the piece the mucous and submucous tissues are swollen and infiltrated; the surface is irregularly coated with tough pseudomembrane. In the lower part of the piece the diseased coats are separating by sloughing, the sloughs adhering by one extremity and hanging down as string-like shreds, for the most part only a quarter to half an inch in length, but a few much longer. Higher up in the colon, it would appear from the report of the autopsy, the sloughs had completely separated in many places, leaving numerous ulcers.

The plate facing page 448 is a reproduction of a nature-size photograph of 1060, Medical Section, and represents the separation of dysenteric sloughs, at least one of which is of considerable dimensions as compared with those described in the last case. The disease was not recognized as dysentery during the life of the patient. The patient presented the symptoms of acute mania with homicidal impulse, and after shooting a comrade was placed in confinement, where he became very noisy, screaming, singing, etc. It was observed that his bowels were loose and the stools sometimes involuntary, but dysentery was not diagnosticated, nor was the fatal peritonitis, dependent upon intestinal perforation, recognized until the abdomen was laid open during the autopsy. The following history of the case was furnished by Surgeon J. F. Hammond, U. S. A.:

CASE 894.—Private Joseph Von Gilden, company H, 4th cavalry; age 23; enlisted at New York City, November 25, 1869, and arrived at Austin, Texas, in February, 1870. For some time after his arrival he was an exemplary soldier, but for some unknown cause he incurred the ill-will of a portion of the men of his company, and they worried and perplexed him until he gave evidences of homicidal mania. June 13th, he fired a ball from his carbine, at a distance of ten or fifteen paces, through the leg of a soldier of the same company, comminuting his tibia, for which crime he was confined in the guard-house. He soon exhibited other signs of mania, and, on the 16th of July, was removed to a separate apartment in the post hospital at Austin. The condition of his bowels had never, at any time during his confinement for the crime, attracted attention as being abnormal, notwithstanding his stools were involuntary and while in hospital varied from three to nine per diem. July 20th, the first pre-



Am. Photo-Relief Printing Co., *1002 Arch St., Phila.*

RECTUM WITH SLOUGHING PSEUDO-MEMBRANE.

No. 703. MEDICAL SECTION.

scription for the condition of his bowels was given. His stools were lax, dark, feculent and abundant; mucus or blood had not been noticed in them. July 21st, the clinical thermometer gave his temperature at 12 M. as 99°.6; pulse 72. As he was very noisy, screaming and singing day and night, I recommended the general commanding the department, July 22d, to send him to the Government asylum in Washington under charge of a proper guard. 23d, he refused food for the first time, and also vomited that day. Active treatment was instituted, but he died about 6 A. M. the next day. During his whole confinement he made no complaint of any kind. *Autopsy* (Surgeon Hammond and Actg. Asst. Surgeon W. C. Crooks) 6½ hours after death: Small muscular development; some emaciation; no rigor mortis; several ulcers at various points on his limbs and body. The dura mater was strongly adherent, its vessels turgid; the pia mater congested, most so posteriorly; cerebellum apparently softened, and more than the usual quantity of serum in the lateral ventricles. The convolutions of the brain were generally ill-developed, except on the front of the left anterior lobe. Lungs melanotic externally, no adhesions, crepitant throughout, ecchymoses at one or two points of the surface; both lungs full of dark blood; apparently some miliary tubercles on the surface of the left lung. The pericardium was distended with serum. The heart normal; clots of fibrin and black blood-clots in the right ventricle. The cavity of the abdomen contained a quantity of purulent serum. The stomach and entire intestinal canal were much congested, and contained a good deal of dark, fluid, feculent matter The ascending colon near its caput was firmly adherent to the parietes of the abdomen. Two large perforations of the colon were found just above these adhesions. The liver was deeply colored and dense. The gall-bladder was much distended with bile. The spleen was normal in size but dense. The kidneys and bladder were normal. The peritonæum generally was much inflamed. [No. 1060, Medical Section, Army Medical Museum, is from this case.]

In a note dated July 27, 1870, Surgeon Hammond stated that diarrhœa and dysentery were prevailing generally among the citizens of Austin at the time. The number of cases among the troops, however, was not large. Besides the fatal case of dysentery just reported, three other cases of acute dysentery and eight of acute diarrhœa, none of them fatal, appear on the post sick report for July, the mean strength of the command being 192 officers and men. The specimen represented in the plate consists of the cæcum and a portion of the ascending colon of this patient. A glass rod has been passed through the two perforations and can be seen in the upper portion of the piece. The mucous membrane is swollen but free from adherent pseudomembrane, and quite smooth except where sloughing is taking place. Patches of sloughing may be observed on various parts of the surface. The perforations evidently originated by this process. Near the lower extremity of the piece a large slough is separating, and exposes an irregular excavation about an inch and a half long by three-quarters of an inch wide, at the bottom of which the circular muscular coat of the colon is exposed. This slough is still adherent on the side farthest from the ileo-cæcal valve; its edges and the surfaces of the still adherent sloughs present a shreddy appearance, not unlike the sloughing surface shown in the last plate. On the peritoneal side of the piece the traces of the adhesions described in the autopsy can be seen. These appear to have prevented any considerable fæcal extravasation.

Still greater are the dimensions of the sloughs shown in the plate facing page 450, which is a reproduction of a photograph of No. 970, Medical Section. The specimen was too large to be shown of the size of nature on the page of this work, and the photograph has therefore been reduced in size one-fourth.

CASE 895.—Private John Bowers, company A, 44th United States infantry; German; age 41; admitted to post hospital, Washington, D. C., from Reynold's barracks, July 19, 1868. Acute dysentery. The patient was taken sick the day before admission. He had frequent discharges, as often as every forty-five minutes, which consisted of liquid fæcal matter mixed with mucus and blood: pulse 82, full but not strong; skin rather hot; tongue coated brown in the centre. The discharges were at first attended with great tenesmus, and there was moderate abdominal tenderness. There was thirst, anorexia, and the intellect was dull. Up to the fourth day after admission the discharges diminished in frequency, the blood gradually disappeared and remained absent until the day before death. The pain and tenesmus also gradually subsided, and by the end of the first week all complaint of pain had ceased. After the fourth day the operations increased in frequency, became somewhat yellowish, were liquid, very offensive, and continued so to the end. From about this time until the close of the case the stools were passed involuntarily. About the seventh day the abdomen became tympanitic and continued so; the hebetude increased, with occasional delirium of a low character; the pulse increased in frequency, and during the latter part of the time varied from 90 to 100 per minute; the temperature was continuously increased, varying from 99° to 102°; the tongue remained furred and soon became dry, continuing so until death, which occurred August 3d, fourteen days after admission. *Autopsy:* The descending colon and rectum presented extensive sloughing ulcers, as in the specimen.—Assist. Surgeon John Brooke, U. S. A. [No. 970, Medical Section, Army Medical Museum, is from this case.]

The specimen represented in the plate is a portion of descending colon from this case. As in No. 1060, but little pseudomembrane adheres to its mucous surface except at the points where sloughing is taking place; yet a large portion of the mucous membrane is infiltrated with exudation and was much swollen when the specimen was fresh. The sloughs, in places, are separating in shreds, but in the lower part of the piece they represent fragments of considerable size, which still adhere at points to the surface of the gut. The largest of these fragments is three inches and a half in length. Even larger sloughs than these are sometimes encountered in autopsies, still adhering at one extremity to their original seat, while the greater portion of the slough hangs down the intestinal canal. No. 997, Medical Section, [Case 94,*] is a striking example of this possibility, and shows a slough of this kind nine inches long which still adheres at one extremity.

The losses of substance produced by the separation of diphtheritic sloughs may be conveniently described as diphtheritic ulcers. Such ulcers are of the most diverse size, and vary from mere abrasions to deep excavations that expose or even invade the muscular coat. For the most part the edges of these excavations are irregularly bevelled, so that the bottom of the ulcer is smaller than the surface of mucous membrane destroyed. Sometimes, however, the edges are overhanging in places at least, in consequence of the sloughing extending farther in the submucosa than in the mucous layer itself. Very often, indeed, death ensues before the process of sloughing is completed, and the diphtheritic ulcers, so far as they have been developed, present no indications of the reparative process; but when the area of mucous membrane destroyed is not too extensive the patient may survive, the ulcers sometimes cicatrizing so that complete recovery ensues, or, more frequently, remaining in an indolent condition and a chronic flux persisting, which, after a variable period, proves ultimately fatal. The chromo-plate facing page 452 exhibits one variety of these diphtheritic ulcers. The following is an account of the case:

CASE 896.—Private Daniel Snow, company F, 2d New York heavy artillery; enlisted January 6, 1864, and is reported present with his company until after the first of May. On the muster-roll for May and June he is reported missing, and on that for July and August: "Absent; confined as a deserter by the provost-marshal." While in confinement he was attacked with dysentery, and became so sick that he was admitted to the field hospital of the 2d Army Corps at City Point, Virginia, September 6, 1864, where the diagnosis recorded was chronic dysentery. He appeared to be so ill that next day he was put on board the steamer Connecticut for transfer to general hospital. He was admitted to Douglas hospital, Washington, D. C., September 9th, and the following particulars were communicated by Asst. Surgeon Wm. F. Norris, U. S. A.: The patient was much emaciated, and, in addition to the usual symptoms of the advanced stage of dysentery, had jaundice and frequent bilious vomiting. The abdomen was flat and tender, the skin cool, the pulse feeble. He had stupor, low delirium and involuntary stools. Died, September 17th. *Autopsy:* Body somewhat emaciated and intensely jaundiced. Organs of the thorax healthy. [The state of the small intestine is not recorded.] The large intestine was greatly thickened, contracted in calibre, and presented, from the cæcum to the anus, numerous large, irregular, ragged ulcers, most of which involved the muscular coat. The ulcers had sharp, abrupt, ragged edges. In the caput coli there was a perforation the size of a dime. Externally the peritonæum covering the intestine was roughened and adherent to the right lobe of the liver for an extent of two inches. There was but little fæcal matter in the large intestine, which contained a number of black and gray fibrin-like clots. The liver contained numerous yellow metastatic foci from a quarter to half an inch in diameter; these were mostly in the right lobe and in the course of the branches of the portal vein; many of them contained a small drop of yellow fluid in the centre, and consisted, as seen under the microscope, of disorganized liver tissue, granular matter and fat globules, but no pus. The other abdominal viscera were healthy. [Nos. 448 and 449, Medical Section, Army Medical Museum, are from this case.]

A portion of the descending colon and the liver from this case were brought to the Museum on the day of the autopsy, and water-color drawings of the appearances presented made by Mr. Hermann Faber; these are reunited in the chromo-plate. The very large ulcer shown near the middle of the piece, and parts of some of the others, laid bare the muscular coat, which was smooth and shining, while the bottoms of some of the ulcers

* Page 65, *supra*.

CÆCUM WITH SLOUGHING PSEUDO-MEMBRANE.

No. 1060. MEDICAL SECTION.

only penetrated more or less deeply into the submucous connective tissue. The prevailing tint of the mucous membrane between the ulcers was yellowish, but it was streaked with bluish, gray and greenish tints, and in places brownish, reddish-brown or even bright red. Greenish or bluish neutral tints prevailed on the surface of the ulcers; their edges were rounded or bevelled, in but few places overhanging. The liver was dark brown externally, except where the metastatic foci described in the report of the autopsy were visible. Its cut section presented the nutmeg appearance in a marked manner and numbers of the metastatic foci. The description, given in the report, of the microscopical characters of these foci and of their relations to the portal vein was verified at the Museum. This case, then, is to be regarded as one of acute diphtheritic dysentery in which the sloughs had completely separated before death. The exact duration of the dysentery cannot be determined, but it probably set in some time after the deserter was captured by the provost-marshal, so that it is improbable that it commenced earlier than July, and it may not have done so until some time in August. The metastatic foci in the liver were quite like those which occur in pyæmia, and I am disposed to regard them as consecutive upon the colon ulcers.

Somewhat similar is the character of the ulcers shown in the chromo-plate facing page 454. The following is a history of the case:

CASE 897.—Private Taylor W. Glascow, company H, 110th Pennsylvania volunteers; age 34; admitted to Emory hospital, Washington, D. C., October 17, 1863. Chronic diarrhœa. This man enlisted September 25, 1862, and is reported on the muster-rolls of his company as present until March, 1863. Some time during April he was taken sick and sent to division hospital. June 14, 1863, he was admitted to the 1st division Alexandria hospital. Diagnosis, typhoid fever. He was, however, now in a convalescent condition, and was returned to duty with his regiment, August 11th. Shortly after he was attacked with dysentery, for which he was finally admitted to Emory hospital, as above stated. His disease now presented the aspect of a chronic flux. He was treated at first with pills of camphor and opium, but as the discharges from the bowels continued unabated, he was put to bed on the 21st, and tannic acid and opium substituted. Light diet. The diarrhœa was checked for a few days, but again grew worse about November 1st, when a chalk mixture was prescribed and a diet of boiled milk and toast. November 5th, he complained of pain in the abdomen. The diarrhœa was about the same. Substituted Parrish's camphor mixture and laudanum. November 11th, the patient complained of being unable to sleep. The diarrhœa remains about the same. Ordered mercury with chalk, and Dover's powder at night. November 16th, is worse. Stools more frequent. The patient appears much debilitated. Ordered pills of acetate of lead, opium and ipecacuanha; stimulants. Under this treatment he was again temporarily better, but again became worse about the 25th, when calomel and opium were substituted. December 3d, is much weaker; the diarrhœa unchecked. Stopped the pills; continued the stimulants. December 4th, at the request of the patient, procured him some blackberry brandy, which he seemed to relish; but in a few days discontinued its use, as it seemed to nauseate him. December 8th, is considerably emaciated, greatly prostrated and growing rapidly weaker. The stools are very frequent and tinged with blood. Ordered beef tea, brandy and a laudanum injection at night. Died, December 13th. *Autopsy:* The colon was considerably thickened and extensively ulcerated. [The condition of the other organs is not recorded.]—Acting Assist. Surgeon W. H. Combs. [No. 115, Medical Section, Army Medical Museum, is from this case.]

A portion of the descending colon from this case was brought to the Army Medical Museum immediately after the autopsy, and a water-color drawing made by Mr. Hermann Faber, of which the chromo-plate is a reproduction. The piece presents a number of ulcers, some of them of considerable size, which for the most part do not penetrate to the muscular coat, but invade the submucous connective tissue more or less deeply. The general surface of the mucous membrane between the ulcers is cream colored, with bluish and greenish streaks and patches. There are also a number of reddish patches in which the congested condition of the small veins is recognizable with the unaided eye. The bases of the ulcers are for the most part quite smooth, and similar in tint to the mucous membrane itself, but two of them are stippled with minute granulations; their edges are bevelled or rounded, not overhanging. This case, like the last, is to be interpreted as one of acute diphtheritic dysentery, which, in this instance, occurred not long after convalescence from typhoid fever. The precise duration of the disease is not shown by the record. It clearly commenced some time after the 11th of August, when the patient had sufficiently recovered from typhoid

fever to be returned to his regiment for duty; but it cannot have commenced very long afterwards, for when admitted to Emory hospital the disease had already so far advanced as to present the characters of a chronic flux. The duration of his last illness must therefore have probably been somewhere between three and four months, a sufficient time to permit the complete separation of all the diphtheritic sloughs, but the resulting ulcers were too numerous and extensive to permit recovery. The physician who made the autopsy was unacquainted with the fact that the patient had previously suffered from typhoid fever, and does not appear to have examined the small intestine for traces of that disease.

Another illustration of the characters of these diphtheritic ulcers will be found in the plate facing page 456, which is a reproduction of a nature-size photograph of No. 136, Medical Section. The following history of the case was contributed by Surgeon Geo. F. French, U.S. V.:

CASE 898.—Private Wm. B. Thornburg, company B, 95th Ohio volunteers; age 25; nervous temperament. Admitted to hospital No. 3, Vicksburg, Mississippi, October 12, 1863. Chronic dysentery. This man enlisted August 2, 1862, and was present for duty with his regiment until March, 1863, when he was detailed as an ambulance driver. He returned to his regiment in July. He says that he had diarrhœa much of this time, but had been free from it for awhile, when in September, 1863, he had a severe attack of dysentery, for which he was admitted to field hospital near Vicksburg on the 18th. At that time his stools were very bloody, the tenesmus severe, and there was almost constant pain in the region of the ascending colon. In about a week the stools began to assume a gelatinous appearance. For four days after the commencement of the attack the daily number of stools ran as high as twenty or even forty, but subsequently they diminished in number to from three to five in a day. The characters of the stools varied; sometimes they were of a dark jelly-like consistence, sometimes shreddy, flocculent or white. October 12th, when transferred to this hospital, the removal was attended with considerable suffering. October 18th, the patient complained of severe pain in the right hypochondriac region, which in a few days subsided into a dull heavy ache; subsequently he complained only of the degree of abdominal tenderness and pain usual in cases of dysentery. Cold night sweats were now frequent, and slight sordes appeared on the teeth a fortnight before death. November 1st, some œdema of the lower extremities is noticed. The patient is now greatly emaciated, his pulse very rapid and tremulous, his tongue smooth and very dry in the centre. Died, November 2d. Before entering this hospital the patient seems to have had very proper treatment and suitable diet. His bowels were first unloaded by a mild cathartic, to which in due time succeeded emollient and anodyne injections. Fomentations were applied to the abdomen, which was also painted with tincture of iodine. Diet: milk, beef essence, chicken broth and stimulants *ad libitum*. The same course of treatment was pursued after admission. *Autopsy* fourteen hours after death: The conjunctivæ were tinged slightly yellow, but the skin presented no appearance of jaundice. The lungs were perfectly healthy. There was an abscess in the anterior superior part of the right lobe of the liver containing twenty ounces of pus which had the odor of sour milk. The surface of the liver over the abscess bulged, and the abscess appeared to be pointing toward the cavity of the abdomen. The upper border of the right lobe of the liver was glued by strong adhesions to the diaphragm. The wall of the abscess in its thinnest part was one-sixteenth of an inch thick. The spleen was normal. The left kidney was fatty, considerably larger than the right, and of a livid green color; its pelvis contained a puruloid fluid. The stomach presented evidences of local congestion, and the first inch or two of the duodenum had a similar appearance. The valvulæ conniventes throughout the small intestine were tinged with bile. In the upper part of the ileum there was a tract about twelve inches long of an extremely dark red color, with softening of the mucous coat; farther down the mucous membrane presented here and there a livid green color. The mucous membrane of the whole tract of the large intestine was of a mottled, livid, greenish color, stained here and there with dark red spots, and overspread, as if worm-eaten, with ulcers of varying depths, some penetrating the mucous coat, others the muscular coat, and two through the serous coat of the bowel. In the lower half of the colon the ulcerations were so numerous as to present a reticulated or honey-comb appearance, like tripe. Some of them had rough ragged borders; in others the borders and bottoms of the ulcers were smooth and glazed; others were lined with a white, opaque, plastic lymph which was tenaciously adherent. In some places what were supposed to be cicatrices were observed. The shape of the ulcers, although very irregular, was mostly oval, the long diameter extending transversely across the bowel. Close beside the appendix vermiformis there were two perforations through the cæcum, one nearly the size of a dime, the other the size of a pea. Sufficient feculent matter had escaped into the abdominal cavity to discolor the wall of the abdomen contiguous to the cæcum. The tissues were deeply infiltrated, and not merely stained on the surface. There were also extensive adhesions of the upper part of the cæcum to the right iliac fossa, and around the perforations the intestine was glued to the wall of the abdominal cavity. Most of the adhesions were quite strong, those around the perforations, however, were soft and easily torn. [Nos. 132 to 137, Medical Section, Army Medical Museum, are from this case.]

The specimens preserved in this case are a series of pieces of the colon, all of which exhibit ulcers closely resembling in character those shown in the plate. In Nos. 132, 133, 134 and 135, which are portions of the ascending and transverse colon, the ulcers are less numerous and less closely set than in Nos. 136 and 137, which are portions of the descending colon; but in all of them a considerable part of the mucous surface of the colon has been destroyed. The ulcers are for the most part oval in shape, with their long diameters

DESCENDING COLON WITH SLOUGHING PSEUDO-MEMBRANE.

(*Reduced in size one-fourth.*)

No. 970. MEDICAL SECTION.

transverse to the axis of the bowel. In their central portions they expose the circular muscular coat, while towards the edges they only penetrate to the submucous connective tissue, so that for the most part they have bevelled edges, though in some places the edges are abrupt or even overhanging. In this case, between a month and a half and two months only elapsed from the commencement of the dysenteric attack to the fatal issue. The patient had previously suffered a good deal from diarrhœa, but had been free from it for some time before the commencement of his last illness, which is to be interpreted as an acute diphtheritic dysentery in which the process was so intense that the complete separation of all the diphtheritic sloughs took place within the period indicated. Symptoms due to the hepatic abscess found on the autopsy were first observed fifteen days before death, which resulted immediately from peritonitis, the consequence of the perforation of two of the ulcers and subsequent fæcal extravasation.

Death may occur at any stage of the diphtheritic process. In a few instances the patient, overwhelmed by the violence of the disease, succumbs before the sloughs have had time to begin to separate. In other cases the separation of the sloughs has commenced and progressed more or less; while in others complete separation takes place before the fatal issue. If the patient survives the separation of the diphtheritic sloughs a chronic flux often results, which persists for an indefinite period with ultimate recovery or death. It is a most important pathological fact, of precious significance in connection with the prognosis, that even very extensive ulcers resulting from diphtheritic sloughing may under favorable circumstances completely cicatrize. The cicatricial tissue contracts considerably, and the edges of the ulcer are then approximated, so that the resulting cicatrix is much smaller than the original loss of substance. The approximation sometimes takes place laterally, a circumstance which it might be supposed the surviving functional activity of the circular muscular coat would favor; but very often also it takes place longitudinally, and oblique or transverse cicatrices result. The cicatrices are very generally more or less puckered, and in extreme cases stricture of the bowel may result from this circumstance.* I have not been able to collect statistics with regard to the frequency of cicatrization. The patients survive an indefinite length of time, and when they ultimately die of some other disease, even if an autopsy is made, the intestinal cicatrices are apt to be overlooked.

The plate facing page 458, which is a reproduction of a photograph of No. 1003, Medical Section, in which the preparation is represented one-half larger than the natural size, is a striking representation of the cicatrices of diphtheritic ulcers. An account of the case has been given in the previous section, [case 875.] The patient, a mulatto man, who is said to have been a soldier and afterwards an officer's servant during the war, died November 11, 1868, of pleuropneumonia. It is stated in the report that he "is supposed to have suffered from diarrhœa during the war." The flux, however, was undoubtedly diphtheritic dysentery, and numerous large ulcers must have existed, for cicatrices similar to those represented in the plate were found "over the entire surface of the large intestine." The plate represents a portion of this colon about five inches long, on the surface of which, besides several minor ones, are three conspicuous cicatrices. The first or uppermost is a linear one, slightly curved and about an inch and a half long in the specimen, which runs obliquely downward as it goes across the piece from left to right. Just below this is a second much larger and more complete cicatrix, fully three inches long in the specimen,

* An excellent description of these cicatrices will be found in ROKITANSKY'S *Lehrb. der Path. Anat.*, 3te Aufl., Vienna, 1861, Bd. III, S. 209.

which consists of a perpendicular sigmoid portion on the left, from near the centre of which a linear cicatrix runs with a sinuous course across the whole piece. In the course of this transverse line there are two points at which the cicatrix extends so as to cover an irregular somewhat stellate area. The lower half of the piece is occupied by a third, much larger, irregularly branching cicatrix, which consists of two perpendicular portions (one seen a little to the left of the middle of the piece, the other at its edge on the right) connected together by irregularly branching transverse cicatricial lines. The enterotome has unfortunately made two perpendicular cuts in the central perpendicular portion of this cicatrix which gap widely in the preparation, and are of course so represented in the photographic plate. A similar, but much smaller, accidental cut appears near the right extremity of the central cicatrix. Notwithstanding these accidents the specimen displays the characteristic features of diphtheritic cicatrices so much more handsomely than any other specimen as yet received at the Museum that it was selected for this illustration. The ulcers thus healed must have been numerous, of large size, and must have penetrated deeply into the submucous connective tissue, if not quite to the muscular coat.

After the edition of the plate just described had been struck off I obtained a photograph of a part of the same preparation enlarged rather more than three diameters, which showed all the details in the characters of these cicatrices with such admirable distinctness that I have thought it worth while to present it to my readers as an additional illustration. The plate facing page 460 is a reproduction of this photograph, which was obtained indirectly by a photographic enlargement of the negative from which the former plate was prepared. By this device, notwithstanding the enlargement, the greater portion of the piece shown is nicely in focus, and the first negative, having been made by an excellent photographic combination (Dallmeyer's wide angle recto-linear) from the preparation floating in a bath of distilled water, has borne the enlargement in a satisfactory way. In examining this plate the eye is at once struck by the presence in almost all parts of the surface of the intestine of numerous black circular depressions, rather larger than pin-pricks, which are in fact the orifices of the tubular glands of Lieberkühn, and which can be advantageously studied with a magnifying glass. These disappear on the summits of the more prominent folds of the mucous membrane, simply because out of focus. This plate represents a considerable part of the central and lower cicatrices shown in the last plate, and between them two smaller isolated cicatrices. The unfortunate accidental cuts in the lower cicatrix make a conspicuous appearance, but do not interfere with the representation of the cicatrices.

It will be seen that the characteristic feature of these cicatrices is the presence of a smooth central cicatricial area or line, from the margins of which branching cicatricial ridges radiate and entangle the adjacent glands of Lieberkühn in their meshes. On the left of the accidental cut in the lower cicatrix there is an area of mucous membrane of some extent, which is thickened and deformed by these cicatricial ridges. Such areas represent portions of mucous membrane adjacent to the original ulcers, which, however, were not destroyed by the ulcerative process. The site of the original ulcers is indicated by the central cicatricial area or line, the size of which, however, is many times smaller than the original loss of substance. Between the cicatrices may be seen some forty or fifty small oval or circular depressions, looking as though cut out of the mucous membrane by a punch; they are also shown, though less distinctly, in the previous plate, and are in fact tiny follicular ulcers. These probably represent a slight recent intestinal catarrh accompanying the fatal pleuro-

pneumonia, as often happens in such cases. The statement in the report that the patient "had no symptoms of any abdominal disease while in hospital," must be received with reserve, since the reporter was not the attending physician, and no record of symptoms and treatment was kept, at the time, in the almshouse in which this man died.

In this connection I may also refer to specimens Nos. 922 and 923, Medical Section, which are portions of the colon from a case of diphtheritic dysentery reported in the last section, (case 874.) Each presents several large irregular granulating ulcers, and of these one in each piece particularly well illustrates the healing process. The excavation made by the ulcerative process in these ulcers has been filled nearly to the surface with granulation-tissue; the edges of the ulcer appear already to have considerably approximated, and the surrounding mucous membrane is a good deal puckered. It is easy to see that, had the process continued to completion, a linear cicatrix running in a transverse direction would have resulted in each place.

On an examination of the previous sections of this work, I find fifty-five autopsies in which, either from the mention of pseudomembranous or diphtheritic deposits, or of other details recorded by the reporter, or from the specimens preserved at the Museum, I am satisfied that the cases were examples of diphtheritic dysentery. I find, also, fifty-three other autopsies in connection with which the testimony is not so positive, but which were probably of the same nature. To the first group belong cases 92, 93, 94, 97, 132, 141, 143, 160, 161, 169, 176, 192, 204, 206, 239, 271, 278, 284, 286, 302, 306, 309, 315, 317, 340, 344, 346, 354, 357, 358, 362, 367, 369, 372, 373, 382, 392, 400, 425, 429, 430, 436, 502, 561, 566, 579, 587, 684, 685, 811, 841, 852, 857, 867 and 874. It will be seen by examining the histories of these cases that in twenty-nine of them specimens have been preserved in the Museum. These specimens, the numbers of which are mentioned in connection with the record of the autopsy in each case, afford a tolerably complete series representing the various phases of the diphtheritic process and of the ulcers which result from the separation of diphtheritic sloughs.

In many of the cases just enumerated the disease may properly be spoken of as acute. In some of them death took place during the second week or even earlier; in others the time at which the patient was taken sick is not definitely stated, and only the duration of treatment in general hospital is given, which varies from a few days to two months or more, the longer periods not being very frequent. In ten of the cases only does the record extend beyond three months, viz: in cases 97, 161, 309, 852 and 874 between three and five months; in cases 382 and 566 over six; in cases 354 and 685 over seven; and in case 857 over nine months. Some of these were undoubtedly cases of diphtheritic dysentery, in which the ulcers left after the separation of the sloughs, served to keep up the chronic flux that finally destroyed life. I do not doubt that such ulcers often cause chronic fluxes, and think it highly probable that many of the cases of these fluxes hereafter to be referred to, in which the record of the autopsy simply describes the large intestine as "extensively ulcerated," were really of this nature. I am by no means sure, however, that this explanation applies to all the ten cases just enumerated. In one of them, for example, case 566, the patient appears to have had a chronic flux for six months, which, however, did not prevent him from doing duty, and was, therefore, most probably dependent, as so many such fluxes were, upon a chronic intestinal catarrh. Acute dysentery supervened only three weeks before death. Perhaps a similar explanation applies to some of the other protracted cases.

In most of the cases of this first group the diphtheritic process was limited to the large intestine. In cases 92, 93, 362, 372, 392, 587 and 867 the small intestine appeared to be healthy. In some of the other cases the condition of the small intestine was not recorded, but in the majority of them congestion, redness, enlargement of the solitary follicles or other evidences of catarrhal inflammation were observed. In cases 94, 204, 284, 340, 354, 373, 382, 400 and 811 the diphtheritic process had extended into the ileum, as evidenced by the presence of the characteristic exudation upon the mucous surface for a greater or less distance above the ileo-cæcal valve.

The second group of cases which belongs in this place comprises those in which the record of the autopsy is less explicit indeed, yet describes phenomena that on the whole more closely resemble those of diphtheritic dysentery than any other morbid process. Here are included cases 81, 82, 107, 197, 203, 205, 215, 216, 221, 226, 238, 242, 243, 244, 246, 253, 256, 257, 259, 270, 313, 325, 338, 437, 439, 472, 508, 514, 516, 589, 591, 594, 613, 616, 627, 628, 630, 652, 669, 677, 679, 682, 693, 710, 712, 750, 779, 784, 800, 816, 824, 827 and 832. The record indicates that almost all of these were cases of acute dysentery. In many of them, however, the reports only give the duration of treatment in general hospital, which varies from a few days to two months or more. In none of the cases does the record cover a longer period than three months. In all the cases of this second group the record of the condition of the colon lacks technical precision, yet the language used generally indicates quite clearly the nature of the process. Thus, we are told that the mucous membrane was extensively mortified; that it was gangrenous, gangrenous throughout, gangrenous in patches, spots or places; that it presented patches of sloughing, or oval sloughs; that it was disorganized by ulceration and sloughing; that it was disorganized; that it was extensively ulcerated and almost gangrenous; that it was so far destroyed by ulceration that only islets of mucous membrane were left; that it was extensively ulcerated, and the like. In cases 197, 244, 313, 325, 516 and 613 the small intestine is stated to have been apparently healthy, and in a somewhat larger number its condition is not recorded, but in a majority of them it is either distinctly stated that more or less of the mucous membrane of the small intestine was inflamed, or it is spoken of as congested, much congested, softened, its solitary follicles enlarged, and the like.

The general remarks which follow apply to both the groups mentioned above. In eleven cases perforation of the intestine is said to have occurred. In cases 132, 244, 338 and 750 the perforation took place in or near the cæcum; in the last named case there were also two perforations in the colon. In case 627 there was probably a perforation in the transverse colon; in case 215 at the junction of the transverse and descending colon. In case 561 there were two perforations in the descending colon. In case 253 it is merely recorded that there was a perforation in the colon. In case 436 it is stated that there were more than twenty perforations in the colon. In case 243 the record states that the ileum, as well as the large intestine, was ulcerated, and that several of the ulcers had perforated, without mentioning whether this accident occurred in the large intestine or the small. In case 382 a perforation in the cæcum communicated through an abscess-cavity in the iliac region with a perforation in the ileum just above the ileo-cæcal valve. In some of these cases it is recorded that evidences of peritonitis, with or without fæcal extravasation, were observed; in others the record is silent as to this point. I am inclined, nevertheless, to regard most of them as cases of actual perforation, though it must be acknowledged that

the rents made by unskilful dissectors in removing the colon, when its walls are greatly weakened by ulceration or sloughing, have sometimes been mistaken for perforations when none actually existed.

Evidences of more or less extensive and severe peritoneal inflammation were observed, besides, in a number of instances in which no perforation existed, as, for example, in cases 238, 437, 811 and 816. In cases 221, 358 and 867 the intestines were agglutinated by general peritoneal adhesions. In case 784 the adhesions were limited to the ascending, in case 613 to the descending, colon. In several cases, also, local peritoneal adhesions were observed which, in some of them, possibly resulted from former local peritonitis unconnected with the dysenteric attack. Thus in case 325 the transverse colon was adherent to the liver. In case 253 there was a similar adhesion, and others also existed between the liver and diaphragm, and between the right kidney and the liver. In case 508 a limited portion of the cæcum was adherent to the abdominal parietes. In case 97 the cæcum was more extensively adherent, and the vermiform appendix had also contracted adhesions to the abdominal parietes of such a character that its extremity was attached just below the umbilicus. In all these instances the intestinal canal was involved in the adhesions; but in case 340 they were limited to the liver, spleen and adjoining abdominal walls; in cases 317 and 710 they connected the liver and the diaphragm, and in case 176 the record simply states that there were old adhesions about the spleen.

In this connection, also, must be mentioned case 141, in which, from the autopsy, it would appear either that typhoid fever had supervened during the progress of a chronic flux, or perhaps more probably that diphtheritic dysentery had set in during convalescence from typhoid fever. The ulcers in Peyer's patches, as seen in one of the specimens from this case, [Nos. 232 and 233 Medical Section, Army Medical Museum,] look as though the healing process was well under way, while in the other specimen the diphtheritic sloughs have completely separated, leaving the characteristic ulcers. Both processes, therefore, were in an advanced stage; perforation had taken place in three of the ulcers of the small intestine, and general peritonitis resulted. The association of diphtheritic dysentery with the characteristic typhoid lesion of Peyer's patches, illustrated by this case, was by no means of rare occurrence. Among the cases under consideration, 192, 226, 278 and possibly 800 may be cited as additional examples of this coincidence, and several others will be brought forward in the chapter on camp fevers, where the subject of this complication will be more fully discussed. There are also among the cases at present under consideration quite a number in which the small intestine, especially the ileum, is said to have been ulcerated, and some of these may possibly have been examples of the complication with the typhoid process. Cases 203, 204, 205, 271, 286, 317, 346, 502, 616, 750, 784 and 832 are the ones referred to. An examination of the record in these cases will show that some of them are simply examples of diphtheritic or catarrhal ulceration resulting from an extension of the inflammatory process to the small intestine; but in others the description is so imperfect that the nature of the ulcers is uncertain. It is worthy of note, also, that in several other cases the disease at some period during its progress was erroneously diagnosticated typhoid fever, while on the autopsy only the lesions of diphtheritic dysentery were found. Cases 197, 246, 302, 338, 344 and 425 are examples of this error.

A few other facts with regard to the condition of the intestinal canal recorded in the autopsies under discussion are of interest. Intussusceptions of the small intestine unaccom-

panied by symptoms of obstruction of the bowels during life, or by indications of resulting inflammation observed after death, were less frequent than in the cases of catarrhal inflammation enumerated on page 310. But two examples are recorded, viz: Case 627, in which one intussusception was observed, and case 677, in which there were two. Accumulations of gas in the alimentary canal must have occurred much more frequently than is mentioned in the reports. Only in cases 253, 472 and 628 are we told that the intestines were distended with gas. Scybala are mentioned in but one case, 243, in which it is stated that "a quantity of scybala was impacted in the cæcum."

The condition of the *stomach* is not recorded in all the cases, nor is the character of its contents often mentioned. It is spoken of as distended with flatus in cases 243, 270, 271, 325, 425, 429 and 784; distended with mucus containing some pus in case 216. On the contrary it is said to have been contracted in case 160, and much contracted in case 302. More or less congestion of the gastric mucous membrane, either in patches or universally, is said to have been observed in cases 94, 132, 197, 204, 246, 284, 340, 354 and 710. It is affirmed that it was inflamed in cases 143, 161, 325 and 508. In case 284 the mucous membrane was much injected, and small patches of pseudomembrane were adherent at several spots; in case 271 it was covered with a pseudomembrane the color of bile. The gastric mucous membrane is said to have been softened in case 344; thickened and softened in cases 425 and 429; abraded in case 306. In case 874 an oval spot the size of a ten cent piece, apparently a healed ulcer, was found on the mucous membrane of the lesser curvature of the stomach. The condition of the *œsophagus* was not often recorded. In case 346 it is stated that a large patch of its mucous membrane, beginning two inches below its commencement and extending downward four inches, was softened and ulcerated: "There were several separate ulcers, some of which were coated with a greenish disorganized substance."

*Lesions observed in other organs in diphtheritic dysentery.**—In most of the cases in which the *appearance of the body* is recorded it is spoken of as emaciated, much emaciated or extremely emaciated. In cases 203, 338, 373, 429, 566 and 710, however, it is stated that there was not much emaciation; in cases 369 and 867 that the body was not emaciated; and in cases 204 and 367 that it was well developed. More or less diffuse ecchymosis of the skin of the trunk, or of the trunk and extremities, was observed in cases 132, 143, 160 and 169. All these observations were made by Dr. J. Leidy. In the record of case 160 he remarks: "The ecchymosed spots, examined with the microscope, appeared to be a staining of the dermis with the coloring matter of the blood-corpuscles." If, as I doubt not, similar discolorations existed in some of the other cases, they were not regarded as of sufficient importance to be made a matter of record. In case 161 the left lower extremity was œdematous; in case 132 bed-sores were noted; in cases 246 and 784 the skin was jaundiced. In case 206 an ulcer of the cornea was observed in each eye. The man had been attacked with diphtheritic dysentery three weeks before admission to general hospital and died seven days afterwards, so that his disease had lasted four weeks. This lesion did not attract attention in any other of the cases under consideration. An abscess was found in the left parotid gland in case 516.

* The statements which follow are based upon an analysis of one hundred and fifteen cases of diphtheritic dysentery, viz: The 108 cases enumerated on pp. 453 and 454, and the 7 cases (Nos. 892–898 inclusive) selected for the pictorial representation of the lesions of this form of disease. I am not acquainted with any previous attempt to tabulate the lesions observed in other organs in any considerable number of cases of diphtheritic dysentery. Most of the studies in this direction refer to a certain number of cases of "dysentery," including all forms of the disease. In a few instances only are acute and chronic cases separated. I shall refer to some of these studies in a subsequent portion of this section in connection with the undetermined cases of chronic dysentery.

DESCENDING COLON WITH OVAL ULCERS.

No. 136. MEDICAL SECTION.

Cranial cavity.—No very significant lesions were observed in the *brain* or its *membranes* in any of the cases in which the head was opened. In cases 340, 344, 346 and 373 the brain is said to have been more or less softened, and in case 354 congested; in cases 197, 203, 204, 205, 367, 373, 710 and 894 its membranes are said to have been more or less extensively congested. In cases 205, 382, 710 and 894 the quantity of subarachnoid fluid is said to have been considerable, or larger than usual; in case 344 the quantity is definitely stated as two ounces and a half. Several globular cysts were observed in the choroid plexus in case 358, and congenital absence of the middle commissure of the brain was noted in cases 354 and 516. In the majority of the cases under consideration, however, the cranial cavity was not opened.

Respiratory organs.—These were generally examined, and often presented important lesions. *Diphtheria* was not noted in any of the cases, unless perhaps case 256, in which it is recorded that "the mucous membrane of the pharynx and larynx was inflamed, thickened and ulcerated," bears this interpretation. Nor was *bronchitis*, unconnected with pneumonia, recognized in any autopsy, perhaps because, so far as I have been able to ascertain, the bronchial tubes were not systematically examined. In case 338 both lungs were congested, and the same condition is affirmed of the bronchial tubes; probably bronchitis existed also in some others of the cases in which the lungs are simply said to have been congested. There are about twenty cases in which this latter condition is affirmed of one or both lungs; in some of these it was recognized to be merely hypostatic, and probably some of the others were of the same character.

Pneumonia was a frequent and important lesion, which in some instances was undoubtedly the immediate cause of death. It was recognized in more than a sixth of all the cases. In one of these, case 197, lobular pneumonia existed on the right side. In the others the affected parts are spoken of as hepatized red or gray, or simply hepatized. This condition involved a portion of the right lung in cases 253, 340, 392, 400 and 630; of the left lung in cases 354 and 677; of both lungs in cases 216, 591 and 679. A similar condition of the lung, combined with pleuritic effusions of serum or lymph, or with recent pleuritic adhesions, involved the right lung in cases 143, 302 and 627; the left in cases 226, 669 and 841; both lungs in cases 313, 344 and 362. In case 160 the lower part of the superior lobe of the left lung contained a multitude of purulent foci, and was adherent by plastic matter to the pleura costalis. These lesions are probably to be interpreted in the same manner as the purulent foci in the liver in case 896.

Pleurisy was observed in several instances. Thus in case 358 the pulmonary pleura between the lobes of the right lung was roughened by whitish points of exudation, and two patches were observed, one in the upper and one in the lower lobe, in which the lung-tissue was carnified. In case 317 a copious effusion of sero-purulent liquid in the left pleural sac compressed the left lung against the vertebral column; both lung and costal pleura were coated with a thick layer of lymph. In case 259 the left pleural cavity was filled with pus, and the lung, collapsed to a fourth of its normal size, formed a firm flesh-like mass adherent to the spine; in this case also an abscess had formed between the fourth and fifth ribs which appeared about to point externally. Pleuritic adhesions, probably old, were observed in a number of instances: on the right side in cases 161, 369, 372, 429, 579, 693, 710, 779 and 784; on the left side in case 892, and on both sides in cases 176, 204, 205, 373, 425, 516 and 874.

Tubercles, for the most part limited to the apex, were found in the right lung in cases 382 and 693, in the left lung in case 894, and in both lungs in cases 81, 204, 346, 630, 832 and 867. In cases 94 and 874 there were not only tubercles in both lungs, but a tubercular cavity existed in each on the right side. Obsolete cretefied tubercles were observed in both lungs in case 340. The *bronchial glands* are spoken of as large in cases 344 and 346; tubercular in case 874. In case 367 the bronchial glands at the bifurcation of the trachea contained a calcareous deposit.

Circulatory organs.—Recent *pericarditis* was observed in case 226; the surface of the heart was coated with fibrinous lymph and the sac of the pericardium contained nearly a pint of fluid; pleuropneumonia existed on the left side in this case, as already mentioned. A very similar condition existed in case 317; the heart was covered with a layer of fibrinous lymph, and there was in the pericardium a considerable effusion of serum in which shreds and flakes of lymph floated free; in this case, as already mentioned, pleurisy existed on the left side, with a bulky effusion and collapse of the lung. In case 894 the pericardium was distended with serum; in case 81 it contained between ten and twelve fluid ounces. Smaller quantities of fluid, varying from two to four ounces, were found in the pericardium in cases 132, 278, 358, 392, 425 and 429, and still smaller quantities in a number of others. In case 259 the pericardium throughout its whole extent was adherent to the heart; in this case, as already mentioned, empyæma and collapse of the lung existed on the left side.

The *heart* is spoken of in several cases as soft, flabby, devoid of adipose tissue, thin-walled or small, and the latter condition is in several others indicated by the weight recorded; thus in cases 354, 357 and 400 the heart is said to have weighed but seven ounces, and in case 226 only six, notwithstanding its coating of lymph. The weight of the heart is recorded in about a dozen other cases, and ranges from the figures just given to eleven ounces; in but one case is a greater weight than this recorded, viz: Case 362, in which the heart weighed 12¼ ounces. In case 271 the heart is spoken of as "somewhat enlarged," and in case 616 as "very large, but apparently healthy; no valvular disease." *Valvular disease* was observed in several cases. In case 338 the aortic valves were thickened and their adjacent edges interadherent; in case 779 the mitral valve was much thickened, and in case 867 the edges of the tricuspid valves are said to have been thickened. Slight atheroma of the aorta just above the semilunar valves was observed in cases 358 and 362, and in case 784 the arch of the aorta is said to have been unusually large.

Whitish or yellowish *fibrinous coagula*, with or without an admixture of black coagula, were observed in the cavities of the heart in a number of the cases. Clots of the first kind were found in the right side of the heart only in cases 226, 338, 354, 362, 429, 630 and 779; in the left side only in case 340, and in both sides in cases 197, 204, 270, 344, 369, 372, 373, 679 and 867. Mixed clots were found in the right side in cases 357 and 894; in both sides in case 143. In case 205 fibrinous clots were found in the right side and black ones in the left; in case 346 fibrinous clots were found in the right side and mixed ones in the left; in case 516 fibrinous in the left and mixed in the right. The fibrinous clots in the cardiac cavities extended into the pulmonary artery in cases 197, 362, 369 and 372; into both pulmonary artery and aorta in case 373. In case 841 "there were large clots in the right side of the heart extending into the pulmonary vessels; a small clot in the left ventricle;" but the nature of these clots is not explicitly stated. In case 160 the heart contained no clots, "but yellow clots occupied the arch of the aorta and the pulmonary

COLON, WITH CICATRICES OF DIPHTHERITIC ULCERS.

No. 1003. MEDICAL SECTION.

[ENLARGED ONE-HALF.]

arteries." The significance of clots such as these will be discussed when the subject again comes up in a subsequent portion of this section in connection with the autopsies in cases of chronic flux.

Abdominal organs.—The *liver* is spoken of as congested in some half dozen cases, in as many more it is said to have been soft or softened; it is also spoken of in a few cases as anæmic or as pale. It is said to have been fatty in cases 161, 197, 226, 242, 302, 309, 344, 358, 382 and 750; and from the description given was probably also fatty in cases 338 and 340. In case 94 the liver was "a good example of the so-called drunkard's liver;" in case 566 the organ presented "some tendency to cirrhosis at its anterior border." In a few cases the liver is spoken of as abnormally small; in others as large or enlarged. These conditions are also shown to have existed in several instances by the recorded weight of the organ, which was but 39½ ounces in case 354, and 33¼ ounces in case 357; while in cases 286 and 362 it weighed 71 ounces, 76½ ounces in case 369, 81 ounces in case 750, 84½ ounces in case 344, and 86 ounces in case 204.

Abscesses of the liver were observed in seven of the cases under consideration. In case 712 there was a single abscess, containing about four ounces of pus, in the right lobe of the liver; in case 92 "the liver was occupied by an enormous abscess, pointing and about to break through the diaphragm into the right pleural sac, almost pointing also below, several square inches of the under surface of the organ being soft and of a dull-green color;" in case 205 the liver "contained a considerable number of metastatic foci, many of which had softened into a puruloid liquid;" and in case 867 there were "a number of metastatic foci in its right lobe." In case 203 numerous little yellowish-white nodules, the largest the size of peas, were scattered through the substance of the liver. Assistant Surgeon McGill, who reports the case, expresses no opinion as to their nature, but a perusal of his account will leave little doubt that they were really metastatic foci similar to those described in case 896. In case 898 there was a single abscess containing twenty ounces of pus in the right lobe of the liver, and in case 896 the liver contained numerous yellow metastatic foci from a quarter to half an inch in diameter. In all we have three examples of single abscesses and four of multiple metastatic foci, or seven cases out of one hundred and fifteen of diphtheritic dysentery. It has already been mentioned that in case 171 two multilocular hepatic abscesses coexisted with evidences of intestinal catarrh without ulceration. Several other cases of hepatic abscess will be mentioned in a subsequent portion of this section in connection with the post mortem appearances of chronic flux; the comparative frequency of hepatic abscess as a complication of diarrhœa and dysentery in this and other countries will then be commented upon. Miliary *tubercles* were observed in case 346 scattered through all parts of the liver; tubercles were also scattered through all the lobes of both lungs.

In many of the cases no mention is made of the contents of the *gall-bladder;* in about a dozen it is said to have contained but little bile, or quantities varying from a drachm to an ounce are mentioned. On the contrary, in cases 160, 197, 243, 246, 256, 278, 286, 306, 372, 429, 566, 627, 677, 710, 779, 784, 867 and 894 it is spoken of as full of bile or distended with bile, and in case 357 "the gall-bladder contained from four and a half to five ounces of bile." In most of these cases the appearance of the bile is not described, but in case 256 it is said to have been tar-like; in case 197 thick and black; in case 306 very dark and viscid; in case 566 thick, greenish and glairy; in case 372 yellowish and turbid;

in case 779 dirty-colored; and in case 243 normal. Gall-stones were observed in case 325, in which the gall-bladder contained two calculi each the size of an ordinary marble; and case 439, in which "two large gall-stones" were found in the gall-bladder.

The *spleen*, in several cases, is spoken of as congested, and in a still larger number as softened. In about a dozen cases it is spoken of as large, or enlarged, and in a somewhat smaller number of instances as small. In a number of instances the weight of the organ or its dimensions are recorded, and these sometimes indicate abnormally great size; sometimes the reverse condition. Thus the weight given is 8 oz. in case 382; in case 340 it is 9½ oz.; in case 362, 10½ oz.; in case 369, 14 oz., and in case 205, 15 oz. In case 392 the spleen measured 7½ inches by 4; in case 425, 8 inches by 4; in case 816 it was "at least five times its natural size, and very hard when cut." On the contrary the weight given in case 357 is 2½ oz.; in case 354, 3 oz.; in case 346, 3¾ oz.; in cases 400 and 579, 4 oz.; in cases 372 and 373, 4½ oz.; in case 367, 5½ oz.; and in case 516 the dimensions reported are 2½ inches by 1½. In case 354 a small supplementary spleen was observed. The *mesenteric glands* are spoken of as enlarged in about two dozen cases. In case 256 they are said to have been very much enlarged and hard; and in case 270, enlarged and engorged with blood. In a few of the cases the condition of the *pancreas* is noted, but nothing of a definite character appears to have been observed. In case 246 it is said to have been "indurated and livid;" in case 710, unusually large but healthy; in case 197 the pancreas weighed 4 oz., and in case 362 it weighed 4½ oz., but is said to have been of normal color.

The *kidneys* are sometimes spoken of as flabby, or as pale, or it is said that their cortex was pale. In case 566 "the kidneys were fatty, and softer than normal; in the inferior part of the external surface of the right kidney there was a cyst of moderate size;" in case 867 the kidneys weighed 5½ oz. each; the cortical substance of both had a waxy appearance; the pyramids were pinkish-red. The weight of the kidneys is given in a number of cases, and in several appears to indicate that one or both kidneys were enlarged. Thus, in case 203 the right kidney weighed 5½ oz., the left 7½; in case 357 the right weighed 5½ oz., the left 7¼; in case 206 the kidneys were enlarged, one of them weighed 7 oz.; in case 362 the right kidney weighed 10½ oz., the left 9½; both kidneys were pale and flabby; in case 816 "the kidneys were nearly double their normal size, and when cut into pus was found in all the calyces." A somewhat similar condition was noted in the left kidney in case 898.

Simple cysts were observed in one of the kidneys in case 566, as just mentioned; in case 340, in which there was "a small cyst" in the lower part of the right kidney; and in case 693, in which the left kidney contained a cyst holding about a drachm of fluid. In case 278 extensive cystic disease existed in both kidneys; the left was largest, being about six times the normal size of the organ. The specimen has been preserved at the Army Medical Museum, [No. 164, Medical Section.] Congenital displacement of one of the kidneys was observed in two cases; in case 97 the left kidney reposed on the promontory of the sacrum, and was supplied by four renal arteries given off from the bifurcation of the aorta, [No. 525, Medical Section;] in case 317 the right kidney reposed upon the second lumbar vertebra, and was converted into a cyst containing several ounces of an amber-colored liquid, [No. 361, Medical Section.] Finally, in case 811 a considerable number of calculi, composed chiefly of oxalate of lime mixed, however, with some phosphates, were found in the pelvis and calyces of the left kidney, [No. 593, Medical Section.]

Heliotype. *James R. Osgood & Co., Boston.*

CICATRICES OF DIPHTHERITIC ULCERS IN THE COLON.

No. 1003, MEDICAL SECTION.

[ENLARGED A LITTLE OVER THREE DIAMETERS.]

In a few cases the appearances of the *suprarenal capsules* is noted, and the descriptions in cases 340, 344, 346 and 354 would appear to indicate an abnormal condition of these organs; in case 346 there were two small cysts in the upper part of the left capsule. No abnormity of the *urinary bladder* appears to have been observed except in case 816, in which it is stated that the mucous membrane of the bladder was "very vascular;" and in case 338, in which "the bladder was hypertrophied." In the majority of the autopsies the condition of the urinary bladder is not mentioned.

PATHOLOGICAL HISTOLOGY OF THE DIPHTHERITIC INTESTINE.—For the pathological histology of the intestine in simple inflammatory dysentery without ulceration, the reader is referred to the account already given of the inflammatory process in the intestine as described in connection with acute diarrhœa. The minute anatomy of follicular ulceration, when it occurs in acute dysentery, does not differ essentially from what will be hereafter described in connection with the chronic fluxes. In this place, therefore, the histology of the diphtheritic process alone will receive attention.*

* The following are some of the more important authors who have contributed original observations on the histology of dysentery: F. GÜNSBURG—*Die Path. Gewebelehre*, Bd. I, Leipsic, 1845, S. 68—recognized the inflammatory congestion and the outpouring of an exudation containing numerous "inflammation-cells." These especially accumulate beneath the epithelial layer, which breaks down into molecular debris and is thrown off. The inflammation-cells are then transformed into a coherent membrane in which numerous nuclei can be seen. The follicles of the colon are much hypertrophied, and sometimes form branching cul-de-sacs with a common duct, Bd. II, 1848, S. 240, and Tab. IV, Fig. 27. The description is evidently drawn from the diphtheritic process. H. LEBERT—*Physiologie Pathologique*, Paris, 1845, Tome I, p. 216; see also Atlas, Pl. VII, Fig. 2—emphasized the vascular engorgement, capillary rupture, the secretion from the mucous surface of an abundance of mucus mixed with pus, and with epithelium detached from the surface. In severer cases the mucosa now passes into a state of softening and disorganization, which reduces to detritus patches of variable extent. The muscular coat is thus laid bare. Considerable masses of pus, blood and mucus concrete in the form of pseudomembranes, which are often found in the stools. Gangrene, with the destruction and conversion into detritus of large portions of the mucous surface, sometimes occurs. He describes the formation of cicatrices, but gives no particulars with regard to the histology of the process. In his subsequent iconographic work—*Traité d'Anat. Path.*, T. II, Paris, 1861, p. 226—LEBERT repeats this description with some modifications. He now recognizes two kinds of ulcers, follicular and irregular, and observes that the mucous membrane is sometimes covered with false membranes and offers characters "tout à fait diphthéritique." G. GLUGE—*Atlas der Path. Anat.*, Bd. II, Jena, 1850, Die Dysenterie—added but little to the descriptions of GÜNSBURG. His microscopical figures, 18te Lief., Taf. III, Figs. 5–17, are not very satisfactory. The abnormal pushing apart of the follicles of Lieberkühn is, however, clearly shown in Figs. 5, 7, 13 and 14. S. BASCH—*Anat. u. klin. Untersuchungen über Dysenterie*, Virchow's Archiv, Bd. 45, 1869, S. 204 and Taf. XIII. The figures in the plate accompanying this paper are especially noteworthy on account of containing excellent representations of the swollen granular endothelial elements of the submucous connective tissue from both small and large intestines in cases of dysentery, as well as the representations of low vegetable forms, to which reference will be made further on. A. THIERFELDER—*Atlas der Path. Histologie*, Lief. 2, Leipsic, 1873, Taf. XII—has published four carefully drawn lithographic figures of the pathological histology of dysentery. Figs. 3 and 6, being magnified only ten diameters, show very little detail, of course, but Figs. 4 and 5, each magnified 300 diameters, are in many respects noteworthy. The figures are taken from a single case of diphtheritic dysentery. According to THIERFELDER the diphtheritic layer, or, as he calls it, the pseudodiphtheritic membrane, consists of mucus, loosened epithelial elements and the elements of the blood. Fig. 4 represents a section through the mucosa adjoining the diphtheritic layer; it shows the follicles of Lieberkühn pushed apart by greatly distended capillaries which are full of blood corpuscles, red and white; the epithelium of the follicles is in a condition of granular metamorphosis or of fatty degeneration. Fig. 5 is a section through the submucosa, and, besides numerous distended bloodvessels in which both red and white corpuscles are distinctly recognizable, shows several characteristic appearances, viz: 1, The bundles of connective tissue are loosened, and in their interstices [lymph spaces] show numerous lymphoid elements or pus corpuscles, which are most numerous in the portion of the submucous layer nearest the surface; 2, in the same lymph spaces, wherever the swarm of lymphoid elements do not conceal them, larger oval nucleated cells resembling endothelial elements, (Endothelien ungemein ähnliche Zellen;) and 3, a peculiar network composed chiefly of granular debris, but containing also red and white blood corpuscles and the large cellular elements just mentioned. This network our author interprets as formed by hæmorrhage into the lymph spaces, the blood mingling with their contents. THIERFELDER has nothing to say about the condition of the closed follicles in dysentery, but his whole atlas, as far as published, aims merely to reproduce selected specimens, and does not attempt a complete account of any subject; it should be judged from this point of view. I must regard Figs. 4 and 5 as constituting a real addition to our knowledge of the histology of dysentery. The sections represented are from chromic acid preparations. KELSCH (memoir cited on p. 324, *supra*) has severely criticised this contribution of THIERFELDER, but I think without just grounds, [Archives de Physiologie, T. V, 1873, p. 583, note.] In the same article which contained this criticism he admited that he had himself as yet never examined the histology of a single case of acute dysentery, [p. 574.] This circumstance no doubt explains why he denied so positively the occurrence of the diphtheritic process, and the prominence he gave to a lesion (the invasion of the closed follicles by the glands of Lieberkühn) which, though it often occurs in dysentery, is not essential to it, being rather characteristic of protracted intestinal catarrh. In a subsequent article in the same volume—*Contribution a l'anatomie pathologique de la dysenterie aiguë*, p. 687—KELSCH contributes at length a single case of acute dysentery in which he has studied the histology of the diseased colon with great care, and interprets the appearances found in accordance with the views to which he had committed himself in his earlier papers. But it is unsafe to attempt to build a general scheme of the pathological anatomy of acute dysentery upon the analysis of a single case. Moreover, I must think that the facts of this single case as detailed by KELSCH illustrate very well one phase of the diphtheritic process, namely, that in which the diphtheritic sloughs have completely separated, leaving large areas of the submucous connective tissue exposed as a smooth raw surface, from which here and there project islets of diseased mucous membrane which have escaped complete destruction. The excellent figure which accompanies this paper [Planche XIX] fully supports this view. I may add that notwithstanding the earnestness with which KELSCH insists upon the microscopical examination of the stools, he does not appear to have himself examined the stools of this case, and therefore is unable to speak with knowledge of the characters of the sloughs whose separation left the diseased mucous membrane in the condition he describes. I must censure, too, the uncalled for arrogance with which in this last article he assails all German investigations of the dysenteric process, [p. 706 *et seq.*] The evident bitterness of feeling betrayed in this part of the essay must provoke a smile everywhere but in France; but notwithstanding these faults the papers cited are a valuable contribution to the histology of dysentery, especially in the chronic forms, and the five lithographic plates (one of them colored) by which they are illustrated are praiseworthy additions to the iconography of the subject. I shall have occasion to refer again to

In what may be regarded as the early stages of this process the alterations recognizable in perpendicular sections of the diseased large intestine do not differ materially from what is seen in simple inflammation of the intestinal mucous membrane, except that the surface of the affected part is coated with a thin diphtheritic layer. This layer consists essentially of the blood-fibrin which begins to transude so soon as the inflammatory process attains a certain degree of intensity. If it does not go beyond a moderate degree of hyperæmia, accompanied by a moderate increase in the activity of the normal migration of the white blood corpuscles, an increased activity of the mucus-secretion, characteristic of the healthy intestinal mucous membrane, alone results. As the inflammation becomes more intense the intestinal mucus becomes modified in quality and a more or less abundant transudation of the plasma of the blood is superadded, which is readily recognized by the characteristic reactions of albumen. When a still greater intensity is attained, the fibrin of the blood begins also to transude.

The behavior of the last named ingredient varies in accordance with its quality and the activity with which it is poured out. It may present almost any degree of firmness, from a jelly-like layer of very slight cohesion, readily floating away from the affected parts with the intestinal fluids, to a tough, firmly adherent, well defined layer which fully deserves to be described as a pseudomembrane. The less coherent layers are apt to be displaced during post mortem examinations and so overlooked; or, even if recognized, are apt to separate and be lost during the preparation of sections for microscopical investigation. To secure a view in situ the specimen should be immersed in alcohol to be hardened, before its surface has been injured by handling, or still better, sections should be prepared by freezing, which will give more correct notions of the quality of the fibrin than can be obtained after the action of alcohol. In such sections the fibrin will be found to vary from a slightly granular material to a characteristic meshwork of distinctly marked fibrillæ. It entangles in its substance a larger or smaller number of lymphoid elements, (migrated white blood corpuscles, pus corpuscles,) and often scattered or aggregated red blood corpuscles, which are especially prone to accumulate in the portion of the layer nearest the mucous surface. Moreover, low vegetable forms, as will hereafter be more fully described, can always be recognized, at least in the superficial portions of the layer, from the very first.

Not merely does this fibrinous layer form a coating of variable thickness upon the surface of the mucous membrane, but the interior cavities of the glands of Lieberkühn are more or less distended with a similar material. Sometimes this distension takes place

---

them further on. See also in this connection the account of the histology of the dysenteric process in HEUBNER'S article on dysentery, in Ziemssen's Cyclopædia, [cited p. 340, *supra*,] and the "Vorläufige Mittheilung" of ARCADIUS RAJEWSKY—*Ueber Diphtherie des Darmcanals*, Centralblatt für die med. Wiss., 1875, S. 691—who observed the lymph spaces (Saftcanälchen) of the submucosa of the dysenteric colon filled with bacteria, [micrococcus,] and made some experiments on the artificial development of dysentery in rabbits, to which I shall refer hereafter. I may also mention here a paper which, although written to illustrate certain points in the pathological anatomy of throat diphtheria, contains interesting details with regard to the diphtheritic process in the mucous membrane of the stomach, that may be advantageously compared with what happens in the colon in dysentery; G. BIZZOZERO—*Beitræge zur path. Anat. der Diphtheritis*, Stricker's Med. Jahrb., 1876, Heft 2, S. 207 and Taf. XIII—saw the diphtheritic process invade the stomach in two cases of throat diphtheria, and observed a subdivision of the pseudomembrane into two layers, a more superficial, consisting of an extremely delicate network, the small meshes of which were filled with "young cells," and here and there contained groups of granules resembling the forms which authors have described as "micrococcus balls," while the deeper layer consisted of the common amorphous substance of the croupous exudation, and in some places was so arranged as to form a coarse network with thick septa, the meshes of which were also filled with young cells. With the exception of this sharp separation of the pseudomembrane into two layers, his description of the changes observed in the mucous membrane of the stomach in these cases closely corresponds with what occurs in the colon in dysentery. Fig. 4 of the plate represents a portion of the mucous membrane of the stomach thus affected. The author also states that in the enlarged solitary follicles, and the thickened Peyer's patches of the small intestine, often observed in cases of diphtheria, he found in the centre of the follicles yellowish easily-separable knots ["diphtheritische Knötchen"] consisting of lymph cells more granular than normal, the spaces between which were filled with fat granules, albuminous granules and large cells containing many small nuclei. Fig. 3 represents a perpendicular section of the ileum magnified 20 diameters, showing such an enlarged follicle. Similar foci were observed in the Malphigian bodies of the spleen and in the mesenteric glands. He adds that in cases of "diphtheritis of the colon" [ulcerous croupous colitis] in children, he has observed similar foci in the follicles of the ileum and the Malphigian bodies of the spleen.

uniformly, and the sections appear as if the false membrane were a secretion of these glands, the accumulation on the surface of the mucous membrane being continuous with that in the glandular cavities. In other cases the lower portions of the glands acquire a cyst-like distension, as though inflammatory swelling had obstructed their orifices, and thus determined the accumulation of the abnormal secretion in their lower portions. In these cases the diphtheritic layer on the surface appears to have been formed by transudation from the capillary network of the mucous surface between the orifices of the intestinal glands. These two conditions of the glands are usually variously commingled, and probably in most cases the diphtheritic layer is derived in part from each of the sources indicated.

Besides this surface exudation, sections of intestine in the condition under consideration exhibit also an increased number of lymphoid elements in the adenoid tissue of the mucosa, in the closed follicles and in the submucous connective tissue, especially that portion of it which lies nearest to the muscle of Brücke, precisely as has been described in simple inflammation of the intestine, but to a still greater degree than usually takes place in acute cases, unless they partake of the diphtheritic characters. By the accumulation of these elements in the adenoid tissue of the mucosa the glands of Lieberkühn are pushed abnormally apart to a degree which varies with the intensity and duration of the process. (See Fig. 7.) By their accumulation in the closed glands more or less enlargement of these organs results, but they seldom attain any very great size unless a protracted catarrhal inflammation has preceded the diphtheritic process. By their accumulation in the submucous connective tissue, taken in connection with other changes in this coat presently to be described, more or less increase in its thickness is determined.

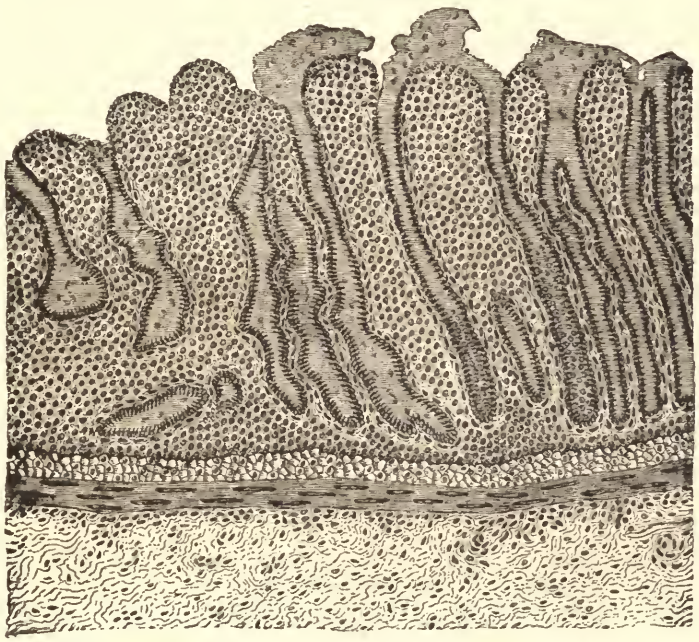

FIG. 7.—Perpendicular section of a dysenteric colon, cut longitudinally. Magnified 110 diameters. The figure is reproduced from a photo-micrograph (Neg. 913, N. S.) of No. 717, Microscopical Section. A. Mucous membrane, showing the glands of Lieberkühn pushed abnormally apart by an accumulation of lymphoid elements in the adenoid layer. On the left and in the middle of the portion shown, several of the follicles have undergone more or less cystic distension. B. The two layers of the muscle of Brücke. C. Submucous connective tissue with an accumulation of new elements, just below the muscle of Brücke. D. Diphtheritic layer (portions of which have been lost) continuous with the contents of some of the glands of Lieberkühn.

In such incipient cases as are under consideration, all these changes, with the exception of the formation of the fibrinous layer, are indistinguishable under the microscope from the similar changes already described as occurring in simple inflammation, and the description given in connection with that process would be substantially applicable here in all its details. All that was there said of the origin of the swarm of lymphoid elements might be repeated here, and the uncertainty expressed with regard to the fate of the columnar epithelium of the mucous surface between the glands, exists also in connection with the diphtheritic process. That during this process the epithelium might be lifted from its attachment, in the form of vesicles, by the exudation and so thrown off, seems

possible enough, and is supported by the occasional observation of columnar epithelial cells either detached or cohering in laminæ in the dysenteric stools. On the other hand, I am satisfied that in perpendicular sections I have several times positively recognized the epithelium in situ beneath the exudation, and I have no doubt that it is often entangled in the diphtheritic layer and shares the fate of the other tissues thus involved.*

The photo-plate facing this page is a reproduction by a mechanical process of a microphotograph representing preparation No. 681, Microscopical Section, Army Medical Museum, which is a perpendicular cut of a portion of colon presenting the slighter degree of the diphtheritic process hitherto described. The cut is one of a series of five from the same intestine, [Nos. 678 to 682, Microscopical Section,] all of which present similar lesions. They are from a boiled preparation stained with yellow aniline and mounted in gum and glycerine. The intestine was obtained from the body of a soldier dead of dysentery in Washington during the year 1864. No further particulars were recorded at the time.

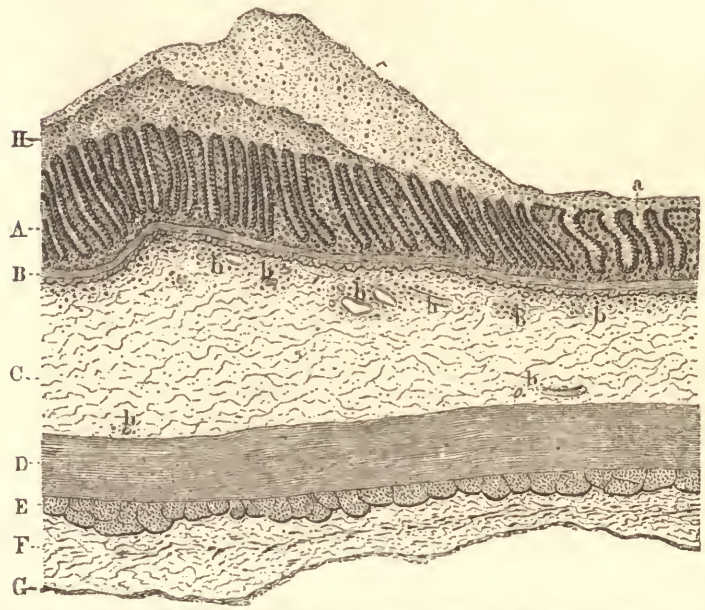

FIG. 8.—Diagram explanatory of the plate facing this page. A. Mucous coat; *a*, *a*, glands of Lieberkühn. B. Muscle of Brücke. C. Submucous connective tissue; *b*, *b*, blood-vessels cut across. D Circular; E. Longitudinal muscular coat. F. Subperitoneal connective tissue. G. Peritoneal epithelium. H. Diphtheritic layer, which is plainly seen to be continuous with the contents of the glands of Lieberkühn.

The portion of No. 681 exhibited in the plate is magnified 63 diameters by a Beck's ⅔ objective. The mucous surface of the piece is coated by a diphtheritic layer composed of a granular fibrinous mass entangling numerous lymphoid elements, (pus corpuscles,) which appear in the plate as black dots, and are most abundant in the left hand of the piece near the mucous surface, where they form an opaque mass. The glands of Lieberkühn are distended by the accumulation in their cavities of a substance similar to that composing the diphtheritic layer and continuous with it; as can be seen especially on the right of the plate. They are also pushed pre-

* The transformation of the epithelium in the diphtheritic processes affecting the soft palate and pharynx, the larynx and trachea, has been carefully studied by E. WAGNER—*Die Diphtheritis und der Croup des Rachens und der Luftwege in anatomischer Beziehung*, Archiv der Heilkunde, 1866, S. 481—according to whom the diphtheritic network described in the text as fibrinous, results from a transformation of the epithelial cells of the affected part. These at first swell up from imbibition of plasma; subsequently a network originates in each cell, the processes of which become continuous with those of the network formed in adjoining cells. This transformation he observed especially in the pavement epithelium of the pharynx and soft palate. E. RINDFLEISCH—*Lehrbuch der pathologischen Gewebelehre*, Leipsic, 1873, S. 314—while admitting that he has seen indications of this metamorphosis at the edges of the pseudomembrane in some cases, has expressed doubts as to how far it can be accepted as affording a general interpretation of the formation of the diphtheritic network. NASSILOFF—*Ueber die Diphtheritis*, Virchow's Archiv, Bd. L, 1870, S. 550—was never able to observe the process described by WAGNER, and points out that the network has the chemical reactions of fibrin, a fact which WAGNER himself seems half inclined to admit: "Die netzförmige Substanz der diphtheritischen und der croupösen Auflagerung unterscheiden sich in chemischer Beziehung nicht wesentlich von einander. Sie stehen unter den bekannten chemischen Stoffen dem geronnenen Faserstoff am nächsten," S. 488, *op. cit., supra.* M. BOLDYREW—*Ein Beitrag zur Histiologie des croupösen Processes*, Reichert und Du Bois-Reymond's Archiv für Anat., Physiol., &c., 1872, S. 75, also Taf. II—has critically examined the diphtheritic process in the larynx and trachea to ascertain whether WAGNER'S view is correct, and arrived at the conclusion that it is not, and that the network is simply fibrinous. He also states that in this situation the ciliated epithelium is thrown off during the catarrhal stage which precedes the formation of the false membrane. F. STEUDENER—*Zur Histologie des Croup im Larynx und der Trachea*, Virchow's Archiv, Bd, LIV 1872, S. 500—from a similar investigation arrived at like results. In this connection I may refer, in corroboration of the statement in the text, that "I have several times positively recognized the epithelium in situ beneath the exudation," to Taf. IV, Fig. 13, illustrative of the paper of OERTEL—*Experimentelle Untersuchungen über Diphtherie*, Deutsches Archiv für klinische Medicin, Bd. VIII, 1871, S. 242—which represents a perpendicular section of the diphtheritic mucous membrane of the trachea of a rabbit. In this figure the fibrinous diphtheritic layer reposes on the surface of the cylindrical epithelium, which is infiltrated, as well as the subepithelial tissue, with lymphoid elements. The diphtheritic layer is also infiltrated with micrococci and large cells. The latter I do not recognize; with this exception the picture is not unlike what I have many times seen in sections of the intestine.

PERPENDICULAR SECTION OF COLON

COATED WITH PSEUDOMEMBRANE. MAGNIFIED 63 DIAMETERS.

PHOTO-MICROGRAPH BY ASSISTANT SURGEON J. J. WOODWARD, U. S. A.

From No. 681. MICROSCOPICAL SECTION.

ternaturally apart by the accumulation of lymphoid elements in the adenoid tissue. The details of this change, and the anatomy of the muscle of Brücke, can readily be made out in the original preparation, but being rather too deeply stained with yellow aniline these parts, as well as the muscular coat of the intestine, were so opaque to the actinic rays that they appear in the photograph as black masses almost without detail. The submucous connective tissue is but little thickened, its tissue elements nearly normal; but between them a considerable number of lymphoid elements are infiltrated, and appear in the plate as black dots. The other sections of the same series exhibit very similar conditions, besides which one or more somewhat enlarged solitary follicles can be seen in each, and in each there is a small ulcer going about half way through the mucous coat, caused by the separation of a superficial slough.* This series represents a very early stage of the diphtheritic process, such as can usually be seen near the spreading margin of the lesion in cases of acute diphtheritic dysentery that have not been preceded by protracted catarrhal inflammation.

In such conditions as have been described there appears to be no anatomical difficulty in the way of resolution. We can readily understand that, should the disease take a favorable course, the abnormal elements might find their way back again into the blood from whence they came, either directly or indirectly, through the lymphatic circulation; the coagulated fibrin on the surface might be swept away into the intestinal canal on the renewal of the normal secretion of the tubular glands, and the mucous membrane would thus entirely regain its normal character.

Certain remarkable changes, consisting essentially in the invasion of the closed follicles by the adjoining glands of Lieberkühn, are sometimes observed even in these incipient diphtheritic cases as well as those of a more intense character. These changes have already been alluded to† as occurring in protracted cases of simple inflammation, and, so far as I have been able to ascertain, are only observed in diphtheritic dysentery when the diphtheritic process has supervened upon a protracted catarrhal inflammation of the mucous membrane. I regard these lesions, therefore, as belonging properly to chronic catarrh; certainly I have frequently failed to find any trace of them, in intestines exhibiting the most intense diphtheritic lesions, when the dysenteric attack has not been preceded by a somewhat protracted flux; but this happens so often that they are very frequently encountered in diphtheritic intestines, so that a picture of the diphtheritic process would hardly be complete without them. I therefore present a brief description in this place.

It has been already mentioned‡ that the apices of the closed follicles of the large intestine penetrate the muscle of Brücke and extend between the glands of Lieberkühn, in the form of cones, almost or quite to the epithelial surface of the intestine; and that the portion of the parenchyma of the closed glands which lies thus in the mucous membrane is not bounded by any distinct capsule, but is directly continuous with the adenoid tissue of the mucosa. These anatomical relations favor the occurrence of the anomaly about to be described; for while the cyst-like distension of the lower portion of the obstructed glands of Lieberkühn is elsewhere limited by the presence of the muscle of Brücke, through which, so far as I have been able to observe, the enlarged glands never make their way,

* In the *Catalogue of the Microscopical Section of the Army Medical Museum*, prepared by Brevet Maj. E. CURTIS, Asst. Surg., U. S. A., Washington, 1867, p. 60, the shallow ulcers in these specimens alone are described, but no mention is made of the diphtheritic layer. It is also stated that the "muscular layers have not been preserved in these sections," which is true of large parts of them, but not of all, as, for example, the part represented in the plate.

† See p. 328, *supra*. ‡ *Supra*, p. 319.

those which lie nearest to the closed follicles find no obstacle to their extension in the diseased parenchyma of these organs, in which the accumulation of new elements seems to be associated with considerable loss of cohesion in the reticulum of the parenchyma.

So far as the glands of Lieberkühn are concerned the process is by no means a passive one. Whether the accumulation of the abnormal secretion in their interiors serves as the stimulus, or this is supplied by the inflammatory condition itself, a genuine hyperplasia of the epithelial lining of the glands results. The glands are not merely distended into bag-like cysts; they shoot out branching buds, which grow into the substance of the adjacent closed follicles, until ultimately several of the glands adjoining each follicle have acquired racemose branches, that lie in the space formerly occupied by the parenchyma of the follicle, the greater portion of which is crowded aside, or, an ulcer having been formed, floats away as pus, to make room for the new growth. Subsequently the branching tubes often undergo cyst-like distension, and these dilatations coalescing may form cysts of considerable size, ($\frac{1}{20}$th to $\frac{1}{4}$th of an inch or more in diameter,) but they always retain more or less of the characteristic lining of columnar epithelium which exists in the glands of Lieberkühn, and the presence of which in the most aberrant varieties of these cystic forms betrays their origin.

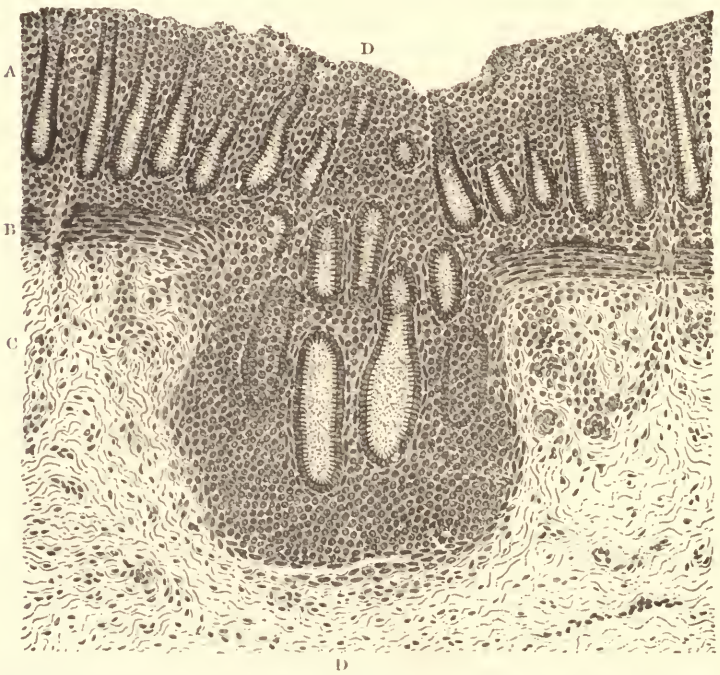

FIG. 9.—Perpendicular section of the colon of a child, cut longitudinally. Magnified 110 diameters by Powell & Lealand's ½-inch objective. Copied from a photo-micrograph (Neg. 924, N. S.) of No. 6103, Microscopical Section. A. Mucous membrane, showing the glands of Lieberkühn pushed apart by the swarm of lymphoid elements in the adenoid tissue. B. Muscle of Brücke. C. Submucous connective tissue, with numerous lymphoid elements near the muscle of Brücke. In the centre of the piece (between D and D) is an enlarged solitary follicle in which several cystic forms, described in the text, appear. The slit-like fissure just below the enlarged gland is a lymph sinus.

Figure 9 represents an early stage of the process under consideration, as it may often be observed in a smart intestinal catarrh uncomplicated by the diphtheritic process and not accompanied by dysenteric symptoms during life. The specimen, from a photo-micrograph of which the figure is copied, is a perpendicular section of the intestine of a mulatto child 18 months old, who died of intestinal catarrh (cholera infantum) in 1873. Some further particulars with regard to the case will be given hereafter when the histology of follicular ulceration comes to be discussed. In such sections the branching dilated tubes which have invaded the solitary follicles appear as isolated oval cysts lined by the characteristic columnar epithelium.

This singular lesion was first accurately described and figured by Kelsch,* to whom belongs the credit of suggesting the true explanation of the method in which it is produced. He erred, however, in supposing it to be peculiar to dysentery. It is in fact essentially a phenomenon of catarrhal inflammation. In protracted catarrhs of the large intestine some

* See note † to p. 324, *supra*.

degree of the process is very frequently present, and it is precisely in some of these cases that its most exquisite development is attained, the adjacent cystic branches opening into each other and their contents accumulating until compound cysts $\frac{1}{8}$th to $\frac{1}{4}$th of an inch or more in diameter are produced, as will be described hereafter.

But since diphtheritic inflammation frequently supervenes upon a previously existing intestinal catarrh, curious cystic forms, having their origin in the process just described, are often encountered in perpendicular sections of the diphtheritic colon. A common variety of these cystic forms is exhibited in Fig. 10, which represents a portion of a perpendicular section of the colon depicted in the plate facing page 442.* The upper portion of the figure represents the diphtheritic layer which is immediately continuous with the submucous connective tissue. All traces of the muscle of Brücke or of the glandular layer have been destroyed,† with the exception of the branching communicating cysts seen near the centre of the figure. These appear as isolated forms in each section, though by an examination of several parallel ones it is easy to see that they communicate with each other. The well known columnar epithelium of the glands of Lieberkühn forms a complete lining to each cyst. Such cysts may be found associated with any of the phases of the diphtheritic process.

FIG. 10.—Perpendicular section of a diphtheritic colon. Magnified 110 diameters. Copied from a photo-micrograph (Neg. 928, N. S.) of No. 7260, Microscopical Section. A. Diphtheritic layer which is immediately continuous with the submucous connective tissue C. Opposite B, near the middle of the figure, are the cysts described in the text. *a*, *a*. Small veins crowded with blood corpuscles. *b*, *b*. Arteries in the submucous connective tissue.

In the graver forms of the diphtheritic process we encounter not only a more abundant exudation upon the mucous surface, but a denser swarm of lymphoid elements in the adenoid tissue of the mucous membrane and in the submucous connective tissue. In sections the capillaries of the mucosa are found distended with blood, the corpuscles, both white and red, being distinctly recognizable in preparations hardened in alcohol and mounted in Canada balsam. Capillary hæmorrhages are often observed just beneath the epithelial surface, that is, precisely where the capillaries form their rich plexus around the orifices of the glands of Lieberkühn; the red corpuscles are found heaped together in countless multitudes, and form hæmorrhagic areas of considerable size in the superficial parts of the mucous membrane and in the deeper parts of the diphtheritic layer.

---

* No. 360, Med. Sect. There is in this case no detailed previous history, and consequently no information on record with regard to the duration of the catarrhal affection, which probably preceded the dysentery.

† This disappearance of the glandular layer and the apparent substitution for it of a diphtheritic layer, continuous with the submucous connective tissue, led me, in my earlier studies of this process, into the mistake of supposing the cell-forms in the diphtheritic layer to proceed from the proliferation of the elements of the tissues replaced—see, especially, my paper *On the use of aniline in histological researches*, &c., The Amer. Jour. of the Med. Sci., Jan., 1865, p. 113—a theoretical error which I have long since abandoned.

In the superficial portions of the submucous connective tissue the lymphoid elements obscure the muscle of Brücke and accumulate about the closed glands until their limits can no longer be recognized. In proportion to the increasing severity of the case, the area in which the swarm is so dense as to obscure or conceal all other elements, becomes more extensive until the whole submucous connective tissue is thus infiltrated as far down as the surface of the muscular coat of the intestine. Along with the lymphoid elements a delicate granular material, very similar in character to the exudation on the mucous surface, now makes its appearance everywhere between the new elements, especially in the lymph spaces of the submucous connective tissue, adding to the obscurity of the picture and justifying the belief that a fibrinous exudation similar to that which had formed on the surface of the mucous membrane has coagulated in the interstices of the tissues.

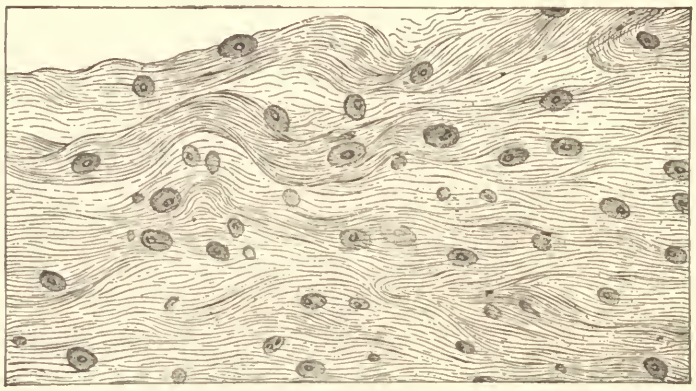

FIG. 11.—Submucous connective tissue of the colon in dysentery. Magnified 300 diameters. Copied from a photo-micrograph (Neg. 945, N. S.) of No. 7236, Microscopical Section. Lying on or between the connective-tissue bundles are two kinds of granular cells. The smaller ones without nuclei are lymphoid elements; the larger nucleated ones are the transformed parenchyma cells described in the text.

Meanwhile other changes are taking place in the submucous connective tissue. These are most readily recognized in those portions in which the structural details are not obscured by the density of the lymphoid swarm. Here the texture of the fibrillated matrix of the submucous connective tissue appears to be loosened as if by œdema, the lymph spaces are larger than normal, and the stellate connective-tissue corpuscles are more or less entirely replaced by oval nucleated granular cells, which vary from $\frac{1}{2000}$th of an inch, or even less, to $\frac{1}{1500}$th or even $\frac{1}{1000}$th of an inch in long diameter, which sometimes adhere to the walls of the lymph spaces, (*i. e.*, to the surface of the connective-tissue bundles,) and sometimes lie free in their cavities. Figure 11 represents the condition in question as seen in a perpendicular section of a portion of the colon in case 266. The connective-tissue bundles were pretty widely parted, but as other bundles form the background of these clefts, the artist has attempted to indicate the portions beyond the focal plane by more delicate and widely separated lines, in which he has not been wholly successful. The larger nucleated cells adhering to the surface of the bundles in focus, or lying between them, are the transformed parenchyma cells; the smaller ones are lymphoid corpuscles. When a section through a portion of the submucous connective tissue thus affected is stained with carmine and teased with needles, single connective-tissue bundles can often be isolated, to the surface of which the large granular cells adhere in more or less continuous rows, as in Figure 12.

FIG. 12.—Portion of the submucous connective tissue of the colon in dysentery, after teasing with needles. Magnified 300 diameters. Copied from a photo-micrograph (Neg. 944, N. S.) of an extemporaneous preparation from No. 163, Medical Section. The central connective-tissue bundle shows the row of granular cells described in the text.

The condition just described is much more common in the large intestine than in the small; but undoubtedly occurs at times in the latter situation. This is strikingly illustrated by Fig. 13, which represents a portion of a perpendicular cut of No. 284, Medical Section. The specimen is a portion of small intestine* greatly thickened, and presenting a number of deep, irregular ulcers, some of which penetrate to the peritoneal coat. The patient died of so-called "diarrhœa" during the winter of 1862 in Douglas hospital, Washington, D. C., and the specimen was presented by Assistant Surgeon (now Surgeon) Warren Webster, U. S. A. No history of the case has been preserved. In this piece the mucous membrane between the ulcers was infiltrated with lymphoid elements, but the swollen villi projected freely on its surface, and no pseudomembrane was anywhere found. The submucous connective tissue was greatly thickened, (to nearly $\frac{1}{10}$th of an inch from the muscular coat to the surface,) and wherever the appearances were not obscured by the lymphoid swarm, the connective-tissue corpuscles had disappeared and were replaced by granular nucleated cells somewhat smaller and rounder than those usually seen in the condition described above as existing in the colon. Moreover, in some parts of the submucosa the lymph spaces were infiltrated by larger or smaller groups of minute granules which, from their behavior towards reagents, were undoubtedly micrococcus. The colon of this subject, which probably presented in a marked degree the lesions of diphtheritic dysentery, was unfortunately not preserved.

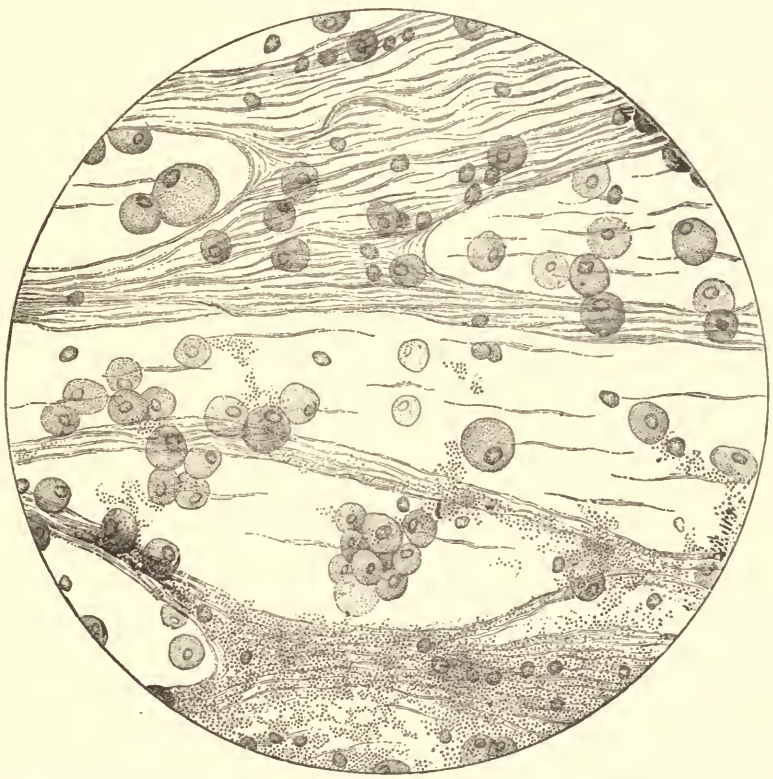

FIG. 13.—Portion of a perpendicular section through the submucous connective tissue of the ileum in a case of dysentery. Magnified 480 diameters. Copied from a photo-micrograph (Neg. 952. N. S.) of No. 7256, Microscopical Section. The lymph spaces are dilated, and lying free in these and adhering to their walls are numerous rounded, granular, nucleated cells, and also a number of smaller granular bodies, (lymphoid elements.) The granules in the lower portion of the piece are micrococcus groups.

The presence of the large granular cells just described in the inflamed submucous connective tissue and the simultaneous disappearance of the normal connective-tissue corpuscles will be best understood if these latter bodies be regarded as endothelial elements,† and it be supposed that they become swollen, granular and lose their adhesion to the fibrillated matrix during the inflammatory process. Basch‡ has described and figured these granular cells in the submucosa of both small and large intestine of dysenteric subjects dissected by him in Mexico. He correctly interpreted them as metamorphosed connective-tissue corpuscles. They have also been figured by Thierfelder,§ who mentions their resemblance to endothelial elements.

* In the *Catalogue of the Medical Section of the U. S. Army Medical Museum*, Washington, 1867, p. 80, this specimen, by some accident, has been described as a "portion of colon."

† See p. 319, *supra*. ‡ *Op. cit.*, p. 461, *supra*. § *Op. cit.*, p. 461, *supra*.

According to Heubner,* this transformation of the connective-tissue cells occurs only in diphtheritic, and never in catarrhal dysentery, an opinion with which I cannot agree. On the one hand I have not only observed it in diphtheritic dysentery in parts of the intestine which the diphtheritic process had not yet reached, but also, especially in old chronic catarrhs with great thickening of the submucosa and follicular ulceration, in colons which nowhere manifested any trace of the diphtheritic process. On the other hand, it is often imperfectly seen, or is altogether absent, in those cases in which the diphtheritic process, having developed without a previous catarrh of any long duration, proves speedily fatal. I cannot, therefore, regard it as characteristic of the diphtheritic process, though it very often accompanies it.

The bloodvessels of the affected submucosa, especially the small veins, are greatly engorged with blood and their walls are often infiltrated by the lymphoid swarm; they can be recognized in sections mounted in Canada balsam not merely by the characteristic tissues of their coats, but very often by the multitude of red corpuscles, which are more or less perfectly preserved in their interiors, and among which a certain number of white corpuscles can always be recognized. In well preserved specimens the outlines of the red corpuscles can be perfectly defined with any good immersion lens; but when post mortem changes have progressed somewhat this is less readily done, and often the capabilities of the best optical instruments are taxed to the uttermost to make out the form of the elements which compose the coagula. I am satisfied, not merely by the study of the numerous preparations made at the Museum, but by my examination of his own admirable drawings, that a part at least of the objects which Kelsch† has described and figured as dilated lymphatic vessels filled with coagulated fibrin entangling lymph cells in its reticulum, were really veins containing blood-clots in the state of partial decomposition just alluded to. When the bloodvessels contain no coagula their endothelial lining is very often found detached and lying free in the lumen, either in consequence of post mortem changes or of the mechanical violence sustained in cutting the sections. Moreover, especially in those cases in which the diphtheritic process has supervened upon a chronic catarrh, the internal coat, or both the internal and middle coats, of the small arteries are sometimes found in a state of amyloid degeneration.‡

As for the lymphatic vessels, their endothelium appears to share in the granular swelling that affects the endothelium of the lymph spaces with which they are continuous, and occasionally they are found distended with fibrin and lymph corpuscles; but any such

---

* *Dysenterie*, in Ziemssen's Handbuch, Bd. II, Th. 1, Leipsic, 1874, S. 525.

† KELSCH—memoir cited *supra*, p. 324, Archives de Physiol., T. V, 1873, p. 583—remarks: "Il y a, en outre, dans cette tunique celluleuse, une altération profonde des vaisseaux lymphatiques et sanguins. Les premiers sont énormément dilatés. Ce fait est si général et si accentué, qu'il frappe tout d'abord quand on examine la celluleuse même à un faible grossissement." He describes these dilated lymphatic vessels as sometimes filled with a fibrinous reticulum, in the meshes of which are cells analogous to those of lymph. In other cases the vessel is plugged with large and small nucleated cells, which are more or less polygonal from mutual pressure. Now, neither in the three admirable colored figures (Pl. I, Figs. 1, 2, 3) which accompany his memoir in the *Comptes rendus de la Soc. de Biologie*, (cited *supra* p. 324,) nor in the four beautiful figures (Pl. XI, Figs. 1, 2, Pl. XII, Figs. 3, 4) which illustrate his first paper in the Archives, is there any reference to these dilated lymphatics, although the enlarged bloodvessels of the submucosa are figured and described. It is only in Figs. 1 and 2 of Pl. XIII that they at length make their appearance; and surely in Fig. 1 the forms lettered *e*, *e*, which are described as "vaisseaux lymphatiques dilatés, remplis de cellules et de fibrine," are merely veins containing coagula. In Fig. 2 the same interpretation is demanded by the upper vessel marked *n*, while a portion at least of the other appearances, explained as lymphatic vessels with their endothelium detached, are not to be distinguished from veins in the same condition. I do not wish to be understood as denying that the lymphatic vessels in the submucosa of the dysenteric intestine are sometimes dilated and filled with fibrin, or that their endothelium shares in the process which we have seen affects the endothelium of the lymph spaces, (connective-tissue corpuscles,) but merely express the opinion that a part of the picture which KELSCH has drawn results from his mistaking veins for lymphatics. I may add that the dark network in Fig. 1, Pl. XIII, which is lettered *h*, and described as "exsudat fibrineux avec globules blancs déposés entre les faisceaux de tissu conjonctif," is, I presume, of the same nature as the dark network figured by THIERFELDER, (see p. 461, *supra*,) and with the micrococcus network which I shall describe a little further on.

‡ See p. 333, *supra*. This condition is I presume the same observed by RAJEWSKY—*loc. cit.*, p. 462, *supra*—who describes it as a hyaline metamorphosis, "Zu gleicher Zeit erscheint in dem veränderten Gewebe eine hyaline Metamorphose der Blutgefässe."

general dilatation as Kelsch has described I have been unable to recognize. Nor have I been able to make out, in a satisfactory way, the condition of the nerves of the diseased intestine. When it is remembered how difficult it is to determine the course of the nerves in the normal human intestine if the dissection be postponed for a few hours after death, it will not seem surprising that the attempts hitherto made to examine into the condition of the nerves in the dysenteric intestine have not as yet given definite results.

For the purpose of illustrating the appearances presented by perpendicular sections of the colon in the more advanced stage of the diphtheritic process just described, the steel engraving facing page 472 has been prepared. It is a reproduction of a photo-micrograph of a duplicate perpendicular cut from the same piece of colon as Nos. 729 to 731, Microscopical Section, Army Medical Museum, and represents some of the conditions just described as seen with a power of twelve diameters. The mucous surface of the piece represented is coated with the diphtheritic layer very much as in the plate facing page 464. In the mucous membrane, which is considerably thickened, the glands of Lieberkühn are pushed apart by the accumulation of lymphoid elements in the adenoid tissue, and their upper portions are completely obscured by this cellular mass; but they have not undergone any cystic change. At several points accidental breaks in this layer have been made by the razor in preparing the sections. The submucous connective tissue is swollen to $\frac{1}{12}$th of an inch in thickness. The infiltrating lymphoid elements, which with the low power used appear as mere dots, are most abundant just below the muscle of Brücke, except on the right of the piece represented in the plate, where the whole submucous layer is infiltrated. The great thickness of the longitudinal muscular coat, especially on the right of the picture, results from the circumstance that the section passes here through one of the *ligamenta coli*.

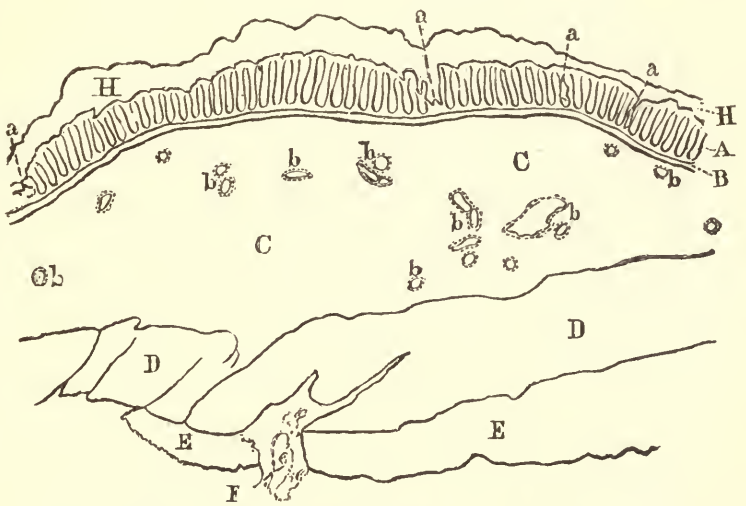

FIG. 14.—Diagram explanatory of the plate facing page 472, representing a perpendicular section of a diphtheritic colon cut transversely. A. Mucous membrane, in which *a, a, a, a*, are rents made by the razor. B. Muscle of Brücke. C. Thickened submucous connective tissue. *b, b, b, b*. Bloodvessels cut across. D. Circular, E. Longitudinal, muscular coat of the intestine. F. Point of entrance of bloodvessels. H. Diphtheritic layer.

The preparation represented by this plate, together with Nos. 729–731, Microscopical Section, which are parallel cuts from the same boiled piece, were mounted in the fall of 1864 in camphor-water acidulated with acetic acid; they were stained with aniline, and have long since perished by molecular changes; the piece of intestine was selected from the colon, a portion of which is represented in the chromo-plate facing page 442, and has been preserved in the Museum, (No. 360, Medical Section.) Long after these preparations had spoiled I had a series of cuts made from the alcoholic preparation which, after staining with carmine and mounting in Canada balsam, show many points in the minute anatomy of the piece even better than the original preparations did when fresh. (These are Nos. 7259–63, Microscopical Section.) Figure 10, on page 467, was drawn from a photo-micro-

graph of one of these cuts; and the next illustration is taken from another part of the same. Figure 15 represents a portion of the infiltrated submucous connective tissue of the colon, the place selected being a point where the section passes through a small artery and vein. The intima of the artery is in a state of glassy swelling, (amyloid degeneration;) its lumen contains a few red and white blood corpuscles and some granular fibrin. The vein is nearly filled with a blood-clot, the red corpuscles of which can be distinctly made out, with white corpuscles scattered here and there. The connective tissue is infiltrated with numerous lymphoid elements; the endothelial cells of its lymph spaces are slightly swollen, their nuclei appearing rather large and oval; but they have not attained to an advanced degree of the transformation described and figured in page 468.

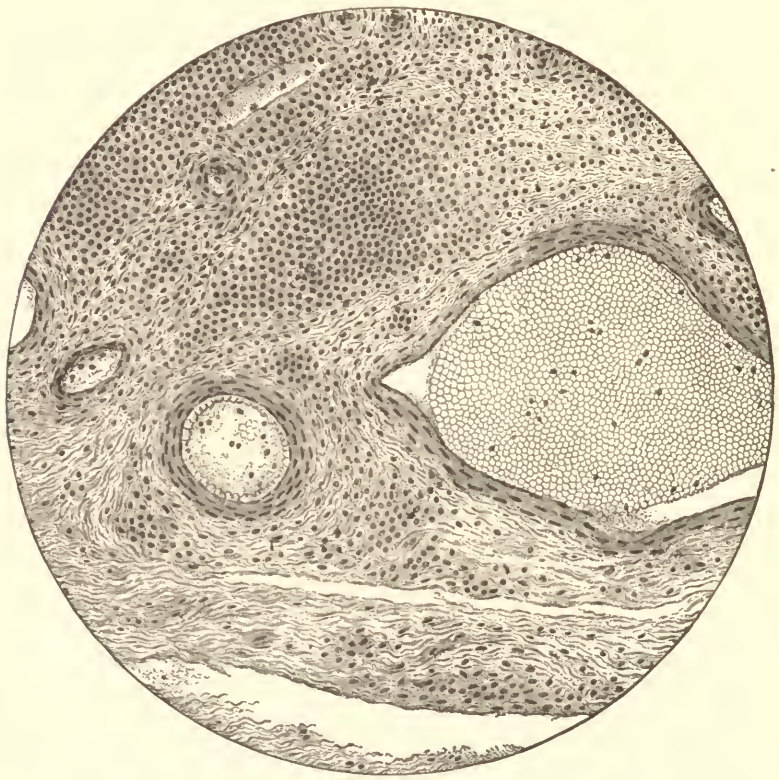

FIG. 15.—Portion of a perpendicular section through the submucous connective tissue of the colon in a case of dysentery. Magnified 175 diameters by Powell & Lealand's immersion ¼th. Copied from a photo-micrograph (Neg. 922, N. S.) of No. 7260, Microscopical Section. The nearly circular vessel to the left and below the centre of the piece is a small artery. The larger elliptical form to the right is a vein. Several smaller vessels are cut across in other parts of the piece. The connective tissue throughout is infiltrated with lymphoid elements.

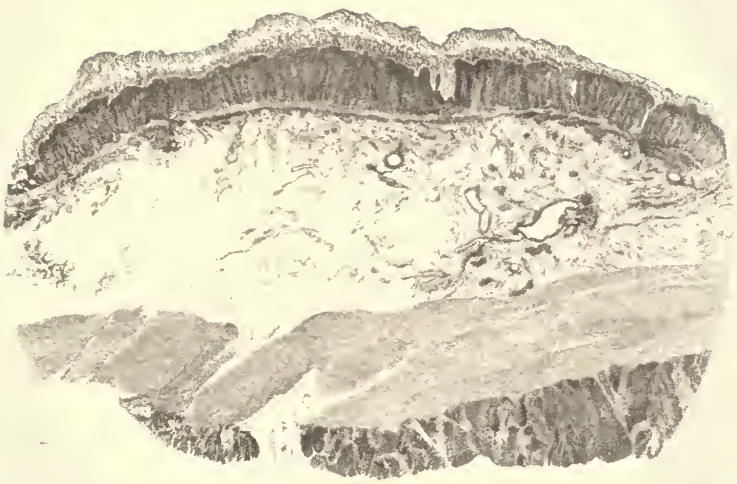
Sooner or later during the progress of the alterations hitherto considered sloughing sets in. This is the characteristic feature of the diphtheritic process, and completes the similitude between diphtheria in the pharynx and the lesions of dysentery. The stage at which sloughing begins varies greatly in different cases. In some, the tissues retain their vitality until the whole mucosa and submucosa are stuffed with lymphoid elements, and thus transformed into a yellowish opaque mass, coated on the surface with a dense yellow pseudomembrane. In others, at a very early period in the disease, the affected parts become considerably swollen by the accumulation in their substance of an exudation rich in albumen, but containing only a moderate quantity of fibrin and a comparatively moderate number of lymphoid elements; and in this condition sloughing may set in as rapidly and destructively as occurs after the tissues have been thoroughly stuffed with lymphoid cells. In this class of cases the process somewhat resembles œdematous erysipelas of the skin, to which indeed it has been compared by Rollo and Wedekind.* But between the most extreme cases of this kind, and those in which the lymphoid elements become most abundant before sloughing occurs, every transition may be observed, so that I cannot but regard both varieties as merely different phases or degrees of one and the same process.

* Consult ROKITANSKY—*Der dysenterische Prozess*, &c., Oest. Med. Jahrb., Bd. XX, 1839, S. 81; also G. F. v. WEDEKIND—*Ueber die Ruhr*, Frankfurt a. Main, 1811, S. 20.



PERPENDICULAR SECTION OF COLON.

The accumulation of new elements in the connective tissue just beneath the mucous layer, which derives its supply of bloodvessels from the vascular plexus that exists in this very situation, has been held in many quarters to afford a sufficient explanation of the sloughing that takes place. It has been supposed that this accumulation interferes mechanically with the circulation in that membrane, and thus cutting off its nutritive supply causes it to perish.* No doubt this explanation has a certain amount of validity in some cases, but it affords no solution of the extensive sloughing which sometimes occurs before any considerable accumulation of new elements has taken place. Whatever its cause, the sloughing may be limited to the superficial parts of the mucosa, or may involve the whole of it, or more or less of the submucous connective tissue may also be implicated. The conditions limiting the extent and depth of the sloughs are not always easily to be determined. When parts of the submucous tissue are stuffed with new elements it is in some cases very clearly seen that the extent of the sloughing appears to coincide with the area of infiltration, if not to be determined by it; but when this infiltration is scanty it is not easy to make out why some portions of the swollen œdematous tissue perish while others retain their vitality.

The tissue-necrosis, whatever may be its extent, is speedily followed by putrefactive changes in the dead parts. These changes may be compared to those which occur in a gangrenous limb, only in the case of the intestine the tissue involved is softer, moister, and therefore more putrescible; and, moreover, it is maintained at very nearly the temperature of the living body, a circumstance which favors the rapidity of the process. The occurrence of putrefaction is manifested microscopically by a granular metamorphosis of all the tissue elements involved, in consequence of which they are speedily converted into a mass of unrecognizable molecular debris. Only when the sloughs separate, before sufficient time is afforded for the completion of this process, can any characteristic structural details be recognized in them. This circumstance explains the difficulty often experienced in detecting structure in the sloughs passed by stool; but fortunately for diagnostic purposes the process generally occurs quite irregularly, so that patches which have undergone comparatively little change are frequently detached, in consequence of the more advanced metamorphosis on their borders, and find their way into the stools.

From the moment that these putrefactive changes begin to occur in the sloughs, the characteristic low vegetable forms that arise whenever nitrogenous matters undergo decomposition rapidly invade them. The diphtheritic sloughs are a fertile soil for the growth of these humble organisms, which are already present in the contents of the diseased, indeed even of the normal intestinal canal, in countless myriads.† It is not surprising, therefore, that these forms should be found not merely on the surface of the eschars, but throughout the whole of their putrid substance; as well as in the coagula filling any bloodvessels which lie in the eschars, or even in coagula, continuous with these, extending far into the adjacent still living tissues. Spherical bodies of extreme minuteness, (micrococcus,) either scattered irregularly, grouped in masses or associated as beaded filaments, are the forms most generally encountered in all parts of the sloughs. Rod-like forms (baccilli, bacteria) are also found to some extent, but as a rule only in the most superficial parts, or in cavities communicating with the surface.

* This suggestion is very clearly presented, for example, by KELSCH, Archives de Physiol., T. V, 1873, p. 579; see note † to p. 324, *supra*.
† See pp. 278 and 367, *supra*.

Figure 16 exhibits both kinds of these forms as they are often seen in a slough involving the mucous membrane. It is copied from a photo-micrograph of a perpendicular section of a portion of the colon of case 587. At the place selected for the photograph the section passes through a slough which is still adherent to the infiltrated submucosa. In this slough there are a number of parallel cylindrical cavities that correspond in size and position to the tubular glands of the intestine which, throughout the sloughs, have quite perished leaving no trace of their structure behind. One of these cylindrical cavities crosses the field obliquely; in its lumen, which communicates with the cavity of the intestine, there are several micrococcus masses and a number of scattered rod-like forms. The rest of the field is occupied by micrococcus and granular tissue-debris; near the margins of the central cavity, however, a few rod-like forms can be seen.

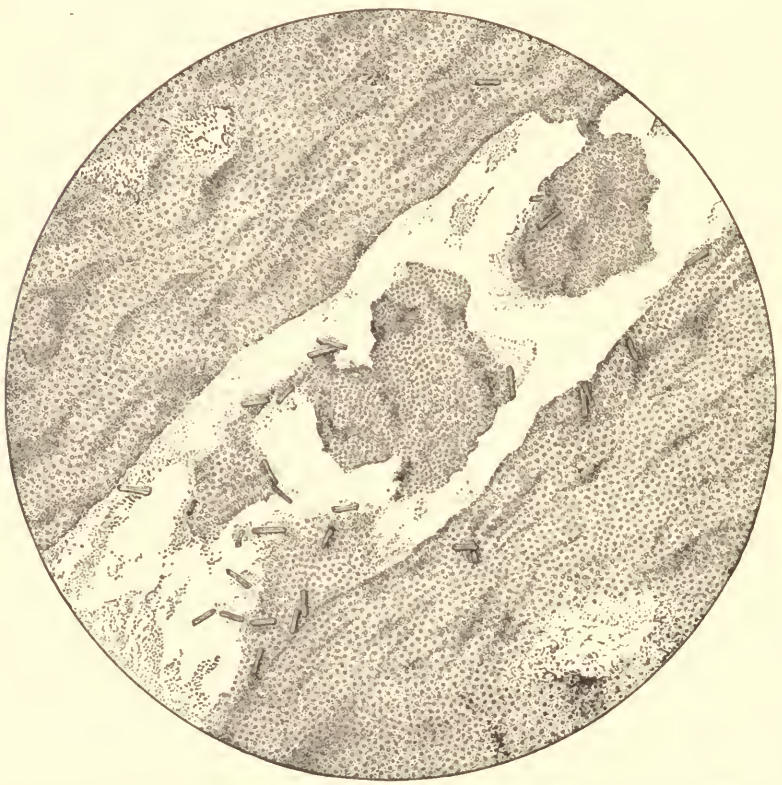


FIG. 16. Portion of a perpendicular section through the eschar in a case of diphtheritic dysentery. Magnified 950 diameters by Powell & Lealand's $\frac{1}{12}$th immersion. Copied from a photo-micrograph (Neg. 932, N. S.) of No. 7223, Microscopical Section, which is a cut of No. 72, Medical Section. The field is crossed obliquely by a cavity, (the former site of one of the glands of Lieberkühn.) in which are several micrococcus groups and a number of rod-like forms. The rest of the field is occupied with micrococcus, with a few rod-like elements near the edges of the central cavity.

Not merely do micrococcus presenting the characters represented in this figure develop in multitudes in the dead eschar and in coagula contained in the bloodvessels leading from it, but, before the slough separates from the adjacent still living tissue, they find their way from the dead into the living parts. In this invasion they follow the paths of least resistance, that is, almost always the lymph passages, under which head, besides the lymphatic vessels, the irregular spaces between the connective-tissue bundles of the submucosa are of course to be included. In perpendicular sections of diphtheritic colons this invading swarm can almost always be recognized, even with quite low powers, (20 diameters or less,) as an opaque, brown network of anastomosing forms, the true nature of which can readily be detected by the use of reagents. These anastomosing forms extend from the diphtheritic sloughs into the submucous connective tissue, in which they spread for long distances in all directions. The lymph passages being larger and more permeable in the lower half of the submucous connective tissue than in the upper, it is in this portion especially that the network is coarse and readily seen; moreover, in the upper portion of the submucosa its finer branches are obscured by the dense swarm of lymphoid elements, which probably offer also a mechanical obstacle to the penetration of this portion of the membrane, its lymph spaces being already pretty well obstructed by them.

This micrococcus network, as I propose to call the characteristic appearance just described, is well shown in Figure 17, which is copied from a photo-micrograph of a portion of another perpendicular section of the colon of case 587. In all the cuts made from the colon of this case the network was prominently developed in the lower portion of the submucosa. This condition was also observed in sections cut from a number of other specimens belonging to the cases enumerated on page 453, as well as in some from cases, which will be discussed hereafter, in which diphtheritic dysentery supervened upon chronic follicular ulceration of the colon.

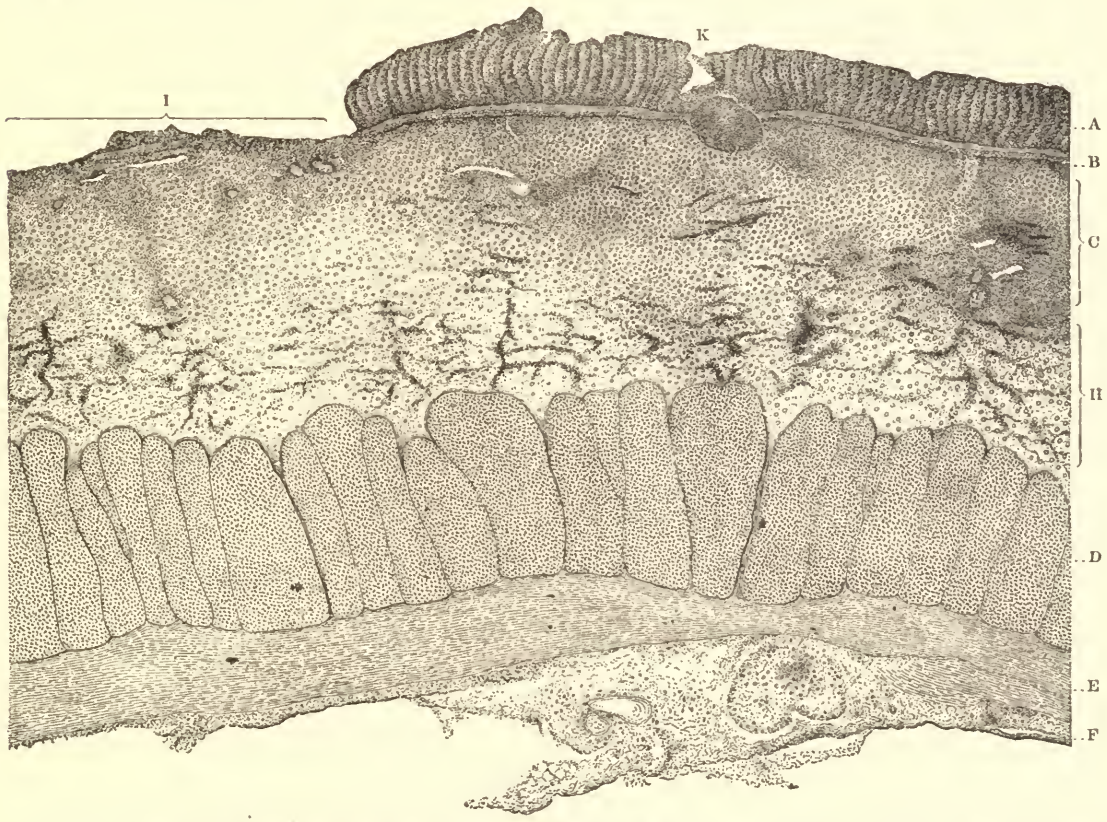

FIG. 17.—Perpendicular section of a diphtheritic colon cut longitudinally. Magnified 22 diameters. Copied from a photo-micrograph (Neg. 939, N. S.) of No. 7224, Microscopical Section, which is a cut of No. 72, Medical Section. A. Mucous membrane, a part of which, corresponding to I. has been removed by the separation of a slough. At K, an enlarged solitary follicle. The pseudomembrane layer, which coated the surface of the mucous membrane, has for the most part broken away; on the left of K a little of it still remains. B. Muscle of Brücke. C. Upper portion of the submucous connective tissue infiltrated with lymphoid elements, the size of which is considerably exaggerated in the figure. H. Lower portion of the submucous connective tissue; the dark branching figures constitute the micrococcus network. D. Circular muscular coat of the intestine. E. Longitudinal muscular coat. F. Subperitoneal connective tissue.

When this micrococcus network is examined with a higher power (300 to 500 diameters or more) it is seen to consist in part of mere heaps of micrococcus spheres without any recognizable arrangement; but whenever the masses are not too bulky to be transparent it will be seen that a considerable portion of the spherules are arranged in rows, forming beaded chains, in which the individual elements are so small that unless objectives of the best defining power are employed the chains resemble fine continuous threads. The network will be observed to occupy the clefts between the connective-tissue bundles (*i. e.*, the lymph spaces) and often to entangle in its substance the granular nucleated cells, explained on page 468 to be the swollen endothelial cells of the lymph spaces. Sometimes, also, considerable numbers of lymphoid elements are thus entangled. The condition thus produced is so complex that it is only in its incipient stages that it is adapted to pictorial representation.

Figure 18 is copied from a photo-micrograph taken from near the margin of an area of the submucous connective tissue of the colon which was occupied by the micrococcus network. Here some of its branches were very delicate, and swollen endothelial elements occupy nodal points. The cut gives a good idea of the early stages of the process as seen with a power of 475 diameters.

The micrococcus network just described has been admirably figured by Thierfelder,* who, however, entirely misconceived its nature, supposing the network to be caused by an infiltration of the lymph spaces with blood, which subsequently breaks up into granular detritus. This possibility is, however, promptly negatived by the use of suitable reagents; the micrococcus network resists the action of strong solutions of caustic potash or soda, as well as acetic acid, alcohol and ether. By the use of these reagents, also, this network is promptly distinguished from the protoplasmic and fatty granules, set free during the putrefactive metamorphosis of the tissues, which optically appear very similar. I do not doubt that the finely granular infiltration which Basch† described and figured as occurring in the submucosa during the advanced

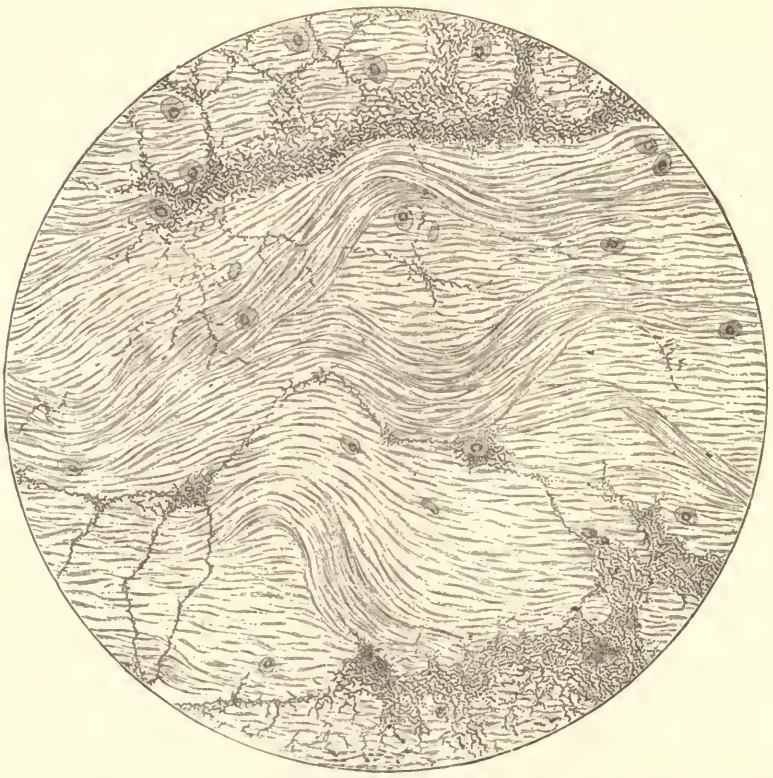

FIG. 18.—Perpendicular section of a dysenteric colon, showing the micrococcus network in the submucosa. Magnified 475 diameters. Copied from a photo-micrograph (Neg. 947, N. S.) of No. 7269, Microscopical Section, which is a cut of No. 462, Medical Section. The specimen is from case 318.

* From the provisional account given by ARCADIUS RAJEWSKY *(op. cit.*, note * p. 461, *supra)* of his investigations of some dysenteric intestines made under the supervision of Prof. v. RECKLINGHAUSEN, at Strasburg, it would appear probable that he has both seen and correctly appreciated this network. According to his account, an intestinal catarrh always precedes the diphtheritic process, which consists in the accumulation of a fibrinous exudation on the surface of the mucous membrane and in its substance. Then follows the necrosis of the mucous tissue (das Absterben des Schleimhautgewebes) and its transformation into a mass of albuminoid granules, *(i. e.*, granules which disappear on treatment with acetic acid.) Simultaneously a hyaline transformation of the bloodvessels takes place. He then adds: "Both in the granularly altered and in the unaltered tissue we found micrococci and bacteria. In the first case they appear as colonies, in the second simply scattered. Even before the tissues are quite broken down (wo das Gewebe noch nicht flüssig geworden ist) lymph-spaces (Saftcanälchen) filled with bacteria can be demonstrated in the submucosa." If by this the author means rod-like bacteria, he merely reaffirms the account of BASCH; if he means spherical bacteria, his observations agree with mine. KELSCH also undoubtedly saw the same network and represented it, though very imperfectly, in one of his figures. See note † to p. 470, *supra*.

† BASCH, *op. cit.*, p. 461, *supra:* "Der endliche Ausgang dieser Metamorphose des submucösen Bindegewebes ist wie bei der Schleimhaut körniger Zerfall." "Die faserigen sowohl als die zelligen Elemente des Bindegewebes sind nur in spärlichen Resten vorhanden und durch eine feinkörnige Masse, die man nach unseren bisherigen Vorstellungen als Detritusmasse auffassen und bezeichnen muss, substituirt." [*Op. cit.*, S. 214; also Fig. 11, Taf. XIII.] The rod-like and thread-like forms observed by BASCH in the lymph passages of the dysenteric intestine are figured in the same plate, but not described in his text as clearly as I could wish. He remarks merely, "Ich habe naturgetreu, so wie ich sie mit einem guten Hartnack'schen Instrument Ocular II Immersion 10 gesehen, in Fig. 13 dargestellt und muss, da ich zu einer Controlluntersuchung gegenwärtig kein Material besitze und seiner zeit dieselben nicht bestimmen konnte, ihre Benennung den Mycologen überlassen." The figure referred to represents three kinds of forms: Shorter or longer wavy rods; minute spherical forms; and, a little on one side of the figure, a peculiar short club-like rod. But the magnifying power employed is left quite uncertain. In the first place, the immersion objectives of Hartnack marked No. X vary considerably in magnifying power, just as the so-called ¼, ⅛, 1/15, &c., of other makers do. According to the price-catalogue of Hartnack's instruments, appended to FREY'S work on the Microscope, [4te Aufl., Leipsic, 1871.] the No. X immersion, with ocular II, magnifies 600 diameters; but this represents rather the power intended than that actually possessed in any given case. Moreover, whatever the magnifying power of the objective and eye-piece, the mode in which the drawing was made (which is not stated) would introduce considerable variations in the dimensions of the picture. If it were made with the camera lucida, the magnifying power of the drawing would vary with the distance from the eye-piece to the paper; and if drawn without that help, personal equation would come in to an extent fatal to precision. The difficulty in appreciating the drawing referred to by BASCH, (Fig. 13,) which results from the foregoing

stages of dysentery, and supposed to be due to the granular metamorphosis of both the fibrillated and cellular elements of the connective tissue, was really to a great extent composed of micrococcus. The attention of Basch, however, was diverted from the consideration of these minute spherical forms by his observation of larger elongated rod-like and thread-like bodies, which he found in the lymphatic passages of both large and small intestine, as well as in the small veins where he could recognize them between the blood corpuscles. The real nature of these larger forms I can only conjecture, especially as the drawings of Basch are not wholly consistent with each other. I will not, therefore, attempt to decide whether these drawings represent merely a somewhat distorted view of the appearances I have described above or elements of a different nature, but simply remark that they do not correspond with my own observations.

In the specimen of colon from case 94 (No. 997, Medical Section) I noticed some peculiarities in the micrococcus invasion of the sloughs, which are represented in Figure 19. In this case, which was one of acute diphtheritic dysentery occurring in a subject whose general health was broken down by lung phthisis and intermittent fever, the greater part of

FIG. 19.—Perpendicular section of a dysenteric colon, showing sloughing of the circular muscular coat. Magnified 70 diameters. Copied from a photo-micrograph (No. 959, N. S.) of No. 7295, Microscopical Section. A. Represents the circular muscular layer which hangs in shreds into the cavity of the intestine. B. Scattered fasciculi of muscular fibre-cells belonging to the longitudinal coat, pushed apart by connective tissue infiltrated with lymphoid elements. A similar infiltrated connective tissue may be observed between the fasciculi of the circular muscular coat, especially on the right of the picture. Towards the upper part of the piece several dark oval bodies can be observed near the free extremities of the sloughs. These are the micrococcus nests described in the text; those lettered *a*, *á*, are represented as seen with a higher power in the next figure.

considerations, is still further increased by the circumstance that the plate contains two other figures, (Figs. 8 and 14,) in which the vegetable forms in question are also shown, but in both of which they are very much smaller than the figure just described, although all the figures purport to be drawn with the same power. On the supposition that Fig. 13 accurately represents the forms as seen with an actual magnifying power of 600 diameters or rather more, (and that in Figs. 8 and 14 they are only accidentally represented smaller.) they would appear to resemble very closely the large forms which are so frequently seen in water in which fragments of flesh are permitted to decompose, or those which BILLROTH—*Coccobacteria Septica*, Berlin, 1874, S. 54, also Taf. IV, Fig. 34—observed in the pericardial fluid of subjects dead of various diseases. If, on the other hand, BASCH has correctly drawn them in figure 8 as magnified by the power specified, they do not differ from certain forms ordinarily encountered in the intestinal contents. BASCH asserts that he found these forms in the central lymphatic sinuses of the villi of the small intestine and in passages which he supposed to be lymph sinuses between the crypts of Lieberkühn and just beneath the mucosa. They could be seen also in the veins of the submucosa between the blood corpuscles. In the lymph sinuses and small veins of the large intestine similar conditions were observed. The vegetable forms lay in the peripheral portions of the lymph sinuses, while the lymph cells occupied the central parts of the passages. They were to be found also between the connective-tissue bundles of the submucosa. Some time after reading the paper of BASCH I re-examined a number of specimens of dysenteric intestines which had been carefully preserved in alcohol since the war, and was readily enabled, in properly cut sections, to make out the appearances described in the text. Those of these specimens which had been placed in alcohol so soon after death that putrefaction had not had time to commence could be stained with carmine quite as readily as recently hardened preparations, and gave results which I believe are quite as trustworthy. A considerable number of the preparations made have been preserved in the Army Medical Museum, where they are now accessible for study by any competent person. In examinations of dysenteric intestines made during the war I had frequently observed the micrococcus infiltration of the sloughs and the micrococcus network in the submucous connective tissue. I confess that I misinterpreted these appearances, supposing the spherical granules observed to be partly coagulated fibrin, partly protoplasmic or fatty granules set free by the processes of necrobiosis. Nor do I now deny that this explanation is true for a portion of the granules observed, but the use of reagents puts it beyond question that there is a considerable portion for which it is not available.

the mucous membrane was destroyed by diphtheritic sloughing; one slough nine inches long is still attached by one extremity to the upper portion of the piece. In much of the surface from which the sloughs have separated the muscular coat of the intestine is laid quite bare and its circular layer has begun to slough, so that it everywhere hangs in shreds from the surface of the piece. In these sloughing shreds the muscular tissue has evidently begun to undergo putrid decomposition; its nuclei could not be recognized, nor could they be differentiated with carmine; the boundaries of the muscular fibre cells could be but indistinctly perceived. The tissue of the shreds merely presented an indistinctly fibrillated aspect, but here and there toward their peripheral extremities they contained peculiar oval bodies, which, on examination with higher powers, proved to be nests of micrococcus spherules.

Figure 20 represents two of these nests, magnified 400 diameters. They are of oval form, one .0015, the other .0025 of an inch in long diameter, and each consists of a large number of exceedingly minute spherical elements apparently imbedded in a transparent matrix, a slight excess of which on the periphery of each mass separates them from the surrounding tissue as if they were enveloped in a cyst. From the surface of the lower one, however, several thread-like processes, composed of similar spherical elements, find their way into delicate clefts between the adjacent fibre-cells of the decomposing muscle. These oval micrococcus nests are very similar to the forms named Ascococcos by Billroth,* who observed them especially in putrid flesh-water. Whether in this case they have any special significance, or whether their size and form are simply determined by the physical conditions of the muscular coat, just as the boundaries of the micrococcus network are determined by dimensions of the lymph spaces of the submucosa, I must leave for future observation to determine. In several of the sections of the colon of case 94 I observed also, in the subperitoneal connective tissue, small veins cut across, the interiors of which were stuffed with micrococcus arranged in the well known thread-like forms described above as occurring in

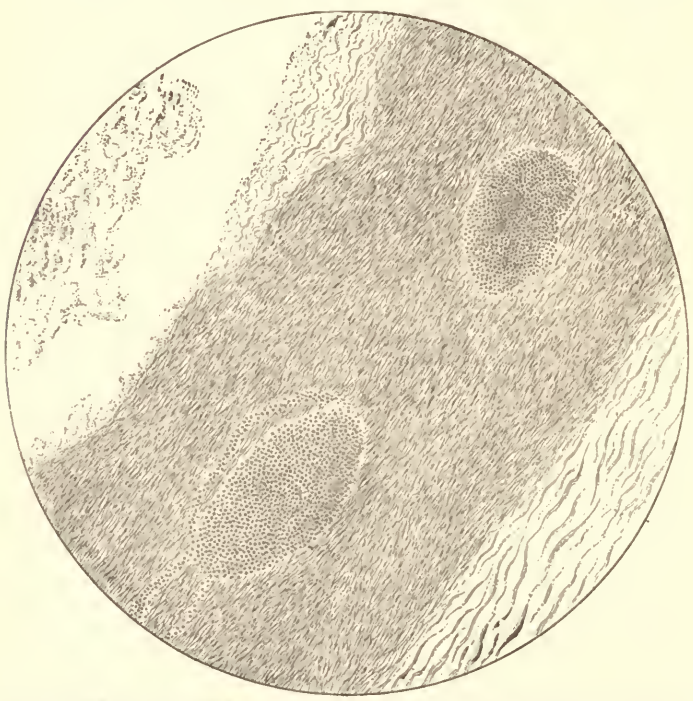

FIG. 20.—Micrococcus nests in a slough of the circular muscular coat of the intestine. Magnified 480 diameters by Powell & Lealand's $\frac{1}{25}$th immersion. Copied from a photo-micrograph, [No. 960, N. S.] The two nests represented are those marked *a*, *d*, in the last figure.

* T. BILLROTH—*Coccobacteria Septica*, Berlin, 1874—describes two forms of Ascococcos: a larger form [S. 12 *et seq.*, and Taf. III] and a smaller one, [Ascococcos parvus, S. 14 and 98, also Taf. II, Fig. 18,] the latter occurring in tiny rounded masses which in size and general appearance resemble the lymph corpuscles. It is the former of these varieties that I have in view. BILLROTH'S figures in Taf. III I suppose represent smaller forms than mine; at least they are said to be drawn with a Hartnack's system 15 and ocular 3, giving a magnifying power of 1185, and if this is correct, of which, in view of the looseness of this mode of recording dimensions, I cannot feel sure, the largest of the oval forms he figures is not more than 30 micromillimetres in length, whereas the larger of the two nests in Fig. 20 is a little more than 60 micromillimetres long. But COHN—*Untersuchungen über Bacterien*, Beiträge zur Biologie der Pflanzen, Bd. 1, Heft 3, S. 141—who adopts this form of vegetation as a new genus with the name *Ascococcus Billrothii*, [S. 151; see also Taf. V, Fig. 2,] says, with commendable precision, that its more spherical forms vary in diameter from 20 to 70 micromillimetres, while the elliptical ones may even attain 120 to 160 micromillimetres in long diameter, so that the forms I have figured fall quite within the observed variations in the dimensions of these bodies. As described by the authors cited, the Ascococcus forms consist simply of micrococcus united into clumps or colonies by a peculiar tough *glia* or jelly-like matrix, which gives them with high powers the appearance of being invested with a cyst

the submucosa of the diphtheritic intestine. From some of these vessels the beaded filaments appeared to have invaded the lymph spaces of the adjacent connective tissue, which contained a rich network of similar forms.

The frequency with which thrombi, having their point of departure in the diphtheritic sloughs, may be invaded by micrococcus during the life of the subject, the possible extent of this invasion, and especially the question of the transportation of these microscopical forms to distant parenchymatous organs and of the pathological consequences of this accident, are matters which as yet have had no thorough histological investigation in cases of dysentery. I have myself, during the war, several times observed in recent specimens the veins leading from the diphtheritic sloughs into the mesocolon occupied by thrombi which had in part been converted into a greenish-yellow fetid fluid, which under the microscope appeared to swarm with actively-moving dark-contoured molecules. I observed similar conditions in the thrombi leading from the diseased stump in cases in which amputations for gunshot wounds had been followed by necrosis of the marrow of the injured bone and pyæmia.* I do not now doubt that in the case of the decomposing thrombi in the dysenteric bowel a considerable part of these actively-moving molecules were really micrococcus, as has been abundantly demonstrated since that time in the case of the decomposing thrombi leading from injured parts; but at the time I did not comprehend the true significance of these molecules, which I supposed to be mere detritus-molecules, the products of putrefactive processes in the thrombi. In several cases in which this condition of the intestinal veins was associated with metastatic foci in the liver, as, for example, in case 896, I made futile efforts to discover visible thrombi in the branches of the portal vein leading to the metastatic nodules, but found that, "on the contrary, the vessel continues generally quite patulous even after it is involved in the substance of the morbid nodule."† The foci themselves contained a small quantity of yellow fetid fluid at their centres, which under the microscope appeared to consist of "disorganized liver tissue, granular matter and fat globules, but no pus."‡ This granular matter consisted of actively-moving, dark-contoured molecules quite like that in the putrid thrombi.

I do not now doubt that these molecules were chiefly micrococcus. I suggested, in 1866, that the immediate cause of the metastatic foci in these dysenteric cases, as in the pyæmic cases following gunshot wounds, was to be sought rather in the introduction into the torrent of the circulation of "the putrefying debris of the coagula which had formed in the veins" leading from the seat of the primary lesion, than in larger, more solid emboli which might be supposed to plug a branch of the portal vein, or of the pulmonary artery, of moderate size. I spoke of the detritus-fluid floating from the primary thrombi as "a liquid more viscid than blood, which could not be expected to circulate as readily as blood," and which "might be expected to be arrested in the capillaries," and "if so arrested, to set up there, by actual contact, a similar form of change"§ to that which was going on in the putrefying tissues from which it had floated. That these views were substantially correct, so far as they go, I do not doubt; but recent investigations of the pyæmic process, as it results from wounds, from throat diphtheria and other allied conditions, have brought up the question whether the micrococcus contained in the putrid semifluid substance, introduced

* J. J. WOODWARD—*Causes and pathology of pyæmia, (septæmia,)* Transactions of the American Medical Association, Vol. XVII, Philadelphia, 1866, p. 173.

† *Op. cit.*, p. 195.

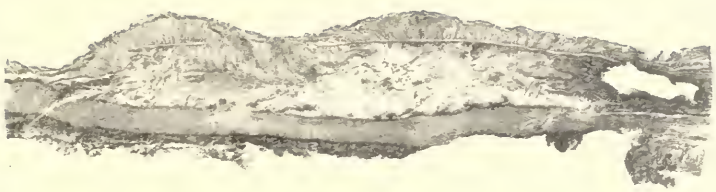
‡ *Catalogue of the Medical Section of the Army Med. Museum*, Washington, 1867, p. 89. § *Op. cit.*, p. 198.

into the circulation from the primary local lesion, is not the essential morbific agent by which the secondary processes are generated.

I will not attempt to enter here upon the discussion of this question. To do so would require a detailed review of the numerous investigations into the pyæmic process which have appeared during the last ten years. Let it suffice to point out that the putrid fluid which floats from the decomposing primary thrombi in these cases consists not merely of the low vegetable forms, but of all the various products of the decomposition of the primary thrombi. Protoplasmic particles in a condition of active molecular change exist side by side with the newly originated vegetable forms, and it seems even more reasonable to suppose that the transportation of these is the immediate means of setting up a similar kind of decomposition, wherever they may be arrested in the distant capillaries, than to assign this role merely to the vegetable forms, and assume that they exercise specific morbid influences, without better evidence than we have yet acquired.

In a general way, indeed, I am disposed to regard the whole train of phenomena which I have sketched above, of the invasion of the diphtheritic sloughs and of the diseased but still living tissues of the dysenteric intestine by the swarm of vegetable parasites, as mere epiphenomena of the morbid process rather than as manifestations of its efficient cause. So long as we remain without means of distinguishing in any way between the vegetable forms constantly present in the normal intestinal canal and those which invade the diphtheritic sloughs, we cannot be logically justified in assigning to these forms any causal significance. On the other hand, if these forms are regarded as mere products of putrefaction, the phenomena of their invasion of the sloughs and even of adjacent living parts, so soon as the vitality of these parts is sufficiently depressed, become perfectly intelligible. In this connection I would particularly point out that, so far as I have been able to observe the process, the micrococcus invasion of the intestinal tissues never occurs until these are either quite dead or at least very greatly diseased, and that the formation of the diphtheritic slough and its invasion by micrococcus always precede the formation of the micrococcus network in the diseased submucosa. I cannot regard phenomena which occur so late in the course of the morbid processes as their efficient cause.*

* In this connection I must mention the attempts at the artificial production of diphtheritic inflammation by chemical irritants. Experiments of this character have been conducted by W. REITZ—*Untersuchungen über die künstlich erzeugte croupöse Entzündung der Luftröhre*, Sitzungsberichte der k. Akad. d. Wiss., Bd. LV, Abth. II, 1867, S. 501; OERTEL—*Experimentelle Untersuchungen über Diphtherie*, Deutsches Archiv für klinische Med., Bd. VIII, 1871, S. 242; H. MAYER—*Ueber die morphologischen Veränderungen in Trachea und Lungen durch Ammoniak*, Archiv der Heilkunde, Jahrg. XIV, 1873, S. 512; and L. GRIFFINI—*Contribuzione alla Patologia generale del tessuto epitelico cilindrico*, L'Osservatore, Gazzetta delle Cliniche di Torino, T. 10, 1874, p. 497. If dilute solutions of ammonia be injected into the trachea of a rabbit or dog, a merely catarrhal inflammation is produced; if strong solutions are used, a pseudomembranous or diphtheritic layer is developed. OERTEL, who performed this experiment on rabbits, admits that the resulting process shares all the anatomical characters of croupous inflammation, but holds that it differs from diphtheritic inflammation in the absence of the local sloughing and of the metastatic processes, which he believes to be produced only by the vegetable forms characteristic of diphtheria—*op. cit.*, S. 347. MAYER, also, experimented on rabbits, and believed himself justified in concluding that the process resulting from the application of ammonia was by no means identical with croup. He regarded it rather as a catarrhal process complicated, if stronger solutions were used, by superficial or deeper necrosis of the tissue. In these sloughs micrococcus and other low vegetable forms ("zahlreiche Pilze, bald nur punkt-und stäbchenförmige Micrococcen"—"bald längere ketten- und fadenförmige Gebilde," *op. cit.*, S. 515) soon made their appearance in great abundance. Finally, GRIFFINI, who experimented on dogs, regards the pseudomembrane produced as identical with that of the croupous process in man, ("le pseudo-membrane croupose naturali dell'uomo.") Generally he found no vegetable forms in the pseudomembranous layer, but in one case, in which the dog had been dead a few hours before he made the examination, he found an abundance of bacteria and micrococcus, ("di abbondanti bacterii e micrococchi,") and he forcibly demands whether the micrococcus or the ammonia is to be looked upon as the cause of the process. I have myself made no experiments in this direction, but those that I have cited certainly appear to me to strengthen the position I have taken in the text, that the vegetable forms found in the pseudomembrane are the consequence, not the cause, of the local process. Here I must mention the experiments of ARCADIUS RAJEWSKY (*op. cit.*, p. 462, *supra*) on the artificial production of the dysenteric (diphtheritic) process in the colon of rabbits. This observer found that bacteria-holding fluids (he does not mention from what source derived) injected into the bowel or into the bloodvessels of a healthy rabbit did not develop the diphtheritic process; but if a smart intestinal catarrh was first developed by the injection of a dilute solution of ammonia, and then a fluid containing bacteria (this time he says "eine Micrococcen enthaltende Flüssigkeit") was injected into the bloodvessels, the diphtheritic process was developed in the inflamed parts, and the micrococci localized themselves in the inflamed mucous membrane. The action of the ammonia in solution alone did not produce this process. The provisional communication cited being accompanied by no details, (the promised complete account of these experiments, if published, has not yet reached me,) it is difficult to form an opinion as to its full significance. So far as it goes, it seems to show that whatever part may be taken by the low vegetable forms, they are of themselves insufficient to develop the diphtheritic process in the intestine.



If, now, the patient survives the occurrence of the tissue-necrosis just described, the sloughs sooner or later begin to separate by the ordinary suppurative process. Lymphoid elements accumulate in a dense swarm in the tissues immediately adjacent to the boundaries of the necrosed portion, the matrix between these lymphoid elements liquefies and they are set free as pus corpuscles. The eschar itself, no longer adherent to the adjacent structures, is readily detached by the peristaltic motion of the bowel. The depth of the primary diphtheritic ulcer which results from this process depends upon the depth of the primary diphtheritic infiltration. The upper portion of the mucosa only may be stripped off, and when sections are cut the remains of the cul-de-sacs of the intestinal follicles may still be recognizable at the bottom of the ulcer. More frequently, however, the whole of the mucosa and more or less of the submucosa is involved in the eschar, and the bottom of the ulcer is formed either by some portion of the submucous layer or by the muscular coat of the intestine.

But whatever its original dimensions, the diphtheritic ulcer may subsequently extend both in area and in depth, either by secondary sloughing or by a true ulcerative process, the lymphoid elements continually floating off from the surface as pus corpuscles, while they continually accumulate in the tissue adjoining the margins of the ulcer. Frequently the muscular coat of the bowel is thus invaded. The lymphoid elements accumulate in the lymphatic passages and in the interstices between the muscular fibre-cells. As to what becomes of the latter I cannot be sure, for they usually retain their integrity till quite obscured by the accumulation of the lymphoid swarm; I am inclined to think that they are converted into granular detritus. Simultaneously with the invasion of the muscular coat, lymphoid elements begin to accumulate in the subperitoneal connective tissue, which, by the time the spreading ulcer has penetrated the muscular coat, is already densely infiltrated. Perforation of the intestine then readily takes place, either by the formation and separation of a little slough, or by the rupture of the thin tissue, which forms the bottom of the ulcer, during a spasmodic peristaltic contraction.

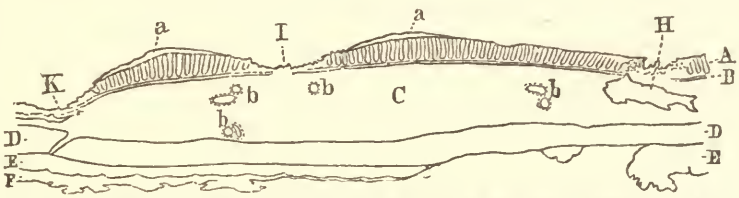


FIG. 21.—Diagram explanatory of plate facing page 480. A. Mucous membrane. *a, a.* Adherent pseudomembrane. B. Muscle of Brücke. C. Submucous connective tissue. *b, b, b.* Blood-vessels cut across. D. D. Circular, E, E. Longitudinal muscular coat. F. Subperitoneal connective tissue. H. Follicular ulcer. I. Superficial diphtheritic ulcer. K. Deep diphtheritic ulcer.

Some of the appearances presented by such ulcers, when perpendicular sections are examined by low magnifying powers, are shown in the steel engraving facing page 480, which is copied from a photo-micrograph representing a portion of No. 687, Microscopical Section, as seen with a magnifying power of twelve diameters. The specimen is one of a series of cuts [Nos. 687 to 691, Microscopical Section] from a boiled piece, stained with yellow aniline and mounted in gum and glycerine. It is a portion of the colon of a soldier who died of dysentery, in Washington, during July, 1865. In this case the diphtheritic process was associated with follicular ulceration, probably the result of a chronic flux, and accordingly follicular ulcers appear also in the cuts. The portion of No. 687 represented in the plate exhibits near its right extremity one of these ulcers; the section has passed through it a little to one side of its orifice, so that it appears rather as a minute abscess, .04 of an inch in diameter, than as an ulcer. Somewhat on the left of the middle of the piece the cut passes through a small superficial diphtheritic ulcer, which is limited to the gland-

ular layer of the mucosa, and does not at its deepest point penetrate below the level of the muscle of Brücke. On the extreme left it passes through the margin of a much larger diphtheritic ulcer, which invades the submucous connective tissue and penetrates almost to the circular muscular coat. The surface of the mucous membrane on each side of the central superficial ulcer is thinly coated with pseudomembrane. The submucous connective tissue is infiltrated with innumerable lymphoid elements which are most densely packed around the margins of the ulcers.

From the account which has been given of the histology of the diphtheritic process, the conditions under which hæmorrhage from the bowels occurs in diphtheritic dysentery may readily be understood. Just as in simple inflammation of the intestinal mucous membrane, this may happen, especially in the early stages of the disease, from ruptures in the capillary plexus surrounding the orifices of the glands of Lieberkühn, or it may occur, at a later stage, from the rupture of vessels of more or less considerable size during the separation of the diphtheritic sloughs, or still later, after the sloughs have separated, from the rupture of capillaries or of larger vessels in the granulation tissue of the edges or bottoms of the diphtheritic ulcers. No doubt, also, sometimes, even when the patient has not been subject to hæmorrhoids, a rupture of the hæmorrhoidal veins may take place during violent tenesmic efforts, and hæmorrhage may result from this source.

After necrosis of any portion of the diphtheritic layer has once taken place, resolution is of course impossible so far as that portion is concerned. The dead part must inevitably separate if the patient survives, and the only mode of recovery is by the healing of the resulting ulcer. This healing takes place always by a process of granulation and the development of cicatricial connective tissue, very much as occurs in the repair of ulcers of the skin. I have not had sufficient opportunity to study the details of the process to be able to give more than a general notion of its character. In its essence it appears to consist in the development of a fibrillated matrix between the lymphoid elements which accumulate at the bottom and margins of the ulcers after the fashion of granulations. By the contraction of this fibrillated matrix the edges of the ulcers are approximated, so that the scar is always much smaller than the original ulcer. The cicatricial tissue is finally coated with a columnar epithelium, which is probably formed by an outgrowing of the normal epithelium at its margins, as occurs in the case of skin ulcers; but, so far as I know, the glandular layer of the mucous membrane is never reproduced.

Simultaneously with the development of the fibrillated matrix in the granulation tissue, by which the ulcer is filled up, a similar matrix is developed between the lymphoid elements that infiltrate the adjoining mucous and submucous layers. The result of this process is the formation of a series of radiating, branching and anastomosing ridges which often extend one-tenth of an inch, or even farther, from the edge of the ulcer into the surrounding mucous membrane. These push the adjacent follicles of Lieberkühn preternaturally apart, and give rise to the peculiar characters of the edges of the cicatrices shown in the plate facing page 460. This peculiar extra-marginal process, which I have never observed in the cicatrices of typhoid or catarrhal ulcers of the small intestine, while it is always present in the cicatrices of colon ulcers, appears to afford a partial explanation of the circumstance that puckering, contraction and actual diminution of the lumen of the intestine more frequently follow dysenteric than typhoid ulcers.

3. Chronic Dysentery.

As was explained at the commencement of this section, it is proposed to include under the designation chronic dysentery* all the chronic fluxes observed during the war, with the exception of those resulting from tubercular ulceration of the intestines. This course is adopted from the purely clinical point of view and as a mere matter of convenience, for it is distinctly recognized that anatomically the chronic fluxes might naturally be divided into two great groups, those resulting from chronic inflammation of the mucous membrane of the bowel with or without ulceration, and those resulting from the large unhealed ulcers left after the separation of diphtheritic sloughs. The fact that a chronic flux remains after the occurrence of all the usual symptoms of acute diphtheritic dysentery would afford just grounds for believing it to belong to the second group; but as the cases of chronic flux usually present themselves in military hospitals in time of war, it is not possible to be so sure of the previous history as to make use of it for diagnostic purposes; and the symptoms of the chronic fluxes resulting from both groups of lesions, as well as the treatment which should be pursued, are so similar that no useful purpose would be subserved by the doubtful attempt to establish clinical distinctions based upon anatomical grounds. The results of any attempt to subdivide these cases into chronic diarrhœa and chronic dysentery, in accordance with the presence or absence of tenesmus, or of mucus, muco-pus, pus or blood in the stools, or any other clinical evidence with which I am acquainted, would not be found to correspond with any anatomical classification. When, after the separation of the diphtheritic sloughs in acute dysentery, a chronic flux remains, tenesmus very often ceases to torment the patient, although it may recur at intervals, and the same happens in chronic fluxes unaccompanied by ulceration of the bowel as well as in those accompanied by ulceration not the result of the diphtheritic process; so too with the other symptoms.

Symptoms.—Whatever the nature of the anatomical lesions from which chronic dysentery results, the local and constitutional symptoms are of the following character: The prominent local symptoms are gripings, flatulence, uneasy or painful sensations in the stomach and bowels, and liquid, variously disordered stools, consisting of the products of digestion, which is impaired by the intestinal disorder, mingled with the morbid discharges from the diseased mucous membrane. The prominent constitutional symptoms result from insufficient nutrition consequent upon the incomplete manner in which the digestive process is performed; steadily progressive debility and emaciation, culminating in extreme marasmus, and often accompanied by a hectic febrile movement, are the more important phenomena.

The disease frequently comes on after one or several attacks of acute diarrhœa, and in such cases might very properly be spoken of as chronic diarrhœa; but usually, after having persisted for several months, if not sooner, muco-pus or pus, with or without blood, makes its appearance in the stools, and if death ensues post mortem examination discloses chronic inflammation of the colon, often accompanied by ulceration, precisely as in those cases which occur after acute catarrhal dysentery. The proportion of cases which commence in diarrhœa and run their course without dysenteric complication cannot be determined from the statistics of the war, but in a very large number, perhaps in the majority, the disease

* In my *Outlines of the chief camp diseases of the United States Armies*, Philadelphia, 1863, p. 252, I applied the designation chronic diarrhœa to this group of cases, out of deference to what was at the time the usage of the majority of our military surgeons, but subsequently, in Circular No. 6, pp. 117 and 123, I gave the preference to the term chronic dysentery used in this work.

either began as acute catarrhal or diphtheritic dysentery, or one of these diseases occurred as an intercurrent affection during its progress. In still another group of cases chronic dysentery remained as a sequel to some form of continued fever.

The *stools* of chronic dysentery vary extremely both in frequency and character. So far as the latter point is concerned they change, on the one hand with the degree to which the digestive processes are impaired, in accordance with which the normal fæces are replaced by a more or less fluid pap that varies in color with the character of the biliary secretion, and is often mixed with wholly undigested fragments of the food, readily recognizable by the naked eye; and on the other hand with the degree to which these products of the digestive process are commingled with discharges from the inflamed or ulcerated intestinal surface, mucus, muco-pus, pus or blood. To these modifying conditions it may be added that variations in color also result from the accidental presence of coloring matters derived from the food, or from certain medicines, concerning which enough has been said in connection with acute diarrhœa.*

Those chronic fluxes in which the stools habitually consist of a semi-fluid pap were described by the ancient physicians under the designation Cœliac affection.† This term was not employed by Hippocrates, and was bestowed by Celsus upon a different disease; by the

---

* Page 274, *supra*.

† The Cœliac affection, κοιλιακὴ διάθεσις or κοιλιακὴ νοῦσος [so called from κοιλία, ventriculus—see ARETÆUS, *Morb. Diut.*, Lib. II, Cap. 7, Boerhaave's Ed., p. 58. Synonyms: morbus cœliacus, fluxus cœliacus, cœliaca, passio cœliaca, affectio cœliaca, passio ventriculosa, alvi fluxus chylosus, diarrhœa chymosa and chylosa, chylorrhœa, fluor albi intestini recti; English—the cœliack passion, chylous flux, chylous looseness, chylous diarrhœa; French—flux céliaque or cœliaque; German—Bauchfluss, weisse Bauchfluss, Milchfluss, Milchruhr, Schleimfluss] is not mentioned in the Hippocratic writings, and the morbus cœliacus described by CELSUS, Lib. IV, Cap. 12, is evidently a very different affection from that to which subsequent writers have given the same name, since it was characterized by obstinate constipation. "In ipsius vero ventriculi porta consistit is, qui et longus esse consuevit; κοιλιακὸς a Græcis nominatur. Sub hoc venter indurescit, dolorque ejus est: alvus nihil reddit, ac ne spiritum quidem transmittit: extremæ partes frigescunt: difficulter spiritus redditur"—Lee's *Celsus*, Vol. I, p. 289. According to ARETÆUS, [*loc. cit.*,] cœliacus is a form of chronic diarrhœa due to deficient digestive power on the part of the stomach, in consequence of which the stools are fluid, whitish, clay-like or mud-like, destitute of bile, offensive and accompanied with flatulence, offensive eructations, rumbling in the bowels, progressive emaciation and dryness of the skin. He remarks that it is a tedious malady and difficult to cure. ARCHIGENES—*De cœliaca affectione* in ÆTIUS, Tetrab. III, Serm. I, Cap. 37, Lyons Ed., 1549, p. 589—used the term in the same sense as ARETÆUS, and emphasized the role of the stomach. According to him, it is not every flux in which the stools are fluid, crude and undigested that deserves the name of cœliac affection, which can be properly employed only when the flux results on account of the inability (imbecillitas) of the stomach to digest the food. GALEN makes occasional mention of the cœliac affection, as, for example, in *Com. V in Epidem. VI*, Sect. 5, § 27, [Ed. Kühn, XVII, B, 291,] and in several places in which he mentions remedies adapted to the treatment of those affected by it. In the *Definitiones Med.*, ascribed to GALEN, the cœliac affection is said to be simply a chronic flux accompanied by emaciation. "Cœliaca affectio est alvi fluxio non recens sed diuturna cum torminibus multis dejectionibus corpore simul marcescente," [Ed. Kühn, XIX, 421.] CÆLIUS AURELIANUS—*Morb. Chron.*, Lib. IV, Cap. 3, Amsterdam Ed., 1709, p. 499—discusses this disease at some length under the designation "ventriculosa passio," which he expressly states is the equivalent of the cœliac affection of the Greeks. It may result, among other causes, from a previous indigestion or dysentery. The stools may be of the most various consistency and color, white, yellow and frothy, green, livid or black, purulent or mixed with blood. Borborygmus and an offensive odor are accompanying symptoms. The patients lose their appetite, or sometimes have excessive appetite, become debilitated, pallid; sometimes there is fever. Their bodies have a bad odor; their feet and hands swell. Dysentery is an occasional and serious complication. The disease is one of solution, yet sometimes it is accompanied by a stricture, (*i. e.*, constipation.) The description, of which the foregoing is an abstract, might have been drawn from the chronic fluxes of the civil war. ALEXANDER of TRALLES—Lib. VIII, Cap. 5, Basel Ed., 1556, p. 413—gives a brief description of the cœliac affection drawn from the writings of PHILUMENUS. It is due to atony of the stomach; the stools are liquid, not well digested, of different colors, sometimes bloody. It is a chronic disease; the body becomes emaciated, is consumed by wakefulness and indigestion; tormina and loss of appetite accompany it. PAULUS ÆGINETA—Lib. III, Cap. 40, Syd. Soc. transl., Vol. I, p. 520—pointed out the great similarity between the cœliac affection and the form of lientery which results from digestive debility, [see note on lientery, *infra*,] and expressed the opinion that the only difference is that in lientery the indigestion is more intense and the passage of the food through the intestines more rapid. In the same sense the two disorders were elaborately described by SENNERTUS—*Pract. Med.*, Lib. III, Pars 2, Sect. 2, Cap. 5, Opera, Paris, 1641, T. III, p. 111—"De Lienteria et Cœliaca affectione." Subsequently, however, prominence was given more and more, in the conception of the cœliac affection, to the whitish character of the stools, which ARETÆUS had insisted upon. SYLVIUS—*Prax. Med.*, Lib. I, 1667, Cap. 13, Opera, Amsterdam, 1679, p. 180—proposed to make two species: In the first, stomach digestion takes place, but intestinal digestion is so imperfect, especially on account of deficiency of bile, that the intestinal contents are not separated into chyle, &c., but voided as a whitish pultaceous mass; such stools are seen in jaundice, whence he proposed to call this species "alvi fluxus ictericius." In the second species chyle is duly separated, but not absorbed by the lacteals, whence he proposed to call this species "alvi fluxus chylosus." DOLÆUS—*Encyc. Med. Dogm.*, Lib. III, Cap. 3, Frankfort, 1703, p. 220, De diarrhœa, lienteria et cœliaca—calls this latter species "diarrhœa chylosa." See also the article Cœliaca Passio in the *Dictionary* of R. JAMES, Vol. II, London, 1745. B. L. TRALLES—*Usus opii salubris et noxius in morb. medela*, &c., Sect. III, Breslau, 1760, Cap. 3, § 20, p. 231—called the first species of SYLVIUS diarrhœa chymosa, the second diarrhœa chylosa. SAUVAGES is certainly wrong in citing the d. chymosa of TRALLES as a synonym of c. chylosa; TRALLES mentions both as two varieties of the cœliac flux, the discharge consisting of chyme in the first case, of chyle in the second. He says: "Lienteriam excipiat fluxus cœliacus, sive diarrhœa chymosa et chylosa. Hæc adest, quando ingesta jam in chymum mutata, aut ipse chylus cum fæcibus ejicitur." SAUVAGES admitted the cœliac affection into his nosology under the designation Cœliaca, although he remarked that its characters are obscure, unless they are taken from the whiteness of the dejections. He made four species: c. chylosa, c. purulenta, c. mucosa and c. lactea, the latter affecting women after delivery—*Nos. Meth.*, 1768, T. II, p. 360. CULLEN, in his nosology, (1769,) abandoned the genus, and made cœliaca merely a species of diarrhœa—Works, THOMSON'S Ed., London, 1827, Vol. I, p. 313. Meanwhile R. A. VOGEL—*Diss. fluxus cœliaci genuina notio et ratio exposita*, Gottingen, 1768; also *Prælect. Acad.*, Gottingen, 1772, p. 225—revived once more the old conception of the cœliac affection which embraced other than white stools, as already mentioned. He rejected the theory of SYLVIUS

other Greek and Roman writers it seems to have been used without regard to the color of the stools, except by Aretæus, who applied it especially to those cases in which they were whitish from deficiency of bile. This latter signification of the term was again brought into general use during the seventeenth century, when Sylvius subdivided these white fluxes into two species, those in which the discharges were more pap-like or pultaceous, and those in which they consisted of a creamy fluid supposed to be composed of chyle. The term chylous diarrhœa [alvi fluxus chylosus] which he proposed for this latter variety was subsequently employed in many quarters as a synonym for the cœliac affection; but after Richter and J. P. Frank had pointed out that the whitish stools called chylous really owed their appearance to the presence of mucus and pus, this term no longer appeared appropriate, and with its discontinuance the older term cœliac affection and its various synonyms have also become obsolete.*

More uniformly since the era of the Hippocratic writings the term Lientery has been bestowed upon those chronic fluxes in which undigested fragments of the food can be recognized in the stools. But since this condition may occur in both diarrhœa and dysentery under the most diverse circumstances, and stands related to the character of the food as well as the degree to which the digestive process is impaired, the term has very properly passed out of use as the designation of a particular species of flux, although the adjective

as to the nature of the disease, and supposed it to arise from a peculiar cachexia caused by obstructions of the mesenteric glands, liver, spleen and pancreas. He altogether denied that the fluid voided could ever be considered as chyle, and regarded it as a mixture of morbid secretions, bile, pancreatic and intestinal juice, &c. This effort to revive the old broader use of the term was, however, unsuccessful. Medical writers continued to limit it more and more to fluxes in which the discharges were whitish, and especially to those in which they were supposed to resemble chyle. These, however, A. G. Richter—*Med. u. Chir. Bemerk.*, Bd. I, Gottingen, 1793, S. 70—explained as consisting merely of mucus, and, comparing such discharges to fluor albus, proposed to call the affection fluor albus intestini recti. See also *Die spec. Ther.* of the same author, Bd. IV, Berlin, 1822, S. 149. John Peter Frank—*De Cur. Hom. Morb. Epit.*, Lib. V, Pars 2, § 683, Milan Ed., 1832, T. III, p. 418—adopted a very similar view, regarding the matter discharged as puriform, comparing it to the sputa of phthisis, and suggesting that the disease might be designated a tabes of the intestinal tube—"tabem puriformem, lutulentam tubi intestinalis constituere putamus." The use of the term cœliac affection and of its various synonyms has gradually been abandoned. In addition to the works referred to above, I may mention the theses of J. G. H. Uhlhoff—*De morb. cœliaco ejusque genuina notione*, Gottingen, 1787, and J. B. Fliess—*De morb. cœliaco*, Halle, 1791, neither of which have I been able to see; and the following works, which may be consulted with advantage: C. F. Meyer—*De affectione cœliaca ex viscerum abdominalium infarctu oriunda*, Frankfort-on-the-Oder, 1794; Renauldin—*Flux céliaque ou cœliaque*, Dict. des Sci. Méd., T. 16, Paris, 1816, p. 46; Andreas Lund—*Von der Milchruhr (Fluxus cœliacus)*, Sammlung auserlesener Abhandlungen zum Gebrauche praktischer Aerzte, Bd. XXI, St. 2, Leipsic, 1804, S. 3; S. G. Vogel—*Von der Milchruhr*, Handb. der pract. Arzneiwiss, Bd. VI, Stendal, 1816, S. 86; C. A. W. Berends—*Der Bauchfluss*, Vorlesungen über pract. Arzneiwiss, Bd. I, Berlin, 1827, S. 134; also *Der weisse Bauchfluss, Milchfluss, Milchruhr*, Bd. VII, 1829, p. 97; J. Mason Good—*Chylous looseness*, Study of Med., 1822, Amer. reprint, Phila., 1825, Vol. I, p. 157; W. Sachse—*Cœliacus fluxus*, in Encycl. Wörterb. der med. Wiss., Bd. VIII, Berlin, 1832, S. 92; M. E. A. Naumann—*Schleimfluss des Mastdarmes*, Handb. der med. Klinik, Bd. IV, Abth. II, Berlin, 1835, S. 170.

* In this connection I may refer to the diarrhœa alba or Hill diarrhœa of certain English writers on the diseases of India, which appears to be very similar to the cœliac affection of Aretæus. Annesley—*Diseases of India*, London, 1828, Vol. II, p. 343—mentions the appellation "white flux," as long employed popularly in India for a form of chronic diarrhœa in which, "owing to obstruction of the biliary secretions," the stools have a whitish color. Craigie—*Elements of the Practice of Physic*, Vol. I, Edinburgh, 1837, p. 914—who makes the hepatic flux a variety of chronic tropical dysentery, states that in certain cases "the stools become of a whitish color, are mixed with portions of half-digested aliment, and are passed with painful straining. In this state the disease is termed by the soldiers the *White flux*." Copland—Art. *Dysentery*, Dict. of Pract. Med., Vol. I, London, 1858, p. 708—adopts the description of the white flux given by Annesley. This white flux, so far as I know, was first connected with the Hill regions by Alexander Grant—*Remarks on Hill diarrhœa and dysentery*, Indian Annals of Med. Sci., Vol. I, 1853-4, p. 311—who wrote: "The Hill endemic may be well designated as a diarrhœa alba," and remarks: "I prefer this term to chylous or milky, or that used by Dr. Good, gypseous or chalky. All depend upon deficiency and vitiation of the secretions from the liver," (p. 320.) He believed that the causes of this condition were "partly malarious partly scorbutic," (p. 317.) W. A. Green—*A short account of Hill diarrhœa and dysentery*, same Volume, p. 517—writes: "The disease has been called scorbutic dysentery, and the general character of the symptoms and the post-mortem appearances bear out the designation." "The first complaint heard of is generally of white purging and abdominal distention and great loss of strength and listlessness. In many of these cases inquiry has shown that there had previously existed a state of soreness of the mouth and gums, and looseness of the teeth, and perhaps purple blotches upon the extremities; or these scorbutic symptoms may have appeared soon after the diarrhœa or dysentery. Here is an index of the condition of the system," &c. This paper is accompanied by the details of a number of autopsies, from which it would appear that the most common anatomical lesion was chronic intestinal catarrh, with or without follicular or other ulcers of the colon. W. J. Moore—*Hill diarrhœa or diarrhœa alba*, Trans. of the Med. and Phys. Soc. of Bombay, No. IX, N. S., 1869, p. 109—combats the opinion that this disease is of malarial origin, and shows that it is not peculiar to the Hill districts of India. He attributes the absence of bile from the stools to deficient secretion, and regards the fact that jaundice does not coexist as favoring the opinion that the biliary coloring matter is formed in the liver rather than preformed in the blood. According to Smart—*The diseases of Hong Kong and the Canton river station*, Lancet, August, 1861, p. 114—a very similar form of flux was observed at the Royal Naval Hospital, Hong Kong, where it was sometimes designated "diarrhœa acholyca," on account of the yeasty or pipe-clay stools. Compare the interesting remarks of Sir J. Fayrer—*Chronic diarrhœa of India and the Tropics*, The Lancet, September 16, 1876, p. 389: "It is known as 'diarrhœa alba,' or white flux—so called from the grey, whitish, light or clay-coloured evacuations, which are frequent, copious, fluid or semi-fluid, often frothy, and occasionally lienteric, especially after any indiscretion in diet; or mixed with mucus tinged with blood, when any fresh source of enteric irritation or congestion may have been induced." When death occurs at an early period, "the intestines are found contracted, but with the mucous lining thickened and congested, even ulcerated." After protracted disease "the coats of the bowel are found to be attenuated and diaphanous, the seat of amyloid degeneration, frequently ulcerated in both ileum and colon," &c. Cases corresponding to this description were common enough during our civil war.

lienteric is still occasionally applied to stools containing undigested fragments of food which can be recognized by the naked eye.* In the chronic fluxes of the civil war the stools very frequently presented the lienteric character. The note of Acting Assistant Surgeon Mercer, in Section 2 of this chapter,† gives an excellent idea of the conditions which some of these cases presented. Whenever the troops were fed chiefly upon hard bread, which was often enough the case, especially in the field, fragments of the biscuit became so common, in the stools of those whose bowels were loose, that the circumstance became a frequent topic of jocular remark. The feculent matters with which these undigested fragments were mingled were often whitish, clay-colored or mud-like, sometimes pale-yellow, yellow, greenish-yellow or greenish-brown, these colors being to a great extent dependent upon the quantity and character of the biliary admixture; it should be added that whitish clay-colored stools frequently existed without any trace of jaundice.

The presence of blood in the stools gave them a pinkish, reddish, dark-brown or black color, in accordance with the quantity of blood admixed and the degree to which it was modified by the presence of the intestinal gases. Occasionally pure blood was passed in considerable quantities.‡ Further modifications were produced by the admixture of mucus and pus; the first appeared in the form of stringy, glairy masses resembling the white of eggs, the latter as a creamy fluid. Both were, as a rule, intimately mixed with the liquid feculent matters, but not infrequently stools composed almost entirely of muco-pus or pus,

* Lientery, λειεντερία [from λεῖος, smooth, slippery, and ἔντερον, intestine. Synonyms: Lævitas intestinorum, Magenruhr] is a term which frequently occurs in the Hippocratic writings as an appellation of those chronic fluxes in which undigested food can be recognized in the stools. Note, for example, in the treatise on *Affections*, § 24, [Ed. Littré, VI, 237,] "Lientery: The food is voided without being digested, the stools are liquid; there is no pain, but the body emaciates." See also *Prorrhetics*, Lib. II, § 23, [Ed. Littré, IX, 53;] and *Regimen*, Lib. III, § 79, [Ed. Littré, VI, 625,] "The food passes moist and undigested, as in lientery, without causing any suffering;" also the same, § 80, [Ed. Littré, VI, 627.] Acid eructations in lientery were regarded as a favorable sign, *Aphorisms*, VI, 1, [Ed. Littré, IV, 563.] Diarrhœa is followed by dysentery, and dysentery by lientery, *Aphorisms*, VII, 76, 77, [Ed. Littré, IV, 605.] HIPPOCRATES clearly did not regard all chronic fluxes as lientery, for in *Aphorisms*, III, 30, [Ed. Littré, IV, 501,] he separately mentions chronic diarrhœas [διάῤῥοιαι χρόνιαι] and lienterics [λειεντερίαι] among the diseases of middle life. See also the statement of the Hippocratic conception of lientery by GALEN, *Com. in Aph.*, Sect. VI, § 1, [Ed. Kühn, XVIII, A, 9.] CELSUS—Lib. IV, Cap. 16—under the designation *Lævitas intestinorum*, describes the very same condition: "Ex torminibus interdum intestinorum lævitas oritur; qua continere nihil possunt, et quidquid assumptum est, imperfectum protinus reddunt." ARETÆUS—*Morb. Diut.*, Lib. II, Cap. 10, [Boerhaave's Ed., p. 62]—attributed lientery to cicatrices in the intestine left after dysentery. The food is passed undigested, and atrophy, pallor and atony seize upon the patient. But sometimes also the disease exists when there are no cicatrices in the intestine, having been established merely by habit and a tendency to diarrhœa, the result of impaired digestion. GALEN used the word lientery quite in the Hippocratic sense. See, besides the passage cited above, *Com. II in Epidem. I*, § 36, [Ed. Kühn, XVII, A, 132,] and other places. In the *Def. Med.*, § 271, [Ed. Kühn, XIX, 422,] the idea of intestinal cicatrices left after the ulcers of dysentery is introduced. So, also, in another Galenical treatise of doubtful origin, *Introductio seu Medicus*, Cap. 13, [Ed. Kühn, XIV, 754:] "Ex dysenteria intestinorum lævitas oritur, ubi ex magna ulceratione multæ cicatrices intestinis oboriuntur, propter quas cibum non retinent: unde ex intestinorum lævitate vocata est leienteria." There is, however, another variety due merely to intestinal debility, [ex intestini imbecillitate,] which, like the former, is a grave disease and not easily cured, *(loc. cit.)* This two-fold conception of lientery is clearly recognized by ÆTIUS—Tetrab. III, Serm. I, Cap. 51, Lyons Ed., 1549, p. 618—and by PAULUS ÆGINETA—Lib. III, Sect. 40, Syd. Soc. transl., Vol. I, p. 520. In subsequent times the word retained essentially the same meaning, and it was introduced in the old sense into the nosology of SAUVAGES—*Nos. Meth.*, Amsterdam, 1768, Tom. II, p. 361—but with the remark that it seems rather a species of diarrhœa and not a distinct genus. Nevertheless SAUVAGES recognized five species of lientery, viz: 1. ex ulcere ventriculi, 1. spontanea, 1. scorbutica, 1. aphthosa and 1. secundaria. CULLEN put into practice the hint of SAUVAGES, and in his nosology makes lientery simply a species of diarrhœa—CULLEN'S Works, Thomson's Ed., London, 1827, Vol. I, p. 313. Consult also, on the subject of lientery, the following works: F. C. LIEBEROTH—*Casum de lienteria in puero observata et curata sistens*, Halle, 1750; C. H. FICK—*De lienteria*, Jena, 1794; MONFALCON—Art. *Lienterie*, Dict. des Sci. Méd., Tom. 28, Paris, 1818, p. 170; S. G. VOGEL—*Handb. der pract. Arzneiwiss*, Bd. VI, Stendal, 1816, S. 75: FRIEDREICH—*Ueber die Lienterie*, Würzburg, 1824, in which much of the literature is referred to; C. A. W. BERENDS—*Vorlesungen über prakt. Arzneiwiss*, Bd. I, Berlin, 1827, S. 131, and Bd. VIII, 1829, S. 427. The last two authors use Magenruhr as the German synonym. Both lientery and the cœliac flux, the latter under the well known designation chylous diarrhœa, reappear once more in the classification of L. M. ANDRIEU—*De la diarrhée*, Paris Thesis No. 188, 1868—which is, with a trifling modification, that taught in the lectures of Professor GERMAIN SÉE, of the Faculty of Medicine of Paris. This gentleman "has divided diarrhœa, in accordance with the chemical characters of the dejecta, into four species: mucous, serous, albuminous, and alimentary diarrhœa;" to these ANDRIEU adds bilious diarrhœa, explaining that the several ingredients are usually commingled, and that the name is given in accordance with the one that predominates. 1, Of mucous diarrhœa there are three varieties: A, from reflex action; B, from direct irritation; C, from inflammation. 2, Of serous diarrhœa there are three varieties: A, from general disturbance of innervation; B, from epidemic infection; C, by metastasis. 3, Albuminous diarrhœa also has three varieties, based on the source of the albumen: A, from the presence of blood; or B, of pus; C, from transudation of the blood serum, (plasma.) 4, Alimentary diarrhœa is divided into two varieties: A, lientery; B, chylous diarrhœa. 5, Bilious diarrhœa is not subdivided. I have elsewhere stated the objections to any classification based like this upon the ingredients of the stools, (p. 274, *supra*,) to which it is unnecessary here to add further comment.

† *Supra*, p. 62.

‡ Thus, Assistant Surgeon GEORGE WINCH, 29th Wisconsin volunteers—*Camp diarrhœa, near Vicksburg*, The Chicago Med. Journ., Vol. XX, 1863, p. 346—in describing chronic diarrhœas observed in General Grant's army before Vicksburg, writes, June 22, 1863: "There have been a number of cases within the last few days with hæmorrhage from the bowels, without much pain. The stools are large and frequent, it soon brings on lassitude and debility, unless checked, in which I have found no difficulty. But I am informed in another brigade, near by, many such cases prove fatal." He lauds the effects of opium, combined with acetate of lead, tannin or alum, especially the latter, in the treatment of these cases.

variously admixed with blood and containing little or no feculent matter, alternated with stools composed chiefly of the latter ingredient. Sometimes, especially when hard bread formed a considerable portion of the diet, the stools appeared to be in a condition of actual fermentation. They were passed frothy and full of bubbles of gas, which continued to be developed and escape for some time after the matter was discharged. As the disease advanced the stools often acquired a more putrescent character, becoming dark-colored and exceedingly offensive.

On microscopic examination the degree of purulent admixture in the stools is readily determined by the proportion of pus corpuscles, which are almost always present in these chronic cases in smaller or larger numbers. The mucous corpuscles, so-called, have the same characters,* but are readily distinguished by the physical properties of the mucous masses in which they are entangled. The presence of blood is always recognizable by the more or less altered blood corpuscles, which can often be detected by the microscope, when an admixture of blood would not have been suspected from the appearances observed with the naked eye. The minute spherical and rod-like bacteria and other low vegetable forms, already described as occurring in the healthy stools as well as in the discharges of acute diarrhœa and dysentery,† are present of course in countless numbers in the stools of patients suffering under chronic fluxes.

To what has already been said on the subject I will here only add a few words with regard to the occurrence of the characteristic fungi of fermentation in the lienteric stools, especially of those patients in whose diet hard bread forms a prominent ingredient. Of these the common yeast fungus is the usual form; it makes its appearance whenever the digestive process is so far impaired that the grape sugar, formed at the expense of the amyloid matters of the food, goes over into acetic acid fermentation. This condition, as is well known, sometimes occurs in the stomachs of dyspeptic patients, giving rise to the so-called yeasty vomiting. In such cases occurring in chlorotic girls, Frerichs not only demonstrated the presence of acetic acid in the vomited matters and showed that the escaping bubbles consisted of carbonic acid gas, but detected the presence of the yeast fungus in enormous quantities.‡ Now the very same condition often occurs in the stools when intestinal digestion is gravely impaired, as so frequently happens in chronic fluxes. The stools are in a true state of fermentation, and the epithet yeasty may be as properly applied to them as to the vomited matters in which a similar condition exists. Frerichs has also shown that in certain conditions of impaired digestion lactic acid fermentation attacks the starchy ingredients of the food, forming at their expense a tough mucous-like mass with the simultaneous development of lactic and butyric acid. He observed this process in the vomited matters of certain dyspeptics. It can also sometimes be recognized in the stools of patients laboring under the chronic fluxes in which the lactic acid fungus then appears, often in considerable quantities.

The question of the occurrence in the intestinal contents and discharges from the bowel of animal parasites supposed to cause the disease has been so fully treated in connection with the subject of acute dysentery that nothing further need be said in this place.

---

* See p. 355, *supra*.

† *Supra*, pp. 273 and 367.

‡ F. Th. Frerichs—*Verdauung* in Wagner's Handwörterbuch der Physiol., Bd. III, Abth. 1, Braunschweig, 1846, S. 804—"Die enorme Quantität der Hefepilze, die Entwicklung der Kohlensäure spricht dafür, dass in solchen Fällen wahre Gährung stattfindet, welche mit der Bildung von Essigsäure ihr Ziel erreicht."

The stools vary in number from two or three to fifteen, twenty or more, in the twenty-four hours. The smaller numbers are most common, but are apt to alternate with periods of greater frequency. Periods of constipation also occasionally occur, especially in the early stages; this sometimes happens spontaneously, sometimes results from the injudicious use of astringent medicines; in either case it is usually followed by a renewal of all the symptoms with increased severity. Sometimes the stools are quite painless; more frequently they are accompanied with a certain amount of colicky pain, and sometimes with a good deal of tenesmus. The latter symptom is very variable, and bears no relation to the extent to which intestinal ulceration exists.

Ructus and flatus.—Belchings of gas, rumbling in the bowels and the escape of flatus per anum, with or without concomitant sound, are annoying symptoms which very often accompany the loose discharges in the chronic fluxes or vex the patient at intervals between the stools; not unfrequently also a sense of oppression or of uncomfortable abdominal distension results from the accumulation of gas in the stomach and bowels. These symptoms occur also in acute dysentery, as has already been mentioned, but do not usually attain the degree of prominence which is common in the chronic cases. Notwithstanding the numerous works devoted wholly or partly to the consideration of flatus in health or disease, I am not acquainted with any analyses of the flatus of dysenteric subjects. Its nature and origin can, however, be approximately understood if we bear in mind the composition of the gases found in the normal alimentary canal and the sources from which they are derived.

The earliest attempt at the analysis of these gases appears to have been made by Van Helmont,* who observed that the gas which rises from the stomach during eructations extinguishes the flame of a candle, while that which escapes per anum takes fire if a candle be held to it; observations which are substantially correct and which modern chemistry explains. Additional observations were published in the latter part of the last century by Jurine of Geneva,† and at the beginning of this by Lameyran and Frémy and by Vauquelin.‡ But our present notions are based chiefly upon the analyses of the gases found in the alimentary canal of executed criminals by Magendie and Chevreul,§ and the recent investigations

* VAN HELMONT—*De Flatibus*, § 48 and 49, Ortus Medicinæ, Amsterdam, 1648, p. 421—"Quod ructus, sive flatus originalis in stomacho, prout et flatus Ilei, extinguant flammam candelæ. Stercoreus autem flatus, qui in ultimis formatur intestinis, atque per anum erumpit, transmissus per flammam candelæ. transvolando accenditur, ac flammam diversicolorem, Iridis instar exprimit. Qui verò in Ileo, sive intestinis gracilibus formatur, nunquam est inflammabilis, sæpe inodorus est, nisi alterius misturam secum deferat, non rarò acer, acutus, pontiensque lancinat in ano." See also the English translation of this work under the title Oriatrike or Physick Refined, London, 1662, p. 424, *Of Flatus's or Windy Blasts in the Body.* According to J. P. FRANK—*De Curand. Hom. Morb. Epitome*, Ed. nov., Milan, 1832, T. IV, p. 44—the observations of VAN HELMONT have long been confirmed, in part at least, by certain boyish pranks: "Puerorum petulantia, diu ante chemicorum recentiorum circa indolem hydrogenii, in crassis intestinis contenti, experimenta, tensis circa nates feminalibus, flatus ano explosos inflammabilis naturæ esse, admoto lumine, docuerat." Whether this experiment is known to the boys of the present day may be left for the reader to decide.

† JURINE'S essay—*Déterminer quels avantages la Médecine peut retirer des découvertes modernes sur l'art de connoître la pureté de l'air par les différens Eudiomètres*, Mém. de la Soc. de Méd., T. X, 1789, p. 19—which was crowned by the Society of Medicine of Paris, contained (p. 77) the analysis of the intestinal gases of a lunatic found dead of cold, and examined immediately after, which he compared with the flatus escaping per anum from a healthy subject, collected while in the bath.

‡ LAMEYRAN et FRÉMY—*L'analyse des gaz formés dans l'estomac des herbivores par la maladie connue sous le nom de météorisation*, Bull. de Pharmacie, T. I, Paris, 1809, p. 358—analyzed the gas obtained by puncturing the abdomen of a tympanitic cow, and VAUQUELIN—see p. 3 of the thesis of CHEVILLOT, cited *infra*—the gas found in the abdomen of an elephant which died at the Jardin du Roi in 1817.

§ MAGENDIE—*Note sur les gaz intestinaux de l'homme sain*, Annales de Chimie et de Physique, T. II, 1816, p. 292. Three subjects were examined, in only one of which the stomach contained enough gas for examination. The general results were that the stomach contained oxygen and nitrogen, carbonic acid and hydrogen. The oxygen existed in smaller proportion to the nitrogen than in atmospheric air; it disappeared in the small intestine, and was not found in the large. On the other hand, the carbonic acid was more abundant in the small intestine than in the stomach, and still more abundant in the large intestine. The hydrogen was much more abundant in the small intestine than in the stomach, but existed in greatly diminished quantity or was altogether absent in the large intestine. The nitrogen existed in diminished quantity in the small intestine, but was more abundant in the large. Carburetted hydrogen and traces of sulphuretted hydrogen were present in the large intestine only. The gas in the stomach he regarded as chiefly composed of atmospheric air swallowed with the food, the intestinal gases as chiefly derived from the fermentation of the intestinal contents. The analyses on which these conclusions are based were made with the assistance of CHEVREUL—*Op. cit.*, p. 293. See, also, F. MAGENDIE—*Précis Élémentaire de Physiologie*, 4me Édit., Paris, 1836, T. II, p. 88 *et seq.*

of Planer and Ruge.* From these investigations it would appear that more or less atmospheric air is constantly carried into the stomach with the ingesta,† where its oxygen is absorbed and replaced by carbonic acid derived from the blood in the proportion, according to Planer, of two volumes of the latter to one of the former. No gas is formed in the stomach during normal digestion. The gases from the stomach are carried by the peristaltic motion into the small intestine, where the remaining oxygen is speedily replaced by carbonic acid in the same way as in the stomach, and where also an additional quantity of carbonic acid and

* PLANER—*Die Gase des Verdauungsschlauches und ihre Beziehungen zum Blute*, Sitzungsberichte der math.-naturwiss. Classe der k. Akad. der Wiss., Bd. 42, Vienna, 1861, S. 307. Abstracts of this important paper will be found in the *Zeitschr. für Rat. Med.*, Bd. XIII, 1862, S. 274, and in the Oest. Zeitschr. für Prakt. Heilkunde, Jahrg. VII, 1861, S. 408. The investigations were made chiefly on dogs killed for the purpose, but he also analyzed the gases of the intestinal canal of three human subjects dead of disease. Two died of lung tuberculosis associated with intestinal catarrh; the third had an old stricture of the sigmoid flexure with dilatation of the colon and part of the small intestine. He found no carburetted hydrogen in the alimentary canals of dogs, and only in one of the human subjects, viz: that in which the stricture of the large intestine existed. In this case he attributed its presence to fermentations favored by the long retention of the food in the intestinal canal. In the two human stomachs examined he found an excess of carbonic acid and a quantity of hydrogen, both of which he suggests (S. 339) may possibly have been formed after death. The following are the results of PLANER'S analyses of the gases of the alimentary canal in these three human subjects:

	Stomach.			Small intestine.			Large intestine.		
	CO_2	H	N	CO_2	H	N	CO_2	N	C_2H_4
1st human subject	20.79	6.71	72.50	16.23	4.04	79.73	30.64	69.36	.....
2d human subject	33.83	47.58	38.22	.....	.....	.....	34.80	65.20	.....
3d human subject	.....	.....	.....	32.27	35.55	31.63	34.19	50.20	12.88

E. RUGE—*Beiträge zur Kenntniss der Darmgase*, Sitzungsberichte der math.-naturwiss. Classe der k. Akad. der Wiss., Bd. 44, Abth. 2, Vienna, 1862, S. 739—examined the gas which escaped per anum in healthy individuals with the following results in seven trials:

	Person A.				Person B.		Person C.
	I.	II.	III.	IV.	V.	VI.	VII.
Carbonic acid	14.94	40.51	21.86	12.77	21.59	54.12	11.87
Nitrogen	45.31	17.50	44.42	43.10	41.82	22.45	40.69
Light carburetted hydrogen	39.75	19.77	32.93	44.13	17.52	8.67	47.44
Hydrogen	.....	22.22	0.79	.....	19.07	14.76	.....

Oxygen, heavy carburetted hydrogen and ammonia were not found in any case, and only traces of sulphuretted hydrogen, even when the flatus smelled badly. In an individual who had taken eight grammes of milk of sulphur during the day, and whose flatus smelled strongly, the quantity of sulphuretted hydrogen was determined by Bunsen's method, and found to amount to but 6 parts in 100,000. The person A in the above experiments gave the following results when fed upon special diets:

	Milk diet.		Vegetable diet.					Flesh diet.		
			1st series.			2d series.				
	After 48 hours.	After 72 hours.	After 48 hours.	After 72 hours.	After 96 hours.	After 48 hours.	After 72 hours.	After 24 hours.	After 48 hours.	After 72 hours.

Hydrogen	43.88	54.23	2.34	1.57	4.03	.....	.....	3.01	2.09	0.69

RUGE collected the flatus of living dogs in the same way and found therein no light carburetted hydrogen, the results agreeing with the observations of PLANER on this animal.

† This was known even in the Hippocratic era. See the treatise *De Flatibus*, [Περὶ Φυσῶν, Ed. Littré, VI, 101]—"When the body fills itself with food, it fills itself also with air." In modern times this fact has been particularly insisted upon by LITTRÉ—*Sur l'hydropisie tympanite*, Hist. de l'Acad. Royale des Sci., Année, 1713, Paris, 1739, p. 19. HALLER—*Elementa Phys. Corp. Humani*, T. VI, Lausanne, 1777, p. 296—remarked: "Sed omnino ære per os inter deglutiendum recepto, uti aquam, qui submerguntur, deglutiunt." See also MAGENDIE—*Mém. sur la déglutition de l'air atmosphérique*, Mém. de la Soc. Méd. d'Émulation, 8me Année, 1me Partie, 1817, p. 103; and BRESLAU—*Über Entstehung und Bedeutung der Darmgase beim neugeborenen Kinde*, Monatsschrift für Geburtskunde, Bd. 25, 1865, S. 238, and Bd. 28, 1866, S. 1. According to this author the alimentary canals of infants who have never breathed contain no gas. With the first respiratory movements, however, movements of swallowing begin. Even before the child begins to take nourishment the air is thus introduced as far as the colon in about twelve hours after the first efforts at swallowing.

an equal volume of hydrogen are set free as products of the chemical changes of digestion. In the contents of the large intestine this process is replaced by a modified form of fermentation of which carbonic acid is the most constant product, although under certain circumstances hydrogen and light carburetted hydrogen are also generated in considerable quantity, and traces of sulphuretted hydrogen often make their appearance, especially in individuals who make use of animal food.

The gases which escape per anum in the healthy condition of the human subject have been analyzed by Marchand and Ruge* and shown to consist of carbonic acid, nitrogen, light carburetted hydrogen and hydrogen, in proportions which, according to the latter observer, vary with the diet. Hydrogen is the most abundant ingredient during the use of milk diet, light carburetted hydrogen during vegetable diet, and nitrogen during flesh diet; ammonia was not found by Ruge in any case, and only traces of sulphuretted hydrogen. That variations of diet are accompanied by variations in the quantity of the flatus is an old observation which dates back to the Hippocratic era.†

The precise nature of the fermentations by which gases are developed in the intestines during healthy digestion still demands further investigation. Frerichs‡ suggested that in the digestion of the starches their transformation into sugar was followed by the conversion of a part of the latter into lactic acid, some of which broke up into butyric acid and equal volumes of carbonic acid and hydrogen, while the production of carbonic acid in the large intestine is probably due to acetic fermentation. But Planer§ searched in vain for butyric or acetic acid in the intestinal contents, or in the products of their decomposition out of the body in closed vessels. Gerardin and Magendie|| found that an empty knuckle of intestine, included between two ligatures and returned to the abdominal cavity, became after some hours distended with gas; which would seem to show that the gases of the blood may transude into the intestinal cavity independently of any interchange with gases already present. This result was confirmed by Frerichs,¶ and the negative observations of Planer** are not

* MARCHAND—*Jour. für Prakt. Chemie*, Bd. XLIV, S. 10; I cite from Wagner's Handwörterb. der Physiol., Bd. III, Braunschweig, 1846, S. 869—made two analyses with the following results:

	CO_2	N	H	C_2H_4	SH
1st analysis	44.5	14.0	25.8	15.5	1.00
2d analysis	36.5	29.0	13.5	22.0	.....

See note *, p. 489, *supra*, for the analyses of RUGE.

† Thus HIPPOCRATES—*De Victus Ratione in Morb. Acut.*, [Ed. Littré, II, p. 483 *et seq.*]—attributed the quality of inducing flatulence to garlic, cheese, pulse, goats' flesh, &c. See also CELSUS—Lib. II, Cap. 26, [Lee's transl., Vol. I, p. 136,]—De his, quæ inflant.

‡ FRERICHS, p. 865 of work cited, note ‖ p. 375, *supra*, gives the following formula for this supposed reaction:

$$C_{12}H_{12}O_{12} = 2\,(C_6H_5O_5) + 2\,HO = C_8H_8O_4 + 4\,(CO_2) + 4\,H.$$

§ *Op. cit.*

‖ GERARDIN—*Rech. phys. sur les gaz intestinaux*, Paris Thesis, No. 15, 1814. According to this writer (p. 24) SCHUYLIUS performed this experiment on the duodenum, and regarded the development of gas in the included knuckle as a confirmation of the opinion of SYLVIUS that the intestinal gas is produced by an effervescence between the bile and the pancreatic juice. COMBALUSIER, however, pointed out that the experiment would succeed equally in any part of the intestine, and the same results were obtained by BELG and GLISSON. In the experiments performed by GERARDIN with the coöperation of MAGENDIE, after tying the first ligature, the intestinal contents were gently pressed downwards by the fingers before applying the second, and, the intestine having been returned, the animal was left to itself from four to nineteen hours. In one instance the animal was killed and the loop examined two hours after the operation, but no gas was found. GERARDIN cited the tympanitic distension of the intestine in certain cases of strangulated hernia as a parallel case, and regarded this exhalation of intestinal gas as "une véritable fonction vitale." The same doctrine had been maintained by H. B. GASPARD—*Diss. phys. sur la gazéification vitale*, Paris Thesis, No. 79, 1812. The arguments in favor of it have been well summed up by PIORRY—Art. *Pneumatose*, Dict. des Sci. Méd., T. XLIII, Paris, 1820, p. 342.

¶ FRERICHS, *loc. cit.*

** PLANER—p. 345, *op. cit.* on p. 489—was not satisfied with pressing out the intestinal contents, but washed out the loop included between the ligatures, lest the fermentation of any remainder might generate gases. None were formed; but the value of this negative result is diminished by the fact that he only waited two hours before he killed the animal and examined the ligated part. This result was precisely what GERARDIN found under the same circumstances. In other experiments PLANER filled the intestinal loop with atmospheric air and hydrogen. After an hour and a half he found in the first case a part of the oxygen replaced by an equal volume of carbonic acid; in the second, a part of the hydrogen replaced by carbonic acid in the proportion of four volumes of the former to one of the latter.

sufficient to prove that this process may not occur to a limited extent. The chief source of the intestinal gases in health is, however, undoubtedly to be sought in the chemical processes going on in the intestinal contents during the progress of digestion, and in the modifications which these processes undergo in disease we must seek the origin of the more abundant and offensive gases which are developed in the course of the various diseased conditions of the alimentary canal.

Numerous works were formerly devoted to the discussion of this subject,* but since chemistry has been sufficiently advanced to permit exact investigations, comparatively few have been undertaken. Since the publication of the observations of Chevillot,† indeed, I know no attempt at a systematic examination of the intestinal gases in disease. The precise nature of the changes in composition which the intestinal gases undergo in chronic dysentery therefore remains a matter of uncertainty. It is probable enough that a considerable increase takes place in the amount of carbonic acid gas eliminated during the digestion of the starches both in the stomach and in the intestines. The copious tasteless or acid eructations‡ sometimes complained of are probably of this nature, and the same gas is undoubtedly present in large quantities in the flatus which escapes per anum in lienteric cases fed largely on amylaceous diet. But the extremely offensive eructations and flatus, which are common enough in these cases, as Cælius Aurelianus§ long ago observed, suggests other chemical processes of a more putrefactive character, and as to the nature of these nothing definite is known.

Tympanitic distension of the abdomen often occurs in the course of chronic fluxes, especially during occasional intervals of constipation and a short period before the fatal issue. This distension is produced for the most part by accumulations of flatus in the large intestine, sometimes also in the small, or in both, determined by diminished power or actual paralysis of the muscular coat of the bowel, which, hence, fails to expel the flatus; by spasmodic contraction of the circular muscular coat at some point above which the accumulation takes place, or by obstruction resulting from other causes.

---

P. BAUMÉS—*Lettres sur les causes et les effets de la présence des gaz ou vents dans les voies gastriques*, Paris, 1832. BAMBERGER—*Gasansammlung*, in Virchow's Handb. der Spec. Path. u. Ther., Bd. VI, Abth. 1, Erlangen, 1855, S. 235. COPLAND—Art. *Flatulency*, in Dict. of Pract. Med., Vol. I, London, 1858, p. 1043.

† CHEVILLOT—*Recherches sur les gaz de l'estomac et des intestins de l'homme a l'état de maladie*, Paris Thesis, No. 194, 1833—analyzed the intestinal gases of a number of subjects dead of various diseases. Unfortunately the peculiar manner in which the results are grouped impairs their usefulness, no single complete analysis being given in the essay. Moreover, the gas was seldom collected till some hours after death, often as late as twenty-four hours. A good abstract of this paper will be found in the Archives Gén. de Méd., T. V, 1834, p. 285.

‡ According to HIPPOCRATES, acid eructations in chronic lientery are a favorable sign if the patient has not previously been subject to them. *Aphorisms*, VI, 1, [Ed. Littré, IV, p. 563.]

§ *Loc. cit.*, p. 484, *supra*. During the recent French occupation of Mexico this symptom arrested the attention of PONCET—*Des maladies qui ont régné dans le corps expéditionnaire du Mexique*, Recueil de Mem. de Med. Chir. et Pharm. Militaires, T. IX, 1863, p. 218—who has emphasized the occurrence of eructations, often smelling of sulphuretted hydrogen, in the course of the camp diarrhœas at Orizaba.

The older physicians believed also that in tympanites* the accumulation of gas often occupied the peritoneal sac. This undoubtedly happens in cases of perforation of the intestine, the flatus being readily expelled through the opening by the intestinal contractions. Under such circumstances I have several times observed considerable accumulations of gas in the peritoneal cavities of subjects dead of dysentery and dissected very soon after death. Accumulations of gas in the peritoneal sac may also frequently be observed when dissection is postponed long enough after death for the putrefactive processes to commence before the abdomen is opened. Perhaps under these circumstances, besides the development of gas during the putrefactive process, the intestinal gases already present may be diffused through the thin intestinal walls into the peritoneal sac. Perhaps, also, under certain conditions gas may be developed during life in the peritoneal sac, as the ancients believed, independently of intestinal perforation or the introduction of gas from without in any other manner. I have never myself seen an example of this accident, which, however, according to Rokitansky and Bamberger,† is occasionally observed, the gas being disengaged from ichorous purulent fluids in certain cases of peritonitis.

Abdominal tenderness.—An examination of the abdomen will very often detect more or less tenderness on pressure along the course of the colon. This is sometimes greatest on the right side over the cæcum, sometimes on the left over the descending colon; sometimes, however, it follows the whole line of the colon; in other cases there is general abdominal tenderness. These symptoms are not unfrequently an indication of the existence of local or general peritonitis, as will be shown further on.

Disordered digestion.—The disturbed condition of the digestive functions is betrayed by various other symptoms besides those already mentioned.

The *appetite* is almost always disordered: sometimes it is diminished, in extreme cases a positive loathing of food existing; sometimes it is abnormally increased; in other cases it is capricious, the patient craving some particular article of food only. Very often, although he loaths camp diet, he can be tempted to eat by dainties or indeed by ordinary food if well cooked. In those cases in which a scorbutic taint exists a craving for fresh

* Tympanites was spoken of in the Hippocratic writings as dry dropsy, [ὑδρωψ ξηρός,] *Aphorisms*, IV, 11, [Ed. Littré, IV, 505,] and *Prenotions of Cos*, § 298, [*Id.*, V, 651.] Two kinds of dropsy are recognized in these writings—the one consisting in accumulations of fluid, [ὕδρωψ ὑποσαρκίδιος, anasarca,] the other in accumulations of gas, [ἐμφύσημα, emphysema.] See *De Victus Rat. in Morb. Acut.*, Appendix, § 20, [*Id.*, II, 497.] In his commentary on this latter passage GALEN calls the second variety tympania, [τυμπανίας,] *Com. IV in Lib. de Acut. Morb. Vict.*, § 93, [Ed. Kühn, XV, p. 891.] On the diagnosis between these two species see GALEN—*De Dignoscendis Pulsibus*, Lib. IV, Cap. 3, [*Id.*, VIII, 951,]—who especially insists upon the drum-like sound evoked by percussion, whence the second variety derives its name. The flatus might accumulate not merely in the alimentary canal but also between the coats of the intestines—*Meth. Medendi*, Lib. XII, Cap. 8, [*Id.*, X, 863,] or in the peritoneal cavity itself—*Meth. Medendi*, Lib. XIV, Cap. 7, [*Id.*, 963.] Compare SENNERTUS—*De tympanite*, Pract. Med., Lib. III, Pars 6, Sect. 2, Cap. 4, Opera, Paris, 1641, T. III, p. 339—by whom the older views are pretty fully discussed. This conception of the subject survived till near the close of the last century. We find it in the nosology of SAUVAGES—*Nos. Meth.*, Amsterdam, 1768, T. II, p. 513 *et seq.*—who classes "tympanites" as a genus of the order Partial dropsies. The species are: 1, t. intestinalis; 2, t. abdominalis; 3, t. enterophysodes. [emphysema of the intestines or abdominal viscera;] 4, t. asciticus; 5, t. spasmodicus; 6, t. Stwartii, [an acute form supervening on rupture of the gall-bladder;] 7, t. verminosus. According to SAUVAGES, meteorismus, which he made a separate genus of the same order, differs from tympanites in its fugitive nature, in the circumstance that it accompanies acute diseases, or in affecting only a part of the abdomen. The species are: 1, m. ventriculi; 2, m. abdominis; 3, m. hystericus; and 4, m. à manzanillâ, [a result of poisoning by the manchineel tree.] The word Meteorismus is derived from the Greek μετέωρος, [elevated, raised,] concerning whose use by HIPPOCRATES and GALEN, as applied to superficial pains, swellings, etc., see the article μετέωρον in the dictionary of GORRÆUS—*Def. Med.*, Paris, 1622, p. 398. I find the word meteorismus used in nearly the same sense as by SAUVAGES in the *Pneumato-Pathologia* of COMBALUSIER, Paris, 1747, p. 7: "Si a collectis flatibus ventriculus et intestina derepente ita turgeant, ut exinde præter modum, ac præsertim hypochondria versus, intumescat, et quasi in sublime tendat abdomen; hæc acuta, nec ultra limites morborum hujus indolis extensa intumescentia, sive dolorem comitem habeat, sive ejusdem expers sit, meteorismus late vocari consuevit." CULLEN, (1769,) separated meteorism and tympanites from the dropsies, and included both in the genus tympanites, which, with the genera pneumatosis and physometra, he made a section of the order intumescentiæ, [Works, Thomson's Ed., Edinburgh, 1827, Vol. I, p. 322.] CULLEN threw doubts on the occurrence of collections of gas between the intestinal coats as a primary disease, suggesting that they occurred only as a consequence of erosion of the internal coat by ulceration. He also regarded the accumulation of gas in the peritoneal cavity as very rare; "but, from several dissections, it is unquestionable that such a disease has sometimes truly occurred," [*op. cit.*, Vol. II, p. 575; see also *First Lines*, Ed. of 1784, Vol. IV, p. 231.] Consult also the article *Tympanite*, in Dict. des Sci. Méd., T. 56, Paris, 1821, p. 162, to which is appended a list of some two dozen theses on tympanites, in two of which—that by VEHR, Frankfort, 1686, and that by VATER, Wittenburg, 1713—it figures under the old designation hydrops siccus. See also J. G. PLENKER—*Diss. de meteorismo*, in J. EYEREL'S *Dissertationes Medicæ*, Vienna, 1790, T. III, p. 92.

† C. ROKITANSKY—*Lehrb. der Path. Anat.*, 3te Aufl., Bd. III, Vienna. 1861, S. 146; BAMBERGER, S. 238 *op cit.*, note *. p. 491.

vegetables, pickles, fruit and acid or subacid drinks become a marked symptom. Uneasy feelings or pains in the stomach often follow meals, and the use of particular articles of diet, which prove especially indigestible to the individual patient, provokes an increase in the frequency of the stools as well as increased pain and flatulence.

The *tongue* is seldom natural: in many cases it is simply coated with a more or less thick whitish fur; in others it is pale, smooth, swollen and indented on the edges by the teeth; perhaps the latter is the most characteristic condition in those cases especially in which evidences of a scorbutic taint are present. Towards the close of fatal cases the tongue assumes other characters: sometimes it becomes brown and dry as in typhoid fever, in other cases it acquires a bright-red color and appears smooth and shining like a piece of raw beef; on the shining red surface aphthæ sometimes make their appearance.

Debility and emaciation.—The most characteristic feature in the constitutional condition of patients suffering from chronic dysentery is a steadily increasing debility accompanied by progressive and ultimately extreme emaciation, the expression, as Aretæus* long ago pointed out, of the impaired nutrition resulting from the disordered condition of the digestive functions. Very often the patient is not confined to bed till he has been sick quite a long time. Indeed he not unfrequently remains with his regiment and carries the musket until the disease has made considerable progress. Sooner or later, however, he breaks down and finds his way to general hospital. In hospital he very often does not keep his bed except during intercurrent acute attacks until near the fatal issue, but his walk becomes progressively feebler, the slightest exertions provoke palpitations, pantings, and are followed by extreme fatigue, while the emaciation steadily progresses and ultimately attains an extreme degree which is but rarely encountered in other affections.

Meanwhile the complexion acquires a pallid hue; the facial bones project, the eyes sink, giving a ghastly expression to the countenance; the skin of the general surface of the body becomes dry, in advanced cases a desquamation of the cuticle in bran-like scales occurs;† the spirits are much depressed, the patient takes a gloomy view of his prospects; very often he falls into a condition which is best described as general nervousness; in other cases the mental condition assumes the form of nostalgia; in others it approaches imbecility;‡ delirium, however, is rare even in extreme cases. The voice shares in the general debility, it becomes feeble and measured; sometimes it has a peculiar muffled sound as if heard from a distance. These conditions are frequently modified by the presence of the *malarial cachexia*, or the *scorbutic taint;* the former is indicated by an icteroid hue of the conjunctivæ and skin, enlarged spleen, a tendency to periodicity in the phenomena of the disease,

* *Loc. cit.*, p. 484, *supra*.

† DE BRULER (*supra*, p. 42) observed in the latter stages of many of his cases that the abdomen became covered with drab or copper-colored spots, varying from the size of a split pea to that of a dime or even a quarter of a dollar. This observation recalls the eruptions described by FINGER—see note † to p. 409—and ZIMMERMANN—see note ‖ to p. 412, *supra*.

‡ W. KEMPSTER—*Entero-colitis, or chronic diarrhœa*, The Amer. Journ. of the Med. Sci., Vol. 52, 1866, p. 337—who has since then attained distinction in the treatment of mental diseases, gives the following graphic account of some of these cases: "There is yet another very distressing affection which sometimes occurs as a result of this disease, and to which I cannot give a name. To those who have suffered long from entero-colitis, or have been subjected to prison diet, it is most marked. I allude to a state of the mind which may with propriety be called mental incapacity. In this condition a feebleness of purpose, a want of stability and incoherence are exhibited. This derangement may continue for some time after the primary disease has entirely left the patients. When a question is asked they hesitate several minutes, apparently endeavoring to find language for an answer, which when made is in the fewest words. This was observed particularly, among those men who had been several months in southern prisons, suffering from the effects of entero-colitis, with the scorbutic diathesis. They would sit by the hour, gazing on the ground, paying no attention to what was going on about them. Their movements were slow; they were irritable; nothing would please them. The face wore an expression of complete dementia. The pulse was slow and soft, the pupil dilated, and the eye presented an unusual brightness. They slept very soundly, and for longer periods than a person in health. The appetite was good, and the functions of the body were normally performed. These symptoms were more like those of brain softening in its advanced stage than any others to which I can compare them. *The brain was starved.* In the cases examined after death, no pathological condition of the brain or its membranes was found which would account for the ante-mortem state above described." "From this state some recovered entirely; others did not while they remained in hospital."—p. 350.

or an occasional outbreak of actual ague; the latter manifests itself by muddy complexion, large flabby tongue, pseudo-rheumatic pains, hemeralopia, swollen gums and purpuric blotches. Either taint may occur singly, but generally they are variously combined. Not unfrequently indeed one or both precede the original development of the flux.

Other symptoms.—The *pulse* is, as a rule, soft, compressible and but moderately accelerated, [85 to 95,] so long as the patient keeps quiet. On exertion of any kind, however, its frequency is greatly increased, merely walking across the hospital-ward proving sufficient in many cases to give it very great rapidity, [120 to 140, or even more.] Cardiac palpitations after exertion are commonly complained of; not unfrequently they take the form of *irritable heart*, so carefully studied by Dr. Da Costa,* who found that of two hundred cases of that cardiac disorder, sixty-one occurred in patients who were suffering or had suffered from diarrhœa. The disease sometimes runs its course without febrile complication, but more or less pronounced hectic fever often accompanies its latter stages; and then increased frequency of the pulse with some rise of temperature is noted in the afternoon and evening, and night sweats become troublesome.

The *urine* very generally presents nothing abnormal; in some cases it is scanty and correspondingly concentrated, in others it is copious, pale and throws down a phosphatic sediment. Sometimes it contains albumen and casts; still more frequently the latter can be detected on careful microscopical examination, although albumen can not be recognized by chemical tests; but neither of these conditions was observed, during the war, as often as might have been expected in view of the number of instances in which the kidneys were found large and pale, fatty or otherwise diseased, after death. The fact is that the urine was very seldom examined in these cases, either chemically or microscopically, unless the renal disease had so far advanced as to produce dropsy; more numerous examinations would undoubtedly have afforded more frequent indications of renal complication. Thus, Prof. Alonzo Clark† investigated the urine of a small number of cases admitted to Bellevue hospital from the army of the Potomac, during the latter part of 1862. He found casts in the urine of all "the bad cases" he examined, as well as in that of some of the convalescents, although no albumen could be detected; in two cases, both of which were convalescent from the flux, the urine was albuminous. *Strangury* and *vesical tenesmus* were not of frequent occurrence in chronic fluxes, except when acute dysenteric symptoms supervened during the progress of the case.

Prolapsus ani is not unfrequently a troublesome symptom in chronic cases; it is, however, impossible to determine the number of instances in which this accident occurred during the war. It will be seen by tables CI and CXII, in the First Medical Volume, that 325 white and 7 colored soldiers were discharged the service on account of prolapsus ani, and it is probable that in a considerable proportion of these cases the accident was

* J. M. DA COSTA—*On irritable heart*, Amer. Jour. of the Med. Sci., Vol. LXI, 1871, p. 37—judiciously comments on these figures, "Sixty-one cases of diarrhœa, or 30.5 per cent., represent certainly more than a mere coincidence."

† ALONZO CLARK—*Proc. of N. Y. Path. Soc.*, in Med. and Surg. Reporter, Vol. IX, 1862-3, p. 312. It is not very clear from this report of Prof. CLARK'S remarks how many cases he examined; whether all or part of the whole number of patients admitted, which is stated to have been 72, of whom 23 died and 11 post mortem examinations were made. The report reads: "The kidneys were larger than natural, and whitened. In one post mortem they were loaded with oil globules; the urine of non-convalescents in no case contained albumen. When the specimens of urine came to be examined under the microscope, there were only two in which casts were not found. The absence of casts may sometimes be accounted for from the manner in which the examination is made. In all the bad cases casts were found, but no albumen; thus, at least, one of the evidences of Bright's disease may be constantly found in these cases. Of 5 convalescents, 3 had casts. Of 6 convalescents examined quite recently, 2 contained albumen. There was rarely any œdema of the legs, and none of the hands in the bad cases, while 2 that are convalescent have been œdematous though less so now than two weeks ago. Thus the relation of the diarrhœa to Bright's disease is pretty clearly established. If the disease of the intestines provokes the disease of the kidneys they are in the same condition as in pregnant women, or in children with scarlet fever. Thus, they may recover from Bright's disease after the disease which caused it has been removed."

brought about by some form of chronic flux. Usually, however, such cases were reported merely as chronic diarrhœa or dysentery, and there are no statistics to show the actual frequency of the accident in question.

COMPLICATIONS.—It has already been mentioned several times that acute dysentery was a frequent complication in the course of chronic fluxes, and often the precursor of a fatal issue.* So also the circumstance that these fluxes were often complicated by the malarial and the scorbutic cachexias has already been alluded to.† Besides these I may mention rheumatism and pseudo-rheumatism, intermittent fever, remittent and continued fevers, peritonitis, dropsy, pneumonia, chronic bronchitis and phthisis, abscess of the liver, perineal abscess and ulceration of the cornea as among the more important complications which require consideration in this place.

Rheumatism and pseudo-rheumatism.—These conditions have already been commented on in connection with acute dysentery.‡ That genuine rheumatism often occurs in patients laboring under chronic fluxes, and that chronic fluxes frequently attack rheumatic subjects, I do not doubt. But undoubtedly also both malarial and scorbutic neuralgia are readily mistaken for rheumatism, and in a large proportion of the soldiers suffering with chronic diarrhœa and dysentery, in whom general debility was associated with the "lame backs" or "weak backs," so common during the civil war, the pains complained of were probably of this nature.§ For these neuralgic conditions, simulating chronic rheumatism, I have proposed the name *pseudo-rheumatism*, and will discuss the phenomena designated by this term in a subsequent chapter.

Intermittent fever.—Ordinary ague was a common complication of chronic dysentery,‖ sometimes preceding the flux, sometimes only appearing after it was fairly under way. Periodical febrile paroxysms without chills, the so-called dumb ague, were also of frequent occurrence. Readily cut short by quinine, these intermittent paroxysms were prone to recur obstinately, and undoubtedly exercised an unfavorable influence on the progress of the disease. Paroxysms of pernicious intermittent fever also occasionally occurred during the progress of a chronic flux, and were sometimes the immediate cause of death. Assistant Surgeon J. T. Calhoun, U. S. A., has published five cases of this complication, in three of

* *Supra*, pp. 350 and 352. † *Supra*, p. 493; compare pp. 288 and 406. ‡ *Supra*, p. 406 *et seq.*

§ Compare with the remarks in the text and those referred to in the last note the following extracts from an address delivered before the Philadelphia County Medical Society by Professor ALFRED STILLÉ, of the University of Pennsylvania—Trans. of the Medical Society of the State of Pennsylvania, Philadelphia, 1862, p. 303. Describing his experience in one of the great military hospitals of that city, he remarks: "The two most ordinary systemic complications of diarrhœa were malarial cachexia and scurvy." Of the latter he says: "It has shown itself in several instances by œdema of the lower extremities and ecchymosis of these and other parts. No instances of spongy gums and loosened teeth have been noticed by me, but in one case the exacerbations of the swelling and discoloration of the legs were coincident with an increase of diarrhœa and an insufferable fetor of the breath. Œdema of the ankles, without ecchymotic discoloration, was observed in many other cases. It is highly probable that a scorbutic condition often existed when the characteristic symptoms of scurvy were absent; but neither the phenomena themselves nor the effects of treatment positively demonstrated it. As to these effects, it appeared to me that lemon-juice and fresh vegetables, the specific remedies for scurvy, were less efficacious than their reputation led me to expect; nor did it seem possible, in the greater number of cases, to carry the improvement beyond a certain point much below the average of good health. Of these cases it may be said emphatically, as with less positiveness it may be of the other chronic affections already noticed, that comparatively few of them can be expected to recover in the wards of a hospital. They stand pre-eminently in need of fresh air, sunshine, and exercise combined. * * * As closely connected with scurvy, if we may conclude from the conditions in which it is found to exist, *muscular rheumatism* may be mentioned; but it must not be forgotten that the scorbutic diathesis, as a merely debilitating influence, predisposes to all diseases excited by external causes, and hence pre-eminently to rheumatism. The direct causes of the latter affection, indeed, surround the soldier at every step of an active campaign, and it is only a matter of surprise that an army of stalwart men is not speedily converted into a horde of cripples. Out of some scores of cases that have passed under my observation, I do not remember a single one in which the attack began as an acute inflammation. They were, all of them, cases of muscular rheumatism, or else of subacute or primarily chronic rheumatism of the external ligaments of the joints, and often resulted in false anchylosis or in muscular atrophy of the affected limb. In some cases of the latter sort the stiffness of the joints yielded to a diligent and persevering use of active and passive motion. A striking example of this result was presented by a man who for months had been bent almost double, but who left the hospital nearly erect." W. KEMPSTER [p. 344, *op. cit.*, p. 493, *supra*] remarks that the most fatal form of chronic diarrhœa is that connected with the scorbutic diathesis. Of this variety he says he believes it "constituted more than two-thirds of all the cases occurring during the last two years of the war. This cachexia is known to exist when we find spongy gums, bleeding on slight pressure. A not unfrequent symptom is hemeralopia, or night-blindness, which can frequently be traced to a scorbutic origin, and which will aid in the diagnosis."

‖ Compare the remarks on p. 237, *supra;* the writers cited in the foot note for the most part refer to chronic fluxes as well as to acute diarrhœa.

which the life of the patient was saved by the liberal use of quinine.* Lastly, in great numbers of cases, whether distinct ague paroxysms occurred or not, a condition of chronic malarial poisoning was superadded to the cachexia resulting from the flux, and increased both the severity of the symptoms and the probability of a fatal issue.†

Remittent and continued fevers.—The existence of a chronic dysentery confers, of course, no exemption from the continued fevers, and as the causes of both groups of diseases continually coexist in camps, the fevers and fluxes very often occur variously combined in the same individual. During the civil war the chronic fluxes were frequently complicated by the development, at some time during their progress, of remittent, typho-malarial or typhoid fevers. When these appeared at an early stage of the bowel affection they often ran their course and terminated in recovery, leaving the patient, however, still suffering from the flux and almost always worse, especially more debilitated, than before. In other subjects the febrile complication determined a fatal issue; and then, on the autopsy, thickening and ulceration of Peyer's patches were very generally found in addition to the lesions of the large intestine characteristic of the flux. Moreover, fevers in the course of which diarrhœa became a prominent symptom, served at times as the starting point of a chronic flux in individuals whose digestive organs had previously escaped disease. Such cases will be more fully discussed hereafter in connection with the subject of fever.

---

* J. THEODORE CALHOUN, Surgeon in Chief, 2d Div., 3d Army Corps (afterwards Assistant Surgeon, U. S. A.)—*Rough notes of an Army Surgeon's experience, during the great rebellion*, The Medical and Surgical Reporter, Vol. X, 1863, pp. 49 and 50—"There is another complication not as often recognized as that just referred to, yet little less fatal if it is not. It is an attack of Pernicious Fever, (Wood,) or what is ordinarily known as Congestive Chills. Patients, I am convinced, frequently die with this complication without the disease being suspected, and the death is entered in the monthly report as 'Colica.' Let me detail a few cases that have come under my immediate treatment or notice, premising that I describe them entirely from memory, as I have no data at hand to which I can refer. Case I.—Private Wm. P., Co. E, 5th Excelsior, had been sick for some time with Chronic Dysentery, but was so far convalescent at Harrison's Landing, that he was in his quarters and walking around camp. One day he fainted at the sink and was brought into the Regimental Hospital. He was vomiting, with an expression of countenance indicative of a state of great depression; the features were sunken and cadaveric, and so altered that I hardly recognized him; the pulse was scarcely perceptible; the muscles of his lower extremities were in knots with the cramp. He declared he had eaten nothing but a little toast, and described himself as in his ordinary health when he was suddenly taken with vomiting and faintness. Friction, heat, etc., externally, with sinapisms to the abdomen and calves of the legs, and stimulants freely given internally failed to have any effect, and he died in a few hours. Circumstances precluded a post mortem examination. Case II.—Private Oscar C., Co. C, 5th Excelsior, had been troubled with a little diarrhœa while lying before Alexandria last fall. I was called to see him in his quarters with the report that he had been suddenly taken very ill. He was well known to me, yet I should not have recognized him. His features were perfectly death-like; pulse to be felt but with difficulty; vomiting; cramps and pain, as in the case just narrated. I had him carried to the Regimental Hospital; placed a strong sinapism on his abdomen, directed frictions to his legs and thighs, and gave him brandy and quinine without regard to quantity. He rallied slowly, but it was not until the next day that he began to look like himself, and when we left him at Convalescent Camp, when we moved to Manassas in November, although he had been treated on a tonic and invigorating plan, he was still very feeble. Case III.—Private Andrew B., wagoner, Co. B, 5th Excelsior, was taken the next day after the case above described, and in precisely the same way, and presenting the same symptoms, though not to so marked an extent. He had a similar treatment, but as he was very intractable it was difficult to get him to take all the stimulants desirable. He rallied, and the next morning was much better and walked around. About ten o'clock, after a few yawns and shivers, the train of symptoms re-appeared, and under a like treatment he again rallied. The succeeding day he had a slight attack, but large doses of quinine prevented the reappearance of the disease. Large doses of quinine and a good diet put the patient on duty again in a few weeks. Case IV.— —— ——, 2d Excelsior. The patient was under treatment by Dr. Younglove, Assistant Surgeon of the regiment, for a mild diarrhœa. A few days after the battle of Fredericksburg, he was taken very ill while in his quarters, and died before assistance could be rendered him. His comrades reported that he vomited freely and complained of cramp and pain. By request of Dr. Ash, Surgeon of the Regiment, I attended the post mortem examination several hours after death. The stomach exhibited no traces of inflammation; the lungs were moderately congested, otherwise there was little evidence of pathological changes. Case V.—Private Wm. M., Co. D, 5th Excelsior, was taken as were the patients above described, and under a somewhat similar treatment by Dr. Lodge, Assistant Surgeon 5th Excelsior, he rallied and was convalescing, when on the fourteenth day after the attack he was seized with another turn. He was again fortunate in sustaining it, and the liberal administration of quinine prevented a return of the disease, and in due time he resumed his duties. These, it seems to me, are clearly cases of Pernicious Fever. The comparatively trivial nature of the illness previous to the attack, the suddenness of the attack, the great and alarming prostration, the periodicity so clearly marked in two of the cases, and the recovery under the anti-periodics and stimulants, seem to me to indicate the nature of the complication. I know that deaths from this complication are seen in other regiments, and for want of a better term are put down as colic. The vomiting leads too many to look only to the stomach and bowels and to ascribe the result to something the patient must have eaten, but he will declare to the contrary, and an inspection of the ejecta proves his truthfulness. The patient is poisoned with malaria. There may be something in the condition of the system, the result of this diarrhœa, which renders the patient peculiarly susceptible to the malarial poison, as I am inclined to think, or it may be simply that he receives a large dose of the poison. It is not alone sufficient to stimulate the patient. We must give quinine without regard to quantity; it is best given when there is clearly an intermission, but if there be none the quinine must be given freely, for in that lies the patient's only protection against a second and most probably a fatal attack. As far as my experience goes the liability to attack of Pernicious Fever is the complication of Camp Dysentery by far the most to be dreaded, and it is most effectually guarded against when quinine is used in the treatment of the dysentery."

† Professor ALFRED STILLÉ (cited last page) declared that "the two most ordinary systemic complications of diarrhœa were malarial cachexia and scurvy. The former impressed upon the patient a peculiar sallow or muddy paleness, and seemed to be a common cause of the gastric dyspepsia which so frequently rendered its treatment abortive, or at least prevented remedies from being permanently curative." In many cases he thought the "malarial anæmia is maintained by the chronic disorder of the bowels." W. KEMPSTER (cited on p. 493, *supra*) has also commemorated the complication of camp diarrhœa by intermittent fever, especially among the troops serving in Louisiana.

Peritonitis.—Perforation of the intestine followed by fæcal extravasation and acute general peritonitis is an occasional accident, in the course of chronic fluxes dependent on intestinal ulceration, and usually proves fatal. General peritonitis with very similar symptoms may also arise independently of the occurrence of perforation, though this is not so common as in acute dysentery. But usually the peritoneal inflammation that occurs in the course of chronic dysentery is of a more subacute or even chronic character, beginning as a local process limited to some portion of the surface of the large intestine and gradually spreading until it involves the whole peritonæum. Such chronic inflammatory processes give rise to extensive adhesions, together with more or less bulky accumulations of serous, sero-purulent or purulent fluid in the abdominal cavity. This condition constituted one variety of the "swelled bellies" which attracted so much attention during the war. A study of the autopsies recorded has satisfied me that both intestinal perforation and local and general peritonitis, occurring independently of perforation, are more frequent in the chronic cases resulting from diphtheritic dysentery, or complicated by it, than in those dependent upon chronic follicular ulceration of the colon. The same remark applies to those cases in which the peritoneal inflammation and perforation occur in connection with the cæcum, and to which the term typhlitis may be properly applied. Case 193* is an example of this accident, in which death took place before the fæcal abscess had time to open externally. Such cases are rare, and probably even more so in the course of chronic fluxes than in acute diphtheritic dysentery. The occurrence of *tubercular* peritonitis will be referred to hereafter in connection with tubercular ulceration of the intestines.

Dropsy.—This symptom in the form of ascites,† with or without œdema of the lower extremities or general anasarca, was by no means an infrequent complication of chronic dysentery, and arose from various pathological conditions. More or less extensive inflammation of the peritoneal surface of the colon, or general peritonitis consecutive to this, giving rise, as mentioned above, to serous, sero-purulent or purulent accumulations in the peritoneal sac, constituted a considerable proportion of these cases. In other instances ascites was the consequence of mechanical obstructions to the circulation, produced by enlarged spleens resulting from the malarial cachexia, or by cirrhosis or other disease of the liver. In still other cases the dropsical effusion was the result of chronic renal disease, and in this class of cases general anasarca was usually developed. There are many reasons for believing that chronic renal disease and liver cirrhosis were sometimes caused by the prolonged action of the malarial influence, as is well known to be the case with the enlarged spleen; under such circumstances more or less advanced disease of all three of these important organs was often variously combined with chronic peritonitis. The appearance presented by patients suffering under this complication was quite striking. The pale or yellow, emaciated countenances, the feeble movements, the bloated bellies and swollen legs made a picture well

* *Supra*, p. 125. Compare the remarks on peritonitis and perforation in acute dysentery, *supra*, p. 388.

† Professor ALFRED STILLÉ, in the address cited on p. 495, remarks: "It has been mentioned in my hearing by more than one hospital surgeon that cases of ascites are common in connection with chronic diarrhœa. My own experience has not furnished me with a single instance of the kind. In some cases of the intestinal disorder distension of the abdomen was occasionally observed, but in all of them it was tympanitic, and appeared sometimes to be produced by the bread, which, being unfermented when eaten, seemed to develop a prodigious quantity of gas during digestion. Tympanites, however, sometimes occurred without any apparent intestinal or gastric disorder, or even the least alteration of the general health. In these cases no treatment of it was efficacious." That this opinion should have emanated from one of the best instructed clinical observers in the United States, only serves to make more apparent the danger of drawing general conclusions with regard to a disease such as this from a single group of cases. Those which fell under Professor STILLÉ's eye, if we may judge from the autopsies made by Professor LEIDY on the Philadelphia cases at the time referred to, were for the most part cases in which there was little or no ulceration of the intestines, that is, precisely those in which peritonitis would be a rare complication. Moreover, early in the war the chronic diseases of the liver, spleen and kidneys referred to in the text were less frequent than they subsequently became; but be this as it may, the occurrence of the complication has been so thoroughly demonstrated by actual autopsies, as will hereafter be shown, that negative testimony to the contrary cannot be trusted.

calculated to impress the spectator who for the first time encountered these victims of war. My attention has frequently been directed to this group of cases by surgeons who had observed them, especially in armies operating in very malarial regions, as on the banks of the Mississippi and James rivers and in the lowlands of North and South Carolina and Louisiana.

Pneumonia.—Sudden and overwhelming congestion of the lungs, sometimes proving fatal in twenty-four hours or less, is one of the modes in which cases of chronic dysentery terminate. Intimately allied is the supervention of catarrhal or croupous pneumonia, or of pleuropneumonia involving one or both lungs. These accidents present no peculiarities which need discussion in this place. They constitute very frequent and fatal complications of the advanced stages of chronic dysentery. Indeed, it may be said that in the United States pneumonia is about as frequent in connection with dysentery as hepatic abscess is said to be in tropical climates. That some of these lung inflammations are of metastatic origin, and caused by the introduction into the circulation of emboli set free by the breaking up of thrombi in the veins leading from the ulcerated intestines, I do not doubt. Cases 139, 195, 247, 333, 393 and 787 were probably of this nature, as will be shown in a subsequent portion of this Section. The attention of those by whom most of our autopsies were made does not appear to have been directed to the possibility of this accident, which was doubtless of more frequent occurrence than is shown by the record. I cannot, however, believe that any very large proportion of the intercurrent pneumonias occurring in chronic dysentery owe their development to this process. Imperfectly as the lung lesions are described in most of the autopsies collected during the war, the frequency with which red or gray hepatization of whole lung lobes is distinctly affirmed is a noteworthy circumstance in this connection. Still more worthy of consideration is the fact, which will be shown when the autopsies of the chronic cases come to be discussed, that these deaths from pneumonia were most frequent during the inclement months; as if they were determined rather by the vicissitudes of the weather to which the sick in our tent and barrack hospitals were particularly exposed than by the course of the intestinal disease. This circumstance inclines me to the opinion that in the majority of cases the lung inflammation was due to the usual causes which at the same season produce pneumonia in healthy individuals, and that it was chiefly on account of the debilitating influence of chronic dysentery that its victims became more prone to this fatal chest disease.

Chronic bronchitis and phthisis.—Chronic bronchitis was another frequent complication of chronic dysentery, both in the Federal and Confederate armies.* Doubtless in very many of the cases in which this complication was observed the bronchial affection was dependent upon tubercular disease of the lungs. The exposure and fatigues of the military service in time of war, together with the impaired nutrition resulting from camp diet, undoubtedly favor the development of lung tuberculosis in predisposed subjects, and the depressing influences of chronic flux hasten the progress of the disease. Doubtless, also, in many even of those cases in which tubercular disease of the lungs is reported to have been observed in the autopsies, the lesion was actually some one of the chronic inflammatory processes we are recently learning to distinguish from tubercular disease, but which of course were confounded with it by those who made these dissections. The question of the

* PAUL F. EVE—*Answers to certain questions, &c., &c., relative to the health, &c., of the late Southern Army*, The Nashville Journal of Medicine and Surgery, Vol. I, N. S., 1866, p. 18—remarks: "One of the most frequent, distressing, obstinate and fatal affections treated in our hospitals was the combination of chronic diarrhœa with chronic bronchitis. A prescription benefiting one was almost sure to aggravate the other, and they were thus often antagonistic in treatment."

true nature of these lesions must be postponed to a subsequent chapter. Meanwhile, if by phthisis we designate all those chronic processes which result in destruction of lung tissue and cavity-formation, it must be admitted that this condition was an exceedingly common and fatal complication of chronic dysentery.

Abscess of the liver.—Deficient biliary secretion and other symptoms indicative of hepatic disorder are frequently observed during chronic dysentery, but suppurative inflammation of the liver was by no means a usual complication during the civil war, even in those forms of chronic flux in which the intestines were ulcerated. It will be shown hereafter that, including both the single and multiple forms, hepatic abscess was observed only in about one out of twenty-five dissections of such cases. It is doubtless true that in tropical climates inflammation, abscess and chronic diseases of the liver are the chief complications of the intestinal fluxes, but in the climate of the United States this part is taken by bronchitis, the various forms of pneumonia and lung phthisis. The frequency of these chest affections has not been sufficiently insisted upon by writers on the dysentery of temperate climates, but the comparative rarity of hepatic abscess in European dysentery has long been well known. The symptoms of this disease, when it occurs in the course of a chronic flux, are so similar to those which accompany it when developed during acute dysentery, that nothing need be added here to what has already been said on the subject.* Some additional considerations with regard to its frequency in this country and elsewhere will be presented hereafter when the autopsies are under discussion.

Perineal abscess and fistula in ano.—The occasional occurrence of perineal abscess in cases of acute dysentery has already been referred to,† and the same accident was probably still more frequent in the chronic cases, but statistical data bearing directly on the subject are wanting. Such abscesses were most likely to occur in tubercular subjects and those who had previously suffered from hæmorrhoids. They were prone to give rise to *fistula in ano;* a circumstance to which, in part at least, we may no doubt attribute the frequency with which the latter affection was observed among the troops. The statistical tables‡ of the First Medical Volume show that among the white troops 2,536 cases of fistula in ano were reported during the war, of whom 494 were discharged the service and 11 died. Among the colored troops the number of cases was 240, of whom 26 were discharged the service. How many of these cases would be traceable to acute or chronic dysentery if their true history could be known, and in how many other patients laboring under these fluxes the same complication occurred without being separately reported, can only be conjectured. It may here be added that patients who already labor under *hæmorrhoids* very often find them become painful and bleed more than usual while they are suffering from a chronic flux; and that sometimes, also, hæmorrhoids make their appearance in patients who had not previously suffered from them.§

Ulceration of the cornea.—This accident undoubtedly occurred much more frequently than is mentioned in the reports to the Surgeon General's Office. Only occasionally did it attract sufficient attention to receive mention; and in post mortem examinations it seems to have very often escaped notice because the eyes were not uniformly inspected. It was especially observed in cases which had advanced to extreme emaciation, and appeared during the last week or ten days of life. Dr. J. P. DeBruler reported,‖ August 30, 1862, that he

* Page 392, *supra.* † See p. 385, *supra.* ‡ Tables C, CI, CXI and CXII.

§ E. ANDREWS—*Chicago Medical Examiner*, Vol. III, 1862, p. 342—in a letter from the camp before Corinth, Miss., May 23, 1862, states that he observed hæmorrhoids in many of the cases of diarrhœa and dysentery among the troops at that point. ‖ *Supra*, p. 42.

had observed this lesion in some eighteen or twenty cases in hospital No. 2, Evansville, Indiana. He does not state the number of cases of chronic flux under observation, but the register and reports of the hospital show 226 admissions for diarrhœa and dysentery from February 22d, when it was organized, to the date of his report. The ulcer was always "in the centre of the lower part of the cornea," and usually affected both eyes. It appeared as a faint opacity which became gradually more dense, and in which an excavated ulcer with well defined edges presently appeared. Meanwhile the vascularity of the cornea was but slightly increased, in some instances not at all. The ulcer rapidly enlarged until it might hold a flax-seed or half a grain of wheat, then became stationary. In one instance both corneæ were perforated. All the cases but three had died at the date of the report. Two of these the reporter thought were improving, but they are referred to in no subsequent report, and it is most probable that they shared the fate of the rest.

In December, 1862, Prof. Alonzo Clark* made a communication to the Pathological Society of New York, in the course of which he stated that during the previous two months 72 soldiers suffering with "diarrhœa" had been admitted to Bellevue hospital from Fortress Monroe; of these 23 had died. "In 5 cases there was ulceration of the cornea of the left eye, all of which were known to be fatal except one, which was removed from the hospital by his friends, and has not been heard from." In reply to a question from Dr. Peaslee, Prof. Clark stated "that the ulceration of the cornea was in every case below the line of the pupil, and did not affect the sight; there was opacity and a little pouting out, and a considerable redness."

Dr. Elliott Coues† [now Assistant Surgeon, U. S. Army] observed several cases of the same lesion, which he described as "sloughing of the cornea," at Mount Pleasant hospital,

---

* A. Clark—*Diarrhœa*, Medical and Surgical Reporter, Vol. IX, 1862-3, p. 312.

† Elliott Coues—*Notes on Soldiers' Chronic Diarrhœa*. Med. and Surg. Reporter, Vol. X, 1863, p. 207. The cases referred to in the text were reported by Dr. J. P. Wyer: "Case I.—Moses Burge, company I, 49th Pennsylvania volunteers; admitted October 2, 1862; illness dated from August. Was for three weeks treated in a hospital tent; but by October 25, illness had become so severe that he was removed into a ward, to avoid all possibility of exposure to the vicissitudes of the weather, which so markedly affect patients suffering with this disease. From this period the evacuations decreased in number, averaging only three or four during the twenty-four hours; scanty in quantity; of a watery consistence; no blood; tongue dry, of a strawberry red; no sordes upon it or upon the gums. Slight tenderness of abdomen on pressure; emaciation extreme; great prostration; anorexia. Complains of great thirst. Pulse averages about 80, soft, readily compressible under the finger. November 20. An opaque spot observed on the right eye, near the juncture of the sclerotica and cornea; within, and at lower border of the latter. This white speck resembled much the ordinary deposit of lymph. It rapidly increased in size, extending in three days over more than half the cornea, and obscuring vision. As the opacity extended it seemed also to increase in density, the layers of the cornea apparently softening and undergoing disorganization. The vessels ramifying on the conjunctiva much enlarged, but there were no signs of active inflammation. Not the slightest pain accompanied the ulcerations. Two days after this appearance on the right eye, the left became similarly affected. November 25. Is gradually failing; pulse 75; one discharge; appetite better, but complains of great pain in stomach and bowels after eating. For the past day or two a slight purulent discharge has been noticed on right eye. Upon viewing the eye by a side view, the loss of tissue is very appreciable. The lower part of the cornea has sloughed away, so that the surface is not oval, but flat. Pulse in evening 65. November 26. Same general condition; only one passage. Both corneæ are sloughing rapidly. November 27. Pulse 75. Appetite failing; much nausea, but no emesis; sloughing of both corneæ progressing; sounds of heart normal, but feeble; no murmurs audible. November 29. Pulse 72. Complains of great distress after eating; is slightly delirious. An ulcer has formed over each malar bone. Tongue dry, red; skin dry, harsh. November 30. Pulse 85. No passage during the night. Anterior chamber of right eye filled with blood—the hæmorrhage from ulceration of the small vessels. December 1. Complains of pain and soreness of fauces on deglutition. The parts are turgid, tender, with a dusky erythematous suffusion. December 2. Pulse 82. Effused blood in the eye not absorbed. No evacuations, but constant and distressing desire to defecate. Tongue and fauces swollen and dry; thirst extreme. Right cornea appears almost or quite sloughed through. December 4. General condition same; failing fast. Complete anorexia. A rash like purpura has appeared on various parts of the body. This condition of things did not change much till December 6, when he died. Intellect good quite up to time of death, answered questions rationally; was quite blind after the first effusion of blood occurred. *Autopsy:* The large organs, the liver, spleen and kidneys of normal size, but considerably congested, especially the latter, in which the cortical and medullary portions cannot be distinguished. Stomach small, contracted. The valvulæ conniventes excessively thickened and in spots softened. No ulcers in any portion of intestines. Descending colon contracted and thickened; mesenteric glands enlarged and irritated. Half of the cornea of the right eye sloughed away, allowing the escape of the aqueous humor and collapse of the eye. Case II.—O. S. Sheppard, company A, 6th Vermont volunteers; attacked with diarrhœa August, 1862, since which time the disease has continued, producing excessive emaciation and debility. Appetite capricious; stomach irritable, rejecting the lightest food. Discharges average six or eight a day, of a watery consistence, passed with some pain. Desire to defecate urgent and frequent. Urine light-colored and abundant, but non-albuminous. Tongue usually dry, glossy, red. Complains of continual chilliness. Pulse weak and languid. December 24. For several days has been rapidly failing; appetite almost gone, and emesis is becoming a serious symptom. The stomach rejects even stimulants. Small abscesses have formed on the face and neck. There is an erythematous blush on the right elbow joint; and the same diffused congestion is perceptible on the fauces. These are tumid, and cause pain on deglutition. These latter symptoms are evidently of a scorbutic character, and are well pronounced. On the right cornea is an opaque, cloudy segment, beyond a doubt the beginning of sloughing of the layers. Cornea of left eye covered with small ulcers of the ordinary kind; only slight conjunctivitis, and *no* pain. Pulse not perceptible at the wrist. Passes urine and fæces involuntarily. Nothing is retained on the stomach. Death same day, and, unfortunately, no autopsy could be made."

Washington, D. C., during 1862. In his published account he criticised the word "pouting" employed by Prof. Clark, remarking that instead "a flatness and loss of tissue was readily perceptible by a side view of the eye." He states that "the ulceration always began at the lower part of the cornea, at the junction of it with the sclerotica." The paper is illustrated by two cases selected from the hospital case-book, which are so interesting that I have reproduced them in the foot note.

To the foregoing it may be added that Assistant Surgeon H. Allen, U. S. Army,* during 1863 and 1864 observed four cases of ulceration of the cornea in 41 autopsies of "chronic diarrhœa" made at Lincoln hospital, Washington, D. C. Also that in Section III of this chapter, in the record of the autopsy in case 720, the remark "eyes mortified," which probably refers to this condition, will be found, and in case 225 it is stated that "the corneæ of both eyes ulcerated about a week before death." These are the only special references to the occurrence of this accident during the civil war that I have been able to collect, but I do not doubt that it happened very frequently.

DeBruler† remarks, in the report from Evansville: "I think it will not do to say that the corneal ulceration depended merely upon the arrest of nutrition, for in many of our cases of typhoid fever this seemed quite as extreme as in the diarrhœa, without, however, leading to ulcers of the cornea." To this I may add that no cases of corneal ulcers occurring in the latter stages of fever were brought to the notice of the Surgeon General's Office during the war. Nevertheless such ulcers do occur, both in fever and in other severe diseases, although by no means so frequently as in chronic dysentery. Middlemore,‡ so far as I know, was the first to observe this accident in epidemic cholera. It occurred during the latter stages of the disease, "without having been preceded by any appreciable amount of inflammation." According to Thielmann,§ opacities of the cornea followed by ulcers, which sometimes perforate the cornea and evacuate the aqueous humor, occur during the advanced stages of scurvy; they are preceded by a scorbutic conjunctivitis. It has been stated by Arlt‖ that corneal ulcers, similar to those which occur in cholera, are seen sometimes in typhus, [our typhoid fever,] puerperal fever and other severe diseases. They occur in the lower segment of the cornea, and, if the patient recovers, heal, leaving an inconsiderable scar behind. They are preceded by considerable injection of the conjunctiva, especially over the lower half of the bulbus.

I have myself had no opportunities to examine any of the forms of corneal ulcers alluded to except those which occur in chronic dysentery. These, I doubt not, are similar

* H. ALLEN—*Synopsis of autopsies made at Lincoln General Hospital*, Amer. Jour. of the Med. Sciences, Vol. XLIX, 1865, p. 134. I note that this accident is not recorded in any of the cases in Dr. ALLEN's case-book, (see note to p. 156, *supra.*) hence it does not appear in his autopsies reported in the last section. I do not, however, doubt the accuracy of his statement, which is evidently made from personal recollection.

† *Supra*, pp. 42 and 499.

‡ R. MIDDLEMORE—*On certain forms of disease of the eye, occurring in individuals who were suffering from or had recently been attacked by cholera*, London Med. Gazette, Vol. XII, 1833, p. 492. The cases were observed during the cholera of 1832 in the vicinity of Birmingham. They occurred for the most part "as the symptoms of the cholera were subsiding;" the diseases observed were amaurosis, suppuration of the eyeball, opacities of the cornea and ulceration and sloughing of the cornea. See, also, A. v. GRAEFE—*Ophthalmologische Beob. bei Cholera*, Archiv für Ophthalmologie, XII, Abth. 2, 1866, S. 202.

§ H. THIELMANN—*Die scorbutische Augenentzündung*, Med. Zeitung Russlands, 1844, Nr. 1 u. 2. I have not been able to see the original, and cite from the abstract in Schmidt's Jahrbücher, Bd. 42, 1844, S. 332. The observations were made on patients from the Russian fleet treated in the naval hospital at Oranienbaum. THIELMANN described, 1, Blepharitis scorbutica; 2, Taraxis scorbutica; 3, Chemosis scorbutica; 4, Keratitis scorbutica; and 5, Iritis and Capsulitis scorbutica. Abstracts of this paper are also given by J. VAN ROOSBROECK—*Cours d'Ophthalmologie*, T. II, Ghent, 1853, p. 389, and R. KREBEL—*Der Scorbut*, Leipsic, 1866, S. 108 u. 183.

‖ F. ARLT—*Die Krankheiten der Binde- u. Hornhaut*, Vol. I, Prague, 1855, S. 215. He attributed the lesion to imperfect closure of the eyelids, which permitted the fluids secreted by the inflamed conjunctiva to dry on the cornea into a yellowish crust, beneath which the ulcers form. The statements of ARLT are substantiated by subsequent writers on the diseases of the eye, *e. g*, STELLWAG VON CARION—*Diseases of the Eye*, Amer. Transl., New York, 1873, p. 77—who, in common with some other writers, explains such ulcers as of neuro-paralytic nature, and compares them to those which follow section of the fifth pair of nerves. Compare A. v. GRAEFE—*Hornhautverschwärung bei infantiler Encephalitis*, Archiv für Ophthalmologie, XII, Abth. 2, 1866, S. 250.

in their nature to those observed by Magendie* in dogs confined to some single non-nitrogenous article of food. They are phenomena of slow starvation. I find no record of any case of dysentery in which this complication occurred during the civil war that terminated in recovery. But that this unfavorable result is not necessary was long ago pointed out by Finger,† who saw two patients recover from dysentery after the formation of ulcers in the cornea, which in one of them had perforated and determined prolapse of the iris.

TERMINATIONS and SEQUELÆ.—Chronic dysentery very frequently terminated fatally in consequence of an acute diphtheritic dysentery supervening, or the development of some intercurrent phlegmasia. *Sudden death* was a not unfrequent accident, and attracted considerable attention during the war. Patients who, though laboring under a chronic flux, were not supposed to be in any immediate danger, who were perhaps walking about the hospital wards, regarded by the attending medical officers as convalescents, occasionally fell to the ground and expired in a few minutes.‡ In such cases death sometimes took place by syncope, the debilitated heart simply ceasing to beat; in other cases subarachnoid serous effusion or pulmonary congestion was the immediate cause of the fatal issue; but in isolated instances it was produced by various other pathological conditions.§ Where the

* F. MAGENDIE—*Mémoire sur les propriétés nutritives des substances qui ne contiennent pas d'azote*, Paris, 1816. He first observed this accident in a dog fed on white sugar and distilled water; both corneæ ulcerated during the third week of this diet. The ulcers perforated the cornea and evacuated the humors of the eye. Dryness of the eye did not precede the ulceration. The dog died extremely emaciated on the 32d day. In a second dog, fed in the same way, the corneæ began to ulcerate about the 25th day, and the dog died before the ulcers perforated. A third experiment gave similar results. Two dogs fed on olive oil only, died emaciated about the 36th day, but their corneæ were not ulcerated. Another dog was fed on butter only; he died emaciated on the 36th day. In this animal the right eye was ulcerated but not the left.

† FINGER—*Die epidemische Ruhr*, Prager Vierteljahrschrift, Bd. IV, 1849, S. 145. These I understand to have been acuto cases. Out of 231 fatal dysenteries he saw several other examples of cornea ulcers, chiefly in protracted cases, but does not state the precise number.

‡ O. B. ORMSBY, Assistant Surgeon 18th Illinois volunteers, in a letter from the floating hospital Nashville, April 27, 1863—Chicago Medical Examiner, Vol. IV, 1863, p. 236—gives the details of two such cases: "Case I.—C. S., soldier, American, aged 25, was admitted to hospital, April 15th, as convalescent from diarrhœa: Tongue was clean; bowels regular; body emaciated; and the pulse regular, but weak. He had quinia et ferri citras, in small doses, simply as a desirable tonic to aid in building up his strength, and to eradicate any remains of malarious poison which might be lurking in his system. In the meantime he had permission to take exercise both on board and on shore. This course was pursued with apparent benefit until noon of the 17th. During the forenoon he had been quite active and cheerful; and when the dinner-bell rung, he remarked, that he would go and take his place at the first table. He started, and arrived at the head of the stairs, when he fell upon the floor. Word was brought me immediately, but when I reached him he was quite dead. At the autopsy, four hours after death, the rigor mortis was well-marked, the body not *extremely* emaciated, and suggillation, in dependent parts of the body, very distinct. The brain and spinal cord were exposed by the usual incisions, with no noteworthy circumstance attending, except, perhaps, that, upon division of the vertebral veins, fluid blood, to the amount of two quarts, [?] was poured out. There was fluid contained within the membranes of the cord to the amount of, probably, f3iv. The dura mater was abnormally adherent to the skull at the base of the brain, and contained about f3ij of effused fluid. The base of the brain was thought to be slightly softened, but, in the absence of the microscope, it could not be with absolute certainty decided. The membranes and substances of both brain and cord were considerably congested, but the nervous matter of the cord appeared to have suffered no structural lesion. The lungs were healthy. Within the pericardium was found f3iv or v of serum. The muscular tissue of the heart was somewhat softened, and traces of congestion were observed. Stomach was simply congested,—liver healthy. The bowels, with the exception of the duodenum, showed evidence of nothing more than congestion of a passive character. The duodenum had, evidently, been the seat of both inflammation and ulceration; and, in several circular patches, the mucous and muscular coats were destroyed, leaving but the peritoneum. Perforation, however, had not occurred; and the ulcers seemed in process of cicatrization. The kidneys were much congested, but quite firm. This congestion appeared to have been quite recent, and to approach more nearly to an active arterial congestion than any thing discovered elsewhere. Case II.—E. D., Frenchman, aged 25, had been admitted to hospital, April 17th, with chronic diarrhœa. He became convalescent under the use of the usual remedies; and upon the 27th was permitted to go on shore for exercise. He, however, took advantage of the opportunity to go to the sutler's store and obtain some nuts, Bologna sausages, &c., and also to strip off and bathe in the water of an adjacent bayou. During the afternoon of the 28th he was attacked suddenly with spasms, together with complete abolition of consciousness; dilated pupils; feeble and frequent pulse; and slightly stertorous breathing. Chloroform was administered with apparent benefit, and, upon the return of consciousness, also some carbonate of ammonia. He soon relapsed into another paroxysm, which was followed by a third, in which he died. Four hours after death, the body was examined. It was much emaciated,—the rigor mortis well-marked, and but little suggillation. Upon removal of the calvarium, several spots of effused lymph were discovered between the dura mater and parietal bones, together with considerable congestion of its surface. Beneath the dura mater was found two ounces of serous fluid. The brain, however, appeared to be only passively congested. The ventricles,—particularly the fourth,—were filled up with serum. The brain was unusually firm The heart was found empty. Lungs, liver, stomach, and bowels all,—with the exception of some congestion,—healthy. Cases of a similar character to the above have repeatedly occurred here, commencing as early as the 1st of March. As I have noticed but little intermittent here, yet I am not of the opinion that they are the result directly of miasmatic influence, though they bear, apparently, some relation to the pernicious intermittent of this latitude. The patients almost universally present marked emaciation, with great tendency to œdema and anasarca; but, aside from the debility thus indicated, very frequently do not present marked symptoms of disease. One case was of a nurse who had not been taking medicine, and had been on duty regularly. In the evening, saying, he felt unwell, he went to his bed and lay down; and, at the end of four hours, when his watch came on, he was found quite dead, and had evidently been so from one to two hours." See also the account of a number of cases of sudden death by Medical Inspector VOLLUM, p. 96, *supra*.

§ There is, of course, no reason why cerebral thrombosis or cerebral hæmorrhage, the rupture of an aneurism or of an atheromatous artery in any part of the body, &c., should not occur in those suffering with chronic flux as well as in those whose bowels are healthy. Indeed, if the morbid process, which culminates in either of these accidents, has commenced, it will be readily understood that the mal-nutrition accompanying the bowel affection may be expected to hasten the *dénouement*. The question of clot formation in the cardiac cavities will be discussed hereafter.

patient escaped these accidents death took place ultimately from asthenia, preceded by extreme emaciation, unless a favorable change occurred. Recovery was most frequent among patients sent out of the region in which they were taken sick to hospitals in the northern states, and those discharged the service or permitted to return home on furlough. Under these circumstances convalescence sometimes set in after all hope had been abandoned. In any event it was usually slow; frequent relapses were prone to occur, sometimes even for years after, and disagreeable sequelæ often ensued.*

Almost every morbid process which occurs in such subjects has been regarded as a sequel of the former flux, especially if the patient is an applicant for pension. Various forms of tubercular disease, disorders of the nervous system,† rheumatism, heart disease, &c., have been attributed to this cause. It will readily be understood that the protracted disturbance of the nutritive functions which accompanies the chronic fluxes is favorable to the initiation of a great variety of morbid processes, and it must not be forgotten that in the case of convalescents it often happens that more or less debility of the digestive and assimilative processes continues long after the flux has ceased. Nevertheless it must be admitted that in many instances diseases occurring from other causes, in subjects who had long previously recovered from chronic dysentery, have been asserted, without sufficient evidence, to have been caused by the flux.

Certain morbid conditions may, however, justly be enumerated among the sequelæ of chronic dysentery. These are—prolapsus ani, which, if developed during the progress of the disease, occasionally persists; fistula in ano, the result of periproctitis terminating in perineal abscess; hæmorrhoids, which sometimes originate during dysentery in patients who had not previously suffered, and are then prone to continue;‡ and various disorders of the digestive organs. Among these digestive disturbances may be mentioned more or less pronounced dyspepsia; irritability of the bowels, which are often left so sensitive that the slightest irregularity in diet provokes diarrhœa; and sluggishness of the bowels manifested as frequent or even persistent constipation. The latter condition unquestionably very often results from impaired peristaltic action in the long diseased and greatly altered colon; the muscular coat is left in a condition of debility which, in extreme cases, borders on paralysis; the fæcal matters, no longer properly carried forward as in the healthy bowel, accumulate in the debilitated portion of the gut or above it, and alvine evacuations are rarely obtained except by medical assistance.§ Obstinate constipation, and even in some rare instances complete obstruction of the bowels, may result from two other lesions, which are much more difficult for the practitioner to deal with than the paralytic condition just

* According to the *Report of the Commissioner of Pensions for the year ended June* 30, 1871, Washington, Government Printing Office, 1871, p. 22, of 15,816 invalid pensioners at that time on the pay rolls whose disability was due to disease, 2,935 were suffering with "chronic diarrhœa." The table from which these figures are taken includes pensioners from former wars, as far back as 1812, but none whose disability was contracted later than the civil war; so that six years is the minimum duration which can be assigned to any of these cases.

† A curious affection, supposed to be a sequel of chronic diarrhœa, is reported by H. C. ROBBINS—*Case of Hemidiaphoresis*, Boston Med. and Surg. Journ., Vol. I, N. S., 1868, p. 372—"J. W., aged 22, while in the army, six years ago, contracted chronic diarrhœa, which confined him to hospital for several weeks. Upon his recovery, he first noticed the phenomenon of profuse perspiration of the left side of his face, which condition still continues, nearly six years after it was first observed. His health is perfect in every other respect, and his mind is clear and strong, but every few minutes, winter or summer, he is obliged to wipe away the sweat from one side of his face. He is now a farmer, strong and energetic."

‡ See the remarks on these accidents as symptoms, p. 499, *supra*. I have no means of ascertaining the frequency with which they occurred after convalescence from the chronic dysentery of the civil war. It is, however, of some interest to note that the Commissioner of Pensions—*loc. cit.*, *supra*—reports that six years after the close of the war there were still on the pension rolls of the United States 18 cases of prolapsus ani, 87 of fistula in ano and 108 of hæmorrhoids. This includes those surviving cases only in which the local trouble was sufficiently grave to be regarded a cause for pension, and in which no more serious pensionable disease existed. I have not the least doubt that in some of these cases the local trouble had its beginning in camp diarrhœa or dysentery, but it would be idle to conjecture in how many instances this was the case.

§ In extreme cases such fæcal accumulations may even result in obstruction of the bowels and symptoms of ileus. Such a case has been reported by LAUCERAUX—*Dyssenterie en* 1870.—*Obstruction stercorale à la partie inférieure du colon descendant.—Vomissements stercoraux.—Évacuation artificielle de l'estomac.—Douche ascendante. Guérison*, (Recueille par BARETTE,) Journ. de la Soc. de Méd. de Caen et du Calvados, An. I, 1876, p. 148 The patient was a man 40 years old, who had contracted dysentery while in captivity in Germany.

referred to. These are intestinal stricture, resulting from the contraction of the cicatrices of dysenteric ulcers, and constriction of the intestinal canal by peritoneal bands, adhesions, &c., formed externally to the bowel.

Intestinal stricture or stenosis, resulting from the contraction of dysenteric ulcers, is, I believe, much less frequent than might be supposed from the loose language of some of the text-books.* No case has been reported to the Surgeon General's Office either during the war or since; the Army Medical Museum does not possess a single specimen; nor have I found in the American medical journals any case substantiated by post mortem examination, in which this condition is reported to have followed a flux contracted during the civil war.† In view of the vast number of cases of diarrhœa and dysentery that occurred during the war these facts would seem to indicate that in America, at least, this accident is extremely infrequent. Yet I do not doubt that some few cases may have occurred and escaped report; for the coarctation does not generally become sufficiently

---

* *E. g.*, J. WARBURTON BEGBIE—*Dysentery*, in Reynolds' System of Medicine, Vol. III, London, 1871, p. 143. "On the other hand, in those instances of the disease which have been distinguished by an extensive loss of substance, the approach of the edges is impossible, and the deeper layers of the tissue which takes the place of the mucous membrane are frequently condensed into fibrous bands, which form projections into the intestinal cavity, interlaced with one another, and not unfrequently encroach upon the calibre of the intestine, in the form of vulvular or annular folds, thus giving rise to a variety of stricture of the colon." So also S. O. HABERSHON—*Diseases of the Abdomen*, London, 1862, p. 385. "The contraction of the cicatrix sometimes produces considerable constriction of the intestine, and occasionally tends to fatal obstruction. Very frequently above the cicatrix all the coats become hypertrophied, showing that there has been much impediment." Similar passages might readily be multiplied: the use in them of the words "not unfrequently" and "frequently" leads to erroneous notions.

† I have made a very careful search, not only of journals but of transactions of state and other societies, with the result mentioned. Among other transactions, I examined particularly the four volumes of the *Proceedings of the Pathological Society of Philadelphia*, 1860-74, and the *Transactions of the New York Pathological Society*, Vol. II, New York, 1877, which contains reports of the cases and specimens of the diseases of the organs of digestion presented to that society from 1844 to 1876, but without finding a single case resulting from dysentery contracted during the civil war. For the advance sheets of the last-mentioned work, received while I was writing this note, I have to thank the courtesy of the editor, Dr. John C. Peters. I had at first supposed the case reported by Dr. H. B. SANDS to the New York Medical and Surgical Society—*Intestinal obstruction resulting from chronic dysentery, successfully relieved by Amussat's operation for artificial anus*, The New York Med. Journ., Vol. I, 1865, p. 55—to be an illustration of the condition under consideration, as the patient was reported to have been first admitted to the New York hospital in November, 1864, suffering with a chronic dysentery contracted in the army nine months previously. But in reply to a note of inquiry as to the ultimate fate of this man, Dr. SANDS has kindly sent me an account of the subsequent history of the case and of the autopsy, from which it appears that the patient died May 1, 1865, and that his disease was really tubercular peritonitis. The obstruction was due to peritoneal adhesions, and careful examination discovered "no evidence of past or present ulceration of the intestinal mucous membrane." Some account of this case will be found in the *Trans. of the New York Path. Soc.*, Vol. II, (cited *supra*,) p. 129. I note that this narrative contains no reference to the original incomplete publication, so that the connection of the two accounts might readily escape attention unless pointed out. Two other cases of stricture of the lower bowel, one of them, at least, consecutive to a chronic flux, with fermented stools, have recently been reported by Medical Inspector PHILIP S. WALES, U. S. Navy—*A new rectal dilator and explorer, with two cases illustrating their application*, The Medical Record, Vol. XII, 1877, p. 115—who cured both cases by dilatation effected with the aid of a hollow India-rubber instrument capable of distension with water injected by a syringe. In reply to a note of inquiry, Dr. WALES has politely informed me (July 31, 1877) that he has since encountered three additional cases, making five in all. In four of these cases the patients had previously suffered from "malarial fever and chronic diarrhœa," while in the fifth case the patient had had Panama fever. The great good fortune of Dr. WALES in the successful treatment of these cases excites doubts as to their actual nature. The literature of intestinal obstruction abundantly shows that the most accomplished surgeons have supposed stricture to exist when the obstruction was really due to peritoneal adhesions or other lesions exterior to the gut. The case of Dr. SANDS, referred to above, will serve as an illustration. Nor can we overlook the possibility that the obstruction in the cases encountered by Dr. WALES may have been of a purely functional character. The uniform success, so fortunately attained in all the cases, would naturally point to some such explanation. I suggest a comparison of these cases with that reported by MATT. BAILLIE—*Upon a case of stricture of the rectum produced by a spasmodic contraction of the internal and external sphincter of the anus*, Med. Trans. of the College of Physicians in London, Vol. V, 1815, p. 136. In this case all the symptoms of stricture were present, the fæces were passed "nearly as thin as a ribbon," and yet, although the patient was so "averse to the introduction of a bougie" that "this instrument was never passed into the rectum," so that nothing was done "except keeping the bowels free from costiveness, and pursuing a very temperate mode of living," the disease gradually subsided, and seventeen years after its commencement it is reported that "hardly any inconvenience is felt." BAILLIE, as the title of the article cited shows, supposed the stricture in this case to be due to spasmodic contraction of the muscular coat of the bowel. A similar view was taken by THOMAS COPELAND—*Obs. on the principal diseases of the rectum and anus*, London, 3d Ed., 1824, p. 45, etc.—who has an interesting article (Sect. IV) "On the consequences produced by the irregular or too powerful action of the sphincter muscle." WILLIAM GAITSKELL—*Case of spasmodic contractions of the sphincter ani muscle*, The London Medical Repository, Vol. IV, 1815, p. 51—reported a case of the condition described by COPELAND, cured "by passing a large bougie up the rectum night and morning for a fortnight," and keeping the bowels open by castor oil with a few drops of laudanum. A. BOYER—*Remarques et obs. sur quelques maladies de l'anus*, Journ. Complémentaire du Dict. des Sci. Méd., T. II, Paris, 1818, p. 24—relates 14 cases of spasmodic stricture of the rectum, most of them associated with fissure. W. WHITE—*Further obs. on strictures of the rectum*, Bath, 1822—after citing the observations of BOYER, remarks (p. 32): "It does not, however, appear from the preceding observations of M. Boyer, that he had any idea of spasmodic constriction of the anus being connected with stricture higher up the rectum, or occurring as the consequence of it; but he seems to consider it as a primitive affection. Whereas, all the cases that have come under my notice, the complaint has always been attended by stricture some way higher up the rectum, except in one instance." That local spasmodic contractions of the muscular coat of any part of the intestinal canal might produce fatal obstruction was an old belief. SAUVAGES—*Nos. Meth.*, Amsterdam, 1768, T. II, p. 346—made this condition a species of ileus; I. spasmodicus. It would lead me too far to go into the literature of this doctrine. Suffice it to say that it has been controverted with much ability by J. ABERCROMBIE—*Diseases of the Stomach, &c.*, Edinburgh, 1828, p. 136, Path. of the intestinal canal, Part I, Sect. 4—who concludes; "that, in a case of ileus, the distended part is the real seat of the disease; and that the contracted part is not contracted by spasm, but is merely collapsed, because it is empty, its muscular action being unimpaired,"—*i. e.*, that the essence of the disease is local paralysis, not spasm. This view has also been adopted by ROKITANSKY—*Über Stricturen des Darmkanals und anderer der Obstipation und dem Ileus zum Grunde liegende Krankheitszustände*, Oesterreich. Jahrb., Bd. XVIII, N. F., 1839, S. 13—"Ob krankhafte Zusammenziehung (krampfhafte Strictur) eines Darmstückes die

close to produce obstruction until a considerable period has elapsed after convalescence from the dysenteric attack, so that it is not surprising that the connection between the two should be overlooked, and the attention of the practitioner directed rather to the urgent symptoms resulting from the intestinal stenosis than to the remote disease which served as its starting point.

This circumstance, as well as the rarity of intestinal stricture after dysentery, will serve to explain why it so completely escaped the attention of the Greek, Roman and Arabian physicians. Even after the revival of medicine in Europe, and after dissection had again come to the assistance of clinical observation, dysentery does not appear to have been identified as the cause in any of the few instances of intestinal stricture observed, except in the case of a certain soldier related by Rhodius,* and a case cited in the work of Lieutaud,† which are the only examples of the condition under consideration that I have been able to find reported before the commencement of the present century.‡

In the early part of the present century we find the thickening, coarctation and irregular contraction of the ulcerated colon, so frequently observed in those dead of chronic dysentery, brought forward by several writers§ in explanation of the obstinate constipation

---

Ursache einer andauernden Constipation und des Ileus werden könne, wird mit Recht von Abercrombie und allen besseren Pathologen bezweifelt," (S. 53.) A third view may be suggested: Local paralysis of the circular muscular coat may be the primary lesion, and yet in the parts immediately below the resulting dilatation the fibres of the circular coat may acquire preternatural energy, the accumulations in the distended part acting as a continual source of irritation. But whatever view be adopted, we must admit the existence of a group of cases in which the obstruction results from functional disturbance rather than from recognizable organic disease. J. S. BRISTOWE—*Obstruction of the bowels*, in Reynolds' Syst. of Med., Vol. III, Lond., 1871, p. 72—has emphasized the occurrence of these cases after dysentery, adopting the theory of spasm, and suggesting hypertrophy of the muscular coat to account for it: "not very infrequently spasmodic contraction, with great hypertrophy of the muscular tissue, is met with as one of the troublesome sequelæ of dysenteric ulceration of the rectum."

* I cite from BONETUS—*Sepulchretum*, Geneva, 1679, p. 882—"Militi cuidam dysenteria laboranti mutuo utriusque lateris ulcerati contactu intestina coalnere: venter suppressus tandem mortem accivit. I. Rhodius cent. 2. observat. 82." This case is also referred to by TH. BARTHOLINUS—*Hist. Anat. et Med. Rar.*, Cent. VI, Hist. 38. Copenhagen, 1661—"In dysenteria coaluisse intestina, et ex alvo suppressa subsequutam mortem vidit quoque Jo. Rhodius noster Cent. 2. Obs. 77. 82." I suppose the work of RHODIUS here referred to to be his *Observationum Medicinalium Centuriæ tres*, Padua, 1657, which I have not been able to see. ALEXANDER MONRO, JR.—*The Morbid Anat. of the Human Gullet, Stomach and Intestines*, Edinburgh, 1811, p. 155—refers to this case, giving the reference, "Vid. Rhodius, Mis. Cur. Obs. 508," which I confess is unintelligible to me. In a recent work, O. LEICHTENSTERN—*Verengerungen, Verschliessungen und Lageveränderungen des Darms*, Ziemssen's Handb., Bd. VII, 2, Leipsic, 1876, S. 515, Amer. transl., Vol. VII, New York, 1876, p. 628—cites the observation of RHODIUS from MONRO in a manner to give the erroneous impression that the latter had also made a similar observation: "Es werden sogar Fälle beschrieben, wo vollständige Verwachsung eingetreten sein soll (?). Monro, Morb. Anat. p. 155.—Rhodius, Mis. Cur. Obs. 508." I see no reason whatever to doubt the honesty of the observation of RHODIUS; simply we cannot at present accept his explanation of the mode in which the stricture observed arose.

† J. LIEUTAUD—*Hist. Anat.-Med.*, T. I, Paris, 1767, p. 118, Lib. I, Obs. 508: "Quidam post fluxum dysentericum, sævissimis coli doloribus, cum alvo planè sicca exerneiabatur; quibus tandem occubuit. Inter sectionem eadaveris visenda se præbent intestina crassiora passim à veteribus exulcerationibus conglutinata. E. MISCELLAN. CURIOSIS." The value of the work of LIEUTAUD is greatly impaired by the circumstance that he does not give the details of any of his references. I have vainly searched the German Ephemerides in the hope of identifying this case and obtaining further particulars, and regret my want of success the more because the abstracts given by LIEUTAUD are not always wisely made.

‡ F. WANDESLEBEN—*Diss. de intest. recti strictura*, Halle, 1820, p. 3—cites a case from AMATUS LUSITANUS as one of obstruction after chronic dysentery, and refers to several cases of intestinal obstruction collected by SCHENCKIUS as occurring to patients suffering with the same disease: ("Homines torminibus diu laborantes.") But I note that in the report of AMATUS LUSITANUS—*Cur. Med.*, Cent. II, Venice, 1557, p. 227; "Cur. X, in qua agitur de quadam muliere per vulvam stercus emittente"—there is no mention of any intestinal obstruction. We are merely told that the patient had passed blood with her urine and fæces for four years, that at last the intestines being perforated stercus escaped per vulvam, and that the patient lived thus miserably for a long time. In the scholia it is stated that the disease was chronic dysentery, and in explanation of the bloody urine the conjecture is made that the ulcers had eroded the urinary passages also. As for the cases of intestinal obstruction cited from SCHENCKIUS—*Obs. Med. Rar.*, Frankfort, 1609, pp. 395, 425, 431 and 439—neither in that work nor in the originals from which the cases were borrowed does it appear that any of the patients had suffered from dysentery. These originals are: J. FERRANDUS—*De Nephrisis et Lithiasis*, Ed. 2, Paris, 1601, f. 31; BENIVENIUS—Cap. 34, *op. cit.*, p. 435, *supra*; J. HOLLERIUS—*De Morb. Intern. Cur.*, Venice, 1572, fol. 114, Lib. I, Cap. 39, Scholia; and MARCELLUS DONATUS—*De Med. Hist. Mirab.*, Lib. IV, Cap. 10, Mantua, 1586, fol. 211. In the case of HOLLERIUS, indeed, the patient suffered long with "tormina;" but this was after the stricture had formed and not because of it. Except the cases mentioned in the text, I do not find a single one which can be interpreted as following dysentery in the *Obs. Med. Rar.* of SCHENCKIUS, the *Sepulchretum* of BONETUS, the *De Sedibus et Causis Morb.* of MORGAGNI, or the *Hist. Anat.-Med.* of LIEUTAUD; nor do I find any unmistakable references to dysentery as a cause of intestinal obstructions in the dissertations of A. F. WALTHER—*De intest. angustia*, Leipsic, 1731, I cite from Haller's Disp. Anat. Select., T. I, Gottingen, 1750, p. 439; J. F. E. SCHNIZZER—*De alvi obstructione*, Erlangen, 1755, which contains an admirable copperplate with three figures representing obstructions from 1, peritoneal adhesions; 2, intussusception; and 3, stricture from scirrhus; P. HÉVIN—*Rech. hist. sur la gastrotomie*, Mém. de l'Acad. Royale de Chir., T. IV, Paris, 1768, p. 201; and L. F. J. DUCHADOZ—*De Proctostenia*, Montpellier Thesis, 1771, in which 27 cases of stricture of the bowel, partly collected from literature, partly not before published, are given in detail. WALTHER, indeed, enumerates dysentery among the remote causes of intestinal obstruction, but he does so in a general way along with astringent medicines and foods, aromatics, abuse of alcoholic drinks, diarrhœa, worms, checked or excessive menstrual and hæmorrhoidal fluxes and the like, *op. cit.*, p. 464.

§ Thus, for example, METZLER—*Ueber die widernatürlichen Verengerungen des Mastdarms*, Hufeland's Journal, Bd. 33, 1811, St. I, S. 28—affirms that in consequence of inflammation and ulceration of the mucous membrane of the colon and rectum intestinal strictures arise: 'Gewiss ist's, dass bei Entzündungen und Geschwüren der innern Häute, Muskeln, Drüsen, etc., des Colons, und Mastdarms die Wände derselben erstaunlich aufgelockert, in Falten, Tuberkeln, Auswüchse, und, weiss Gott was für scirrhöse Wülste verändert werden, die die Höhlung verengern, den Durchgang der Excre-

sometimes observed after such fluxes. Among the most notable of those who advanced this view may be mentioned Annesley,* who asserted that in India strictures of various parts of the large intestine, especially the descending colon and sigmoid flexure, were of frequent occurrence after dysentery. But it is evident from the descriptions and colored plates with which he illustrated these opinions that Annesley had in view two conditions entirely distinct from the one under consideration, viz: the irregular coarctation of large areas of the colon with thickening of the intestinal walls, so common in chronic fluxes, and constrictions resulting from peritoneal inflammation. Nowhere does he mention the possibility of stricture resulting from the contractions of the cicatrices of the dysenteric ulcers; nor, indeed, do I find any evidence in his work that he had ever observed such cicatrices in any of his dissections.

The merit of having first presented a detailed anatomical account of the strictures which occasionally result from the cicatrization of dysenteric ulcers unquestionably belongs to Rokitansky.† He described two forms of this process; in the first, cicatrices, representing comparatively great losses of substance, contract into fibrous bands which form corded projections into the intestinal cavity, interlace with one another and ultimately encroach upon the calibre of the intestine in the shape of valvular or annular folds; in the second, occurring usually where the loss of substance has not been so great, the sinuous portions of mucous membrane at the edges of the ulcer, as well as the intact islets of mucous membrane which are sometimes scattered over the ulcerated surface, are puckered and compressed by the contraction of the cicatricial tissue into warty, pedunculated, polyp-like excrescences. According to the latest utterances of Rokitansky,‡ the first of these conditions

---

mente zuerst erschweren, endlich unmöglich machen;" and he states further that this condition as it occurs after camp dysentery has been figured by MATT. BAILLIE—*Series of Engravings &c., to illustrate the Morbid Anatomy*, &c., Fasc. IV, Pl. III, Figs. 1, 2, 3, 2d Ed., London, 1812; but an examination of this plate shows that it represents merely the thickening, ulceration and coarctation of the bowel common in chronic dysentery, without evidences of any tendency whatever to stricture. G. A. RICHTER—*Die spec. Therapie*, Bd. II, Berlin, 1821, S. 117—in like manner speaks of induration of the intestine, "Verhärtung und Desorganisation des Darmkanales," as one of the sequelæ of dysentery, and adds that obstinate constipation which nothing can relieve is one of the consequences: "Die Folgen davon sind hartnäckige Verstopfungen, die keinem Mittel weichen, Knoten an dem After, blinde Hämorrhoiden, etc." WANDESLEBEN, [*op. cit.*, in last note,] whose dissertation is rich in references, cites the two foregoing passages in support of his statement that dysentery is one of the causes of stricture of the rectum, and adds as a third authority STOLL—*Rat. Med.*, T. III, Vienna, 1780, p. 292;—but this reference is even less fortunate than the others. The passage referred to simply mentions induration and rigidity of the intestinal coats as one of the consequences of chronic dysentery: "Cadavera horum phlogosin chronicam, et duritiem, rigiditatemque intestinorum potissimum crassorum monstrabant."

* JAMES ANNESLEY—*Diseases of India*, London, 1828, Vol. II, p. 348. "Constriction of a part or parts of the colon, most frequently of the left arch, descending colon, and sigmoid flexure, are amongst the most constant appearances observed upon examinations after death from the chronic forms of the disease now before us. These constrictions may be few or they may be many,—they are often of limited extent, resembling the ligature made by a cord, and frequently embrace a large portion of the bowel." To this passage the note, "See Plates 26, 36, and 37." Now the case which furnished the specimen represented in plate 26 was one of acute dysentery, (p. 98,) dead on the 20th day, in which the patient had general peritonitis, and the constrictions were conditioned partly by the lymph deposits, partly by irregular contractions of the muscular coat. That represented in plate 36 was from a case of acute dysentery, (p. 176,) dead on the 12th day of the disease. The mucous membrane of the colon was inflamed and ulcerated; the constrictions appear to have been due to irregular contractions of the muscular coat. The specimen represented in figs. 1 and 2, plate 37, was from a patient who had suffered from frequent attacks of dysentery, and who had "chronic diarrhœa" until his death. The constriction, which involved the descending colon and the rectum, appears to have been of the same character as that in the last mentioned case. Finally, the colon represented in the 3d figure, plate 37, was from a case of "chronic diarrhœa after acute dysentery," (p. 363.) There is no record of any constipation or obstruction of the bowels; the contractions in the colon were probably of the same nature as those in the last case, and the mucous membrane of the colon was "ulcerated" and "excoriated;" it is represented in plate 38. ANNESLEY speaks of these constrictions as strictures, and remarks: "A knowledge of the frequent occurrence of strictures in various parts of the colon, especially in its descending and sigmoid flexures, is of the utmost consequence in practice." He thinks that "stricture of the rectum is not so prevalent a complaint as is supposed by some," and that "the colon is much oftener affected than the rectum." I note, however, that in his account of the symptoms resulting from these strictures (p. 377) he nowhere mentions having observed complete obstruction of the bowels from this cause. Here, too, I may mention the narrowing of a portion of the intestinal canal which FINGER—*Die epidemische Ruhr*, Prager Vierteljahrschrift, 1849, Bd. IV, S. 133—observed, in the Prague hospital, in two fatal cases of dysentery, involving in one instance the cæcum, in the other the sigmoid flexure. FINGER attributed it to the cicatrization of the dysenteric ulcers, yet admitted that he was not positive that the appearances supposed to be cicatrices were actually such, remarking: "deutliche Vernarbung und Verwachsung der Schleimhaut mit der unterliegenden Haut war jedoch nirgend zu beobachten."

† C. ROKITANSKY—*Ueber Strictureu des Darmkanals*, Oesterr. Jahrb., Bd. XVIII, 1839, S. 13; *Der dysent. Prozess*, Id., Bd. XX, 1839, S. 89; and the several editions of his *Lehrb. der Path. Anat.*

‡ In his original essay on the dysenteric process and in the first edition of his *Pathological Anatomy* [see transl. of Sydenham Society, Vol. II, London, 1849, p. 86] these processes are both described as occurring after dysentery, the second being said to occur also after catarrhal ulceration, [*op. cit.*, p. 65.] In the last edition of his *Lehrbuch*, Bd. III, Vienna, 1861, S. 203 u. 209, he adopts the view mentioned in the text, but adds that dysentery may leave behind it a chronic catarrh which may eventuate in cicatrices with coarctation (Verengerung) of the intestine quite like those which occur in other cases of catarrhal ulceration.

is characteristic of diphtheritic dysentery, the second of the ulceration which occurs in chronic catarrhal inflammation.

Just how many cases served as the basis for these descriptions the great pathologist has nowhere told us. So far as I know, he has only published the details of a single case,* which, it may be added, is one of particular interest as showing the great length of time that may elapse after dysenteric destruction of tissue before the resulting stricture produces a fatal result. In this instance the patient survived the dysenteric attack for about thirty years, during which he continually suffered from various abdominal troubles, chief among which was obstinate constipation, before the occlusion finally became so complete as to terminate in his death. But whatever the number of cases on which Rokitansky based his descriptions, comparison with the few that have since been published leaves no doubt that they are faithfully drawn from nature, and hence it is the less to be regretted that even to the present day they have been so generally borrowed by the text-books, some of the most pretentious of which find little of value to add to these graphic sketches.†

Nowhere have I found any attempt made to reunite the isolated cases of stricture of this kind which are scattered through modern literature. I have sought for information in the principal monographs and dissertations which either treat exclusively of strictures of the alimentary canal or some part of it, or deal with that subject as a branch of some more general theme, such as intestinal obstruction, diseases of the rectum and the like; but many, even of those which have appeared since the publication of the observations of Rokitansky, are quite silent on this head, and the majority of those who mention it at all deal with it in a cursory or superficial manner.‡ I have myself made an attempt to collect the individual cases of this kind scattered through medical literature, but have not been

---

* The case referred to will be found on p. 37 of the paper on intestinal stricture, cited in note †, p. 506. The patient was 60 years old, and had suffered from dysentery almost 30 years before while in the military service. The stricture, which was of the first kind described in the text, was situated at the commencement of the colon, not far from the ileo-cæcal valve. I note that in this paper ROKITANSKY expressly states that he had up to that time seen 32 cases of cancerous stricture of the intestine, but he mentions no figures in connection with the dysenteric strictures.

† In illustration, I may refer to the recent treatment of this subject by O. LEICHTENSTERN—*Verengerungen, Verschliessungen und Lageveränderungen des Darms*, Ziemssen's Handb., Bd. VII, 2, Leipsic, 1876, S. 515; Amer. transl., Vol. VII, New York, 1876, p. 628—who borrows pretty much his whole description from ROKITANSKY, though he only refers to him as authority for the statement that "the symptoms of constriction may first appear only many years—thirty years in a case of Rokitansky's—after the attack of dysentery, and then cause death by occlusion." This citation, however, is not very accurate, for, in the case referred to, I suppose the obstinate constipation which pursued the patient from the time he had dysentery till he died, and the other abdominal symptoms (Unterleibsbeschwerden) from which he never ceased to suffer, must be regarded as "symptoms of constriction." Nor is LEICHTENSTERN more fortunate in some of his few other citations. I have already commented on the mode in which he cited RHODIUS from MONRO, (see note * to p. 505, *supra*,) and shall have occasion to refer to his citation of MECKEL from MONRO a little further on, when his citation of HABERSHON will also be criticised. I will merely add here that his reference to a picture in ALBERS—*Atlas der path. Anat.*, Abth. IV, Bonn, 1862, Taf. XIII, Fig. 5–9—as an illustration of dysenteric stenosis is no more fortunate than the rest. ALBERS makes no mention that the man from whom the specimen was taken had ever suffered from dysentery, but simply says that he died of ileus: "Der Darm ist einem erwachsenen, an Ileus verstorbenen, gemüthskranken Manne entnommen." *Erläuterungen zu dem Atlasse der path. Anat.*, Abth. IV, 2, Bonn, 1862, Erklärung der Tafeln, S. 114.

‡ I will not attempt a complete list of works on the subject referred to in the text; but having examined a number of them with the result mentioned, I have thought that an enumeration of those consulted with this result would furnish a useful indication of the rarity of the condition under consideration. The following, published since the year 1800, but before the first publication of ROKITANSKY, are silent with regard to strictures of the intestine from the contraction of dysenteric cicatrices: C. G. LEHMANN—*Diss. de obstructione alvi*, Jena, 1820. T. COPELAND—*Diseases of the Rectum and Anus*, 3d Ed., London, 1824. G. CALVERT—*Diseases of the Rectum and Anus*, London, 1824. F. SALMON—*Stricture of the Rectum*, London, 1828. F. HOSPITAL—*Essai sur l'occlusion des intestins*, Paris Thesis, No. 165, 1830. N. D. BONNET—*De l'étranglement de l'intestin dans la cavité abdominale*, Paris Thesis, No. 246, 1830. The same may be said of the following, published since the appearance of the observations of ROKITANSKY: BENJ. PHILLIPS—*Obs. on intestinal obstructions depending on internal causes*, Med. Chir. Trans., Vol. XXXI, 1848, p. 1. S. FOSTER HAVEN—*Statistics of 258 cases of intestinal obstruction, with remarks*, The Amer. Jour. of the Med. Sciences, Vol. XXX, 1855, p. 351. WILLIAM BRINTON—*Intestinal obstruction*, London, 1867; a posthumous work. BRINTON analysed 600 necropsies of obstruction of the bowels; HAVEN, 258; PHILLIPS, 169, of which 136 had been previously published. None of these writers have taken the trouble to give references to the published cases used, hence their figures can neither be verified, nor can it be told how far one includes the cases of the others. They may have included cases of stricture after dysentery, but, from the mode in which their material is arranged, it is impossible to say. I may add to this list two valuable papers based on an examination of the necropsy records of two London hospitals, viz: C. H. FAGGE—*On intestinal obstruction*, Guy's Hospital Reports, Vol. XIV, 1869, p. 272, and W. W. WAGSTAFFE—*On intestinal obstructions*, St. Thomas's Hospital Reports, Vol. IV, 1873, p. 179. FAGGE'S paper contains the histories of 77 cases of intestinal obstruction, 22 of which were due to cancerous and other strictures, but none of them consecutive to dysentery. WAGSTAFFE'S paper contains abstracts of 18 cases of intestinal obstruction, 4 of them simple strictures, two of which, cases 5 and 16, are said to have been the result of "old cicatrices," but no mention of dysentery is made. The following contain more or less satisfactory allusions to the subject: CÆSAR H. HAWKINS—*Case of stricture of the colon with an analysis of 44 cases of artificial anus*, Med. Chir. Trans., Vol. XXXV, 1852, p. 85—mentions incidentally a case of supposed stricture following dysentery. *Vide infra.* GEORGE POLLOCK—*Intestinal obstructions*, Med. Chir. Review, Vol. XII, 1853, p. 315—mentions "contractions of cicatrices following ulcerations" as producing one form of non-cancerous stricture. This paper is interesting as containing abstracts of 32 cases of intestinal obstruction

very successful. The time at my disposal and my access to books have not been such that it has been possible for me to make an exhaustive research, nevertheless the laborious examination which I have actually made has covered ground enough to make the very barrenness of the results of value as showing the rarity of the conditions in question. The subject is one which might well be made the theme of a special investigation, and I trust the contribution here offered may serve to suggest such a work to some student possessed of the time and opportunity necessary to make it thorough.

I have found quite a number of cases, which I have not, however, attempted to collect, of non-cancerous stricture of the colon and rectum, in which the attention of the reporter appears to have been so engrossed by the stricture, and the surgical and other devices employed for its treatment, that no mention is made of the previous history of the case. In the records of the autopsies of such cases we are not unfrequently told that the stricture resulted from the contraction of a cicatrix, but there is nothing to show that the mucous membrane has been examined for other cicatrices, and no such description of the lesion is given as would serve to determine whether the ulcer which cicatrized resulted from dysentery or from some other form of disease, (*e. g.*, tubercular ulceration, etc.) Even in those cases in which there is a clear record of antecedent dysentery the report is often by no means as satisfactory as could be desired, and it is usually quite impossible to decide from it whether the cicatrices resulted from diphtheritic or catarrhal ulcers.

I find a small number of specimens of stricture following dysentery described in the printed catalogues of British pathological collections,* references to which I subjoin in the foot note, and a single American specimen in the catalogue of the pathological cabinet of the New York hospital.† I doubt not that a certain number of specimens exist also in the

from the Transactions of the Pathological Society of London, none of which appear to have been consecutive to dysentery. A. A. L. PERRET—*Essai sur les rétrécissements du rectum dus a l'inflammation*, Paris Thesis, No. 325, 1855, p. 33. R. QUAIN—*The Diseases of the Rectum*, 2d Ed., London, 1855—In his section on stricture, has an interesting account of "the cases in which the narrowing of the bowel results from the cicatrization of an ulcer," p. 184 *et seq.*, and gives one case (not fatal) in which dysentery was the cause, (p. 193.) A. P. DUCHAUSSOY—*Anat. path. des étranglements internes*, Mém. de l'Acad. Imp. de Méd., T. XXIV, Paris, 1860, p. 97—an elaborate work, to which a copious bibliography is appended, and in which "rétrécissements cicatriciels et rétrécissements inflammatoires," including syphilitic strictures, are treated under a single head, (p. 264.) T. J. ASHTON—*Diseases, Injuries and Malformations of the Rectum and Anus*, 3d Ed., London, 1860, p. 304—says: "Dysentery and diarrhœa, particularly when neglected or improperly treated, will lead to the formation of stricture, and it may also result from the cicatrization of ulcers attending the former disease. Since the last edition of this work I have had two medical men under my care, with stricture resulting from dysentery. One was an army surgeon, who suffered severely while with the army in the Crimea; the other came from the West Indies, where he had long resided." No further particulars of these cases are given. T. B. CURLING—*Obs. on the Diseases of the Rectum*, 3d Ed., London, 1863, p. 119—relates a case of stricture of the rectum following chronic dysentery, and remarks: "Though contractions in different parts of the large intestines have been noticed by pathologists who have investigated chronic dysentery in warm climates, this disease is by no means a common cause of stricture of the rectum." P. GRUENDLER—*Diss. de enterostenosi*, Berlin, 1864—enumerates among the causes, p. 6, "2, aut cicatrices in tela mucosa et submucosa ex ulceribus, imprimis ex ulceribus dysentericis ortæ, quæ quidem Frerichs sæpius apud nautas multum in maribus ad meridiem spectantibus versatos observavit." I do not know that FRERICHS ever published any such statement, which I suppose to be the mere hearsay of the lecture-room. R. BURKART—*Diss. über Mastdarmstenosen*, Bonn, 1869—says, speaking of cicatrix strictures, (Narbenstriktur.) that all catarrhal and diphtheritic conditions of the mucous membrane (as in cholera and dysentery) may give rise to stricture, and that the cicatrix arising from the healing of the diphtheritic ulcer is especially characterized by its tendency to retraction. W. H. VAN BUREN—*Diseases of the Rectum*, New York, 1870—like CURLING, emphasizes the comparative rarity of rectal stricture after dysentery, (p. 106.) See also J. SCHÜTZ—*Med. Casuistik*, Pragne, 1872, S. 140—Impermeabilität des Darms durch Darmstenose; and ANDR. VON HÜTTENBRENNER—*Die Darmstenosen im Kindesalter*, Jahrb. für Kinderheilkunde, Bd. IX, 1875-6, S. 25—who remarks on the rarity of stricture after dysentery in children, and thinks narrowing of comparatively long portions of the colon from the cicatrization of numerous follicular ulcers more frequent.

* *Catalogue of the Anat. Museum of the Univ. of Edinburgh*, 1831, I, 63, p. 66. *Catalogue of the Museum of the Army Med. Dept., Fort Pitt, Chatham*, London, 1833, Div. IV, No 84, p. 102. *Catalogue of Anat. Preparations in the Hunterian Museum, Univ. of Glasgow*, 1840; great intestines R., Nos. 43, 44 and 45, (from one case,) p. 73. *Descriptive Catalogue of the Anat. Museum of St. Bartholomew's Hospital*, Vol. III, London, 1862, Part I, Series 16, No. 116, p. 110, and No. 126, p. 112. *Appendix to the Path. Catalogue of the Museum of Guy's Hospital*, London, 1863, p. 55, No. 1884[35], is most probably from a case of chronic dysentery; the record is, "Inflammatory stricture and ulceration of the rectum undergoing cicatrization. W. R., aged 37, entered the hospital in a dying state; his disease was found to be phlebitic abscess of the liver, dependent upon an ulcerated condition of the intestine." *Catalogue of the Path. Museum of St. George's Hospital*, London, 1866, Series IX, No. 159. p. 441. There are besides a rather larger number of cases in these catalogues in which the stricture is said to have followed ulceration, or to have resulted from a cicatrix, but with nothing to show whether the ulceration was caused by dysentery.

† The only American specimen of which I have found notice in any printed catalogue is in the *Catalogue of the Pathological Cabinet of the New York Hospital*, New York, 1860. Digestive system, No. 467, p. 205. "Stricture of the rectum, following tropical dysentery. * * * The constriction commences about an inch above the anus, and is also an inch in length. * * * Immediately surrounding the stricture, and extending for some distance above and below it, there exists a great thickening of the tissues, so that the walls of the gut are nearly an inch in thickness. In the constricted portion, which would admit a No. XII catheter, and also a short distance above it, are seen several ragged superficial ulcers of the mucous membrane." No microscopical examination of the thickened tissue was made.

great modern pathological collections on the continent of Europe, but know of no printed catalogues of these treasures. I have also found reports of a few cases in which various modes of treatment are alleged to have been successfully employed, or in which, the reporter having lost sight of the patient, the termination of the case is unknown, as well as a few in which death resulted and a more or less satisfactory account of the autopsy is given. References to these cases are subjoined in a foot note.*

It seems reasonable enough to suppose that dysenteric cicatrices might serve, as other cicatrices sometimes do, as the point of departure for subsequent carcinomatous development, but I have been unable to find an unmistakable case of this pathological sequence. In the few that might at first be supposed to bear this interpretation, an examination of the record makes it more probable that cancer was the primary disease, and that the dysenteric symptoms resulted from the irritation set up by the morbid growth.†

* Here I may mention the case, reported by HAWKINS, [p. 111, *op. cit., supra*, p. 507,] "of a gentleman, 76 years of age, who had suffered from dysentery in a tropical climate, which had probably produced contraction of the colon below the liver." The patient died, but there was no autopsy. G. M. HUMPHRY—*Three cases of stricture of the rectum treated by incision*, Association Medical Journal, Jan., 1856, p. 21. Case 1 followed dysentery; the patient was lost sight of, and its termination is unknown. The same is true of a case of OPPOLZER'S, reported by B. LONDON—*Dysenteria cum strictura ani*, Oesterreich. Zeitschr. für Prakt. Heilk., IX Jahrg., 1863, S. 794. Here belong also the two cases reported by ASHTON, [*loc. cit., supra*, p. 508,] the results of which are not stated. In the following cases cures are said to have been effected, or great amelioration in the symptoms produced: GEORGE BUSHE—*Treatise on the Malformations, Injuries, and Diseases of the Rectum and Anus*, New York, 1837, p. 260—mentions the case of a lady who, six years before, "had an attack of dysentery, in consequence of which, lymph was effused on the mucous membrane within the internal sphincter, and gave rise to such adhesions, that when I first examined her, I could not introduce my little finger. However, by the use of the bougie, and castor oil, I am happy to say, that the orifice is now nearly of its proper size." RICHARD QUAIN—*The Diseases of the Rectum*, 2d Ed., London, 1855, p. 193—a case of rectal stricture said to have followed chronic dysentery of two or three years' duration treated by solid and membranous bougies. The latter is described (p. 217) as "a membranous tube for fluid pressure," which "may be distended with air or water." The patient was discharged greatly benefited. JOLLIFFE TUFNELL—*Practical remarks upon stricture of the rectum*, &c., Dublin Quart. Jour. of Med. Sci., Vol. XXX, 1860, p. 53—reports a case following dysentery said to have been cured by the use of a special form of tubular bougie. HORACE NELSON—*Stricture of the rectum*, &c., The British American Journal, Vol. II, 1861, p. 302—reports the case, observed at Plattsburg barracks in 1850, of a soldier of the 4th U. S. infantry, whose stricture was the sequel of chronic dysentery contracted during the Mexican war. A cure is said to have been promptly effected by division by the knife. JOHN SCOTT—*Two cases of severe stricture of the rectum*, California Medical Gazette, July, 1869, p. 229—reports two cases, said to have followed dysentery, treated successfully by forced dilatation. WILLIAM ALLINGHAM—*Diseases of the rectum*, 2d Ed., London, 1873, p. 191—reports a case of stricture of the rectum in a patient who had "suffered from both diarrhœa and dysentery," said to have been cured by bougies. Here belong also the cases of Med. Inspector PHILIP S. WALES, U. S. Navy, cited above, [note to p. 504.] In the following fatal cases the correctness of the diagnosis was established by post mortem examination: ROKITANSKY—Case cited in note * to p. 507, *supra*. BAUDENS—*Leçon sur l'anus artificiel*, [Hopital Militaire du Gros-Caillou,] Gaz. des. Hôpitaux, Vol. IV, 1842, p. 227—relates a case in which stricture of the rectum followed chronic diarrhœa (dysentery?) in a soldier. The *Trans. of the New York Path. Society*, Vol. II, New York, 1877, contains reports of two cases of stricture of the rectum consecutive to dysentery, viz: "Case 13, by Dr. T. M. MARKOE, 1850," p. 163, and "Case 17, by Dr. L. A. SAYRE, 1852," p. 164, of which further particulars will be found in the New York Med. Times, Vol. II, 1853, p. 175; this patient, a man, had also suffered from syphilis, which complicates the question of etiology. T. B. CURLING—*Obs. on the Diseases of the Rectum*, 3d Ed., London, 1863, p. 119—relates a case of "ulceration of the rectum from chronic dysentery, terminating in a double stricture of the gut." The patient was a sailor, age 31. J. C. MESSER—*Organic stricture of the rectum*, Trans. of the Path. Society of London, Vol. XI, 1859-60, p. 111—reports a case of stricture of the rectum following dysentery, in which the immediate cause of death was ulceration and perforation of the cæcum. The patient was a man, age 79. S. O. HABERSHON—*Dis. of the Abdomen*, 2d Ed., London, 1862, p. 412—relates two cases. In the first, case 172, the patient, a sailor, age 33, after recovering from dysentery, was accidentally killed. At the commencement of the rectum the calibre of the bowel was found greatly diminished by the contraction of cicatrices. It is not stated whether any inconvenience had been experienced from this condition. In the second, case 173, the patient, a young gentleman "who had had syphilis many times," after recovering from dysentery was troubled by habitual constipation, and a stricture could be felt at no great distance from the anus. It was treated by dilatation with temporary benefit, but subsequently an abscess formed in the left iliac region, fistulæ resulted, and the patient died. "Numerous traces of old ulceration" were found in the sigmoid flexure, and much contraction of the intestine had been produced by the cicatrization. Above the contracted parts ulceration had set in, and the intestine had been perforated at three or four points. This had given rise to the abscess-formation, but "fæces do not appear to have been discharged" through the fistulæ. H. M. MADGE—*Case of intestinal obstruction*, &c., The Lancet, Vol. II, 1869, p. 80—reports a case of stricture at the upper part of the sigmoid flexure consecutive to diarrhœa (dysentery?) in a woman; post mortem examination showed that it was "due to the cicatrization of a former ulcer." C. E. A. PINGUET—*Des Rétrécissements du rectum*, Paris Thesis, No. 17, 1873, p. 29—reports a case of stricture of the rectum in a woman, aged 28, who had dysentery 12 years and ribbon-like stools for 7 or 8 years. CASTEX—*Rétrécissement dysentérique du rectum*, Bull. de la Soc. Anat. de Paris, An. LI, 1876, p. 684—reports a case of rectal stricture in a woman, aged 33, who suffered from chronic dysentery of a year's duration.

† Thus Dr. BENJ. MCCREADY, in 1857, exhibited to the New York Path. Soc.—Trans., Vol. II, 1877, p. 161—a specimen of cancer of the rectum in a woman, aged 71, who "had signs of chronic dysentery for two years," without impaired general health, which appear to have been due to cancer of the rectum. Eighteen months before her death "emaciation, debility, and sallowness set in," followed by the passage of fæces and flatus from the vagina. On the autopsy the rectum was found to terminate "in a kind of cloaca, including the upper part of the vagina, with thickened walls," and there were numerous secondary cancer nodules in the liver. This case recalls that long ago reported by AMATUS LUSITANUS, see note ‡ to p. 505, *supra*. I may refer in this connection to a case reported by S. O. HABERSHON—p. 518, *op. cit., supra*—to whom it was communicated by WILKS, of a man, 72 years old, in whom death occurred from a stricture of the transverse colon due to a morbid growth "approaching in character the so-called villous cancer." He comments on this case as follows: "Simple acute disease of a dysenteric character took place in this patient, ulceration followed, and, at the seat of one of these ulcers a villous growth was developed, which led subsequently to constriction," (p. 520;) and again: "The first symptoms were those of dysentery, as shown by the diarrhœa and the discharge of mucus," (p. 521.) Now I note in this case 1st, that the "first symptoms" referred to took place August 11, 1855, and the man died August 29th. The microscopical characters of the tumor are pretty well described, and correspond with what we know of cylindrical epithelioma, which is prone to luxuriate superficially into papillary (villous) forms. Is it at all probable that, as HABERSHON assumes, dysentery should give rise to ulceration, ulceration to cicatrization, and that such a growth as is described should be subsequently developed, all in the brief period of 18 days? Is it not much more likely that the villous growth was an old affair, and that the so-called dysenteric symptoms resulted from it? I point out that in the preliminary history we are told that during the few years preceding this last illness the patient had "suffered at frequent intervals

Peritoneal bands and adhesions, the result of local or general peritonitis, occurring during the progress of either acute or chronic dysentery, may also give rise to subsequent obstruction of the bowels. This may happen in several ways: Plastic lymph, effused during peritonitis, may subsequently contract and produce coarctation of the intestinal canal at one or more points;* or adhesions between adjacent knuckles of the intestines may give rise to obstruction, especially if the adhesion is between displaced portions of the colon;† or peritoneal adhesions may take the form of bands by means of which knuckles of intestine may be incarcerated. An interesting case of the latter accident is reported in the treatise of Savignac.‡ Intestinal obstructions produced in these ways are probably even more frequent than strictures from the contraction of ulcers,§ but the possible connection of dysentery with the etiology does not appear to have received the attention it deserves; and indeed the nature of the accident is often first recognized on dissection, when it is not always possible to obtain a complete antecedent history.‖

POST MORTEM APPEARANCES IN CHRONIC DYSENTERY.—The lesions recognizable in the intestinal canal of those dead from chronic fluxes may be referred to three groups, which may exist either singly or variously combined. These are: 1, Chronic inflammation of the mucous and submucous coats of the intestines, especially of the large intestine, without ulceration. 2, Chronic inflammation accompanied by follicular or other ulcers, especially in the large intestine; in these cases the pathological picture is often complicated by the development, just before the fatal issue, of diphtheritic inflammation between the ulcers. 3, Extensive ulceration of the large intestine, the result of sloughing during a previous attack of acute diphtheritic dysentery. The first and third of these conditions have been

from diarrhœa, with colicky pains in the abdomen, and often from painful defecation. His bowels were at times so irritable that, after swallowing only a cup of tea, it seemed at once to pass through them, almost before he could reach the closet; these symptoms became increasingly severe." Here is unmistakable evidence of an old intestinal trouble. LEICHTENSTERN *(loc. cit.*, note †, p. 507, *supra)* cites this case as an example of the error of mistaking the polyp-like puckering of the mucous membrane around the edges of certain dysenteric cicatrices (see p. 506, *supra)* for cancer, which he says was frequent in the older literature: "In der älteren Literatur häufig als Skirrhus beschrieben. Meckel, Entr. Comment. Leipz. T. XV.—Monro, l. c., p. 155. Vergl. Habershon, l. c., p. 385." In the passage here cited HABERSHON refers to the case discussed above in the following words: "Dr. Wilks has informed me of a case in which the cicatrix presented a growth at its margin, evidently of a carcinomatous character, indicating a greater tendency to heterologous deposit in the new tissue." Now clearly LEICHTENSTERN has cited this passage without seeing the history of the case referred to in it; nor are his two other citations more fortunate. MONRO, in the passage cited, expresses no personal opinion, but simply cites MECKEL: "Scirrhous Tumours have been described by MECKEL, as being sometimes found within the Colon in cases of Dysentery†." To which the note: "† Vid. Meckel, extra Comment. Leipsick, Tom. XV." The reference to MECKEL is misprinted by LEICHTENSTERN, and he does not appear to have verified it; had he done so he would probably have modified it, for I have searched Vol. XV of the Leipsic Commentaries (Commentarii de Rebus in Scientia Naturali et Medicina Gestis, T. XV, Leipsic, 1768–70) in vain for the statement referred to.

* An illustrative case will be found in the *Transactions of the New York Pathological Society*, Vol. II, New York, 1877, p. 148, case 1. The case was reported to the society by Dr. ERSKINE MASON, Jan. 28, 1874; see also The Medical Record, Vol. IX, 1874, p. 209. The patient, a man 76 years old, had two and a half years before suffered from a severe attack of dysentery. Six months after he recovered he was seized with violent pain in the bowels, which recurred at intervals. Ultimately, symptoms of rectal stricture were developed, and lumbar colotomy was performed with temporary relief. Subsequently, however, the symptoms indicated the existence of another stricture higher up, and the patient died. On the autopsy three strictures were found,—one near the caput coli, one in the transverse colon, and one less marked in the rectum, all due to peritoneal adhesions on the exterior of the bowel.

† A case illustrating this accident has been reported by SHAW—*Intestinal obstruction; operation for artificial anus*, Trans. of the Path. Soc. of London, Vol. IV, 1852–3, p. 147. The ascending colon was found in dissection to form a loop upon itself, and "the two portions lying parallel were firmly united by lymph to each other and to the adjacent parts." The patient was a laboring man, 63 years old, and the previous history is incomplete, but as we are told that the mucous membrane of the colon presented "many cicatrized ulcers," there is no reasonable doubt that the condition found had its origin in a previous dysentery. It is expressly stated that "no actual stricture was found in the colon."

‡ J. DELIOUX DE SAVIGNAC—*Traité de la Dysentérie*, Paris, 1863, p. 207, Obs. 2. Case of a naval officer who six years before had suffered from dysentery, in the Black Sea, and who died with symptoms of obstruction of the bowels. On the autopsy it was found that two knuckles of small intestine had been strangulated in a curious ring formed by an intestinal diverticulum 8 to 10 centimetres long, which had become bent upon itself, forming the posterior part of the ring, while its anterior portion was formed by a fibrous band, the result of an old peritonitis, which bound the extremity of the diverticulum to the mesentery. The author remarks: "La bride péritonéale qui complétait cet anneau s'était développée à proximité d'une coarctation intestinale due vraisemblablement à la cicatrisation d'anciens ulcères dysentériques. Il est probable aussi que, au voisinage des ulcérations intestinales, une péritonite locale et par propagation se sera déclarée, laquelle à son tour aura favorisé la formation de la bride, et ultérieurement son adhérence au mésentère."

§ On the frequency of obstructions from these bands and adhesions the reader may consult the essays of PHILLIPS, POLLOCK, HAVEN, DUCHAUSSOY and BRINTON, cited in note ‡ to p. 507, *supra*.

‖ Nos. 1247 and 1248, Med. Section, Army Med. Museum, illustrate this remark. The first exhibits obstruction of the ileum by peritoneal bands and adhesions; the second is a portion of the ileum, dilated, ulcerated and perforated, from just above the obstruction. The patient, a man 29 years old, had suffered at intervals for a year with symptoms of obstruction of the bowels. No anterior history could be obtained.

already so fully described as to require but brief mention in this place; the second will demand a more detailed account.*

Chronic inflammation of the mucous and submucous coats of the intestines without ulceration.—This process has been sufficiently described under the heading of inflammation of the intestinal mucous membrane without ulceration, in a previous portion of this section.† The points then dwelt upon may be briefly recapitulated, as follows: In these chronic cases the bright-red discolorations of acute inflammation are replaced by mahogany-red, brown, green, slate-color, ash-color, or other neutral tints of various hues; black, bluish, or brownish deposits of pigment are observed in the closed follicles, or in patches scattered over the mucous membrane of both large and small intestines, and in the apices of the villi of the latter, especially of the ileum. With these modifications of color, enlargement of the solitary follicles, and more or less thickening of the mucous membrane and submucous connective tissue, especially of the large intestine, are associated. The degree of this thickening varies with both the duration and severity of the case. In its appearance

* After Section II of this chapter was stereotyped I received an interesting letter from Dr. A. E. CAROTHERS, formerly Assistant Surgeon, U. S. Volunteers, giving an account of his observations in "a somewhat large number of autopsies" in cases of chronic diarrhœa during the civil war. Had I received this communication in time, I would have printed it in Section II. As it is, I have thought it of sufficient interest to present to the reader in this place. It may be compared with the reports of cases 842 to 851 in Section III, (p. 252–3, *supra*,) which are accounts of autopsies from the case-book of the Natchez hospital while Dr. CAROTHERS was in charge. It will be evident to the intelligent reader that the three classes of lesions enumerated in the text fell under the writer's observation, and that his description includes phenomena belonging to acute cases. "During my service with the Army of the Potomac and in the 'Defences of Washington,' nearly all of the cases I examined showed a diffuse inflammation of the colon, especially in its lower part, accompanied by thickening of the submucous cellular tissue and softening of the entire mucous membrane to such an extent as to admit of its being easily scraped off with the finger-nail. The solitary glands of the small intestine were seldom affected, the agminated glands frequently but not constantly inflamed, and even ulcerated. The glands of the colon were not affected sufficiently to attract any special attention; in fact, the seat of the disease seemed to be in the whole thickness of the mucous membrane and subjacent tissues, and not in the glandular structures, they being affected only secondarily, if at all. When I was ordered from Alexandria, Virginia, to Brownsville, Texas, in the spring of 1864, I was struck with the great difference of the autopsic phenomena presented by apparently the same disease. I found in nearly every case the condition described by TRIPLER in the Mexican war, viz., circumscribed excavated ulcers with well-defined edges, appearing as though cut out of the whole thickness of the mucous membrane with a punch. They had a dark ash-colored base, were most frequent in the upper portion of the colon, and as you passed downward were found to extend their area, retaining their well-defined margin, until by their coalescence they involved the whole calibre of the intestine in one large ulcer of the same character, accompanied with an enormous thickening of the walls of the gut, caused by deposits of lymph in the areolar tissue. In many of the older cases more or less complete cicatrization had taken place, especially in the lower part of the colon and rectum, and, by the contraction of the inodular tissue, had lessened the calibre of the bowel greatly. I have seen it but little larger than a goose-quill in some cases. In others, however, instead of pursuing this slow course, the ulcerative action became intensified at points, and penetrated to the peritoneal covering, which contracted inflammatory adhesions to whatever part it happened to be in contact with. Perforation sometimes ensued, when, if from an accident the adhesions gave way, extravasation and peritonitis caused rapid death. In one case I found four such perforations in the transverse colon, caused by adhesions to the omentum, and in another the ulcer had, in the sigmoid flexure, perforated both peritoneal surfaces, and penetrated over an inch into the subjacent muscle. But the chief point of interest lay in the cæcal portion, where the traces of disease seemed more recent. Here its primary seat seemed to be in the follicles, in which it could be traced with the naked eye through all stages from the small black point indicating the orifice, looking much like the black specks on the face in a case of acne, through congestion and inflammation, to ulceration commencing at the orifice of the follicle and ultimately destroying the entire gland, leaving in its place the excavated ulcers above described. * * * There was comparatively little disease in the small intestine, the glands of Peyer being inflamed sometimes, but seldom ulcerated. In fact, the healthy condition of the upper bowel was a subject of remark, when compared with the extensive disease of the colon. It is proper to remark in this connection that the troops among whom these cases occurred were almost universally affected with scurvy, and also that they had been serving at Vicksburg and Morganza, notably malarious places, before going to the Rio Grande. How far this condition of the glands of the large intestine may have been due to an attempt to eliminate one or the other of these poisons, is, in the present state of our knowledge of the physiology of the glands of the alimentary canal, difficult to determine; but I am inclined to the opinion that there is some connection between them, in view of the excretory function of the lower intestine, as contrasted with the absorbent action of the upper. In the fall of 1864 I took charge of the general hospitals at Natchez, Mississippi, where I found many of the class of cases just described, especially among soldiers who had served in Louisiana and Texas, but I also found a new class of morbid appearances, that of an erythematous inflammation of the mucous membrane, in which the primary lesion appeared as a bright rose-colored or red line surrounding a patch of the mucous membrane, from which the epithelium had entirely degenerated, and which appeared to have spread from a central point, like erythema-centrifugum or lichen circumscriptus, destroying the epithelium in its course. This denuded surface took on ulcerative action, attended with thickening of the coats of the bowel, coalescence of the patches, destruction of the mucous membrane, cicatrization, contraction, &c. These appearances existed mainly in the colon, and, if I remember aright, were accompanied with a species of exudation of pseudomembrane about the ileo-cæcal valve, and were much more rapid in their course than the others. Perforation sometimes occurred from gangrene of all the coats of the intestine, but usually involving large patches, and appearing to have resulted from the pressure of the lymph; deposited in the areolar tissue, obstructing capillary circulation. I have thus briefly and imperfectly presented, as I believe, three distinct lesions in this disease, encountered by me in different commands in widely separated parts of the country, the troops being exposed to different climates and zymotic influences, viz., the great exposure, incessant fatigue, and rigorous climate to which the 'Army of the Potomac' was exposed, coupled with the comparatively more luxurious life which its soldiers had previously led; the burning sands of the Texas coast, the absence of vegetables in the diet of the troops, and the consequent scurvy; and the moist heat and malarial dews of the Mississippi valley operating on the more hardy western men. In none of the cases examined by me did I discover hepatic abscesses, although I looked for them; but a constant phenomenon in all was great enlargement and induration of the mesenteric, and especially meso-colic glands; so much so as to resemble deposits of tubercle. This condition of these bodies must have greatly impeded the absorption of food into the system, or at least of certain articles such as the fats, and explains the great and progressive emaciation shown in those suffering from this disease. As to diagnosis, the question naturally arises whether it is possible to discriminate between these different forms of disease. I can only say that the cases were usually so far advanced by the time they were sent to a general hospital as to present the same list of symptoms in all cases." * * *

† See p. 296 *et seq.*, *supra*.

to the naked eye and the character of the histological changes it precisely resembles the thickening that occurs in cases of follicular ulceration. Hence the description to be presently given of that process, if read in connection with the remarks on chronic cases in the previous portion of the section just referred to, will give a sufficiently complete presentation of the anatomy of the non-ulcerative cases, and no further details with regard to this form of chronic inflammation are necessary in this place.

There is, however, a curious lesion occasionally encountered in such cases which deserves remark in this place. I allude to the development beneath the mucous membrane of small cysts containing a thick mucoid or glue-like fluid. These vary in size from $\frac{1}{10}$th to $\frac{1}{4}$th of an inch in diameter, and project from the surface in the form of hemispheres; they are sometimes observed in cases of well marked follicular ulceration, but also occur in cases in which no ulceration can be detected. The latter condition was noted in the specimen represented by the chromo plate facing this page. The patient was a confederate prisoner of war, who died of dysenteric diarrhœa of nearly three months' duration, which made its appearance while he was under treatment for a gunshot wound of the chest. The following is a brief history of the case:*

Case 899.—Private T. P. Coleman, company A, 19th Mississippi (confederate) volunteers; age 19; was wounded near Petersburg, Virginia, November 5, 1864, by a ball which passed through the lower portion of the left side of his chest, fracturing the eleventh rib and the transverse process of the eleventh dorsal vertebra, and probably wounding the lung. He was treated at first in a confederate hospital at Richmond, Virginia, and, May 6, 1865, was transferred to the hospital at Point Lookout, Maryland. Thence, July 24th, he was transferred to Armory Square hospital, Washington, D. C., and finally, August 17th, to Douglas hospital. The patient stated that on the reception of the injury he had a free hæmorrhage from the wound, spat blood and had great difficulty in breathing, but that he was doing well under treatment, when, about the beginning of June, while still at Point Lookout, diarrhœa set in and persisted in spite of treatment. When he entered Douglas hospital he was still suffering from diarrhœa, which was of a dysenteric character, and he was terribly emaciated. August 18th, the ball, which had lodged behind the tenth rib, about an inch and a half from the wound of entrance, was removed by Asst. Surgeon Wm. F. Norris, U. S. A. His dysenteric diarrhœa was treated by nitrate of silver, used both internally and by injection. He could hardly be prevailed upon to take beef tea or milk, which appeared to make him vomit, but he swallowed whiskey greedily, and it was freely administered. He was restless and noisy, but did not complain of dyspnœa, and had no cough. He sank rapidly, and died August 19th. *Autopsy* thirteen hours after death: The right pleural sac contained three ounces of sanguineous effusion, and there were old pleuritic adhesions on both sides. The lungs were crepitant, with the exception of the lower lobe of the left lung, which was converted into an abscess cavity containing detritus of lung substance, and the external walls of which were inseparably adherent to the costal pleura. The liver and kidneys were fatty; the spleen contained less blood than usual. The small intestine was pale; in the descending colon and the rectum the solitary follicles were enlarged, forming cyst-like vesicles the size of peas, with minute circular openings at their summits, and each containing a transparent gelatinous mass. History by Acting Assistant Surgeon Carlos Carvallo. [Specimens, viz: No. 660, Medical Section, and No. 1561, Surgical Section, (the injured ribs,) presented by Assistant Surgeon Wm. F. Norris, U. S. A.]

The diseased intestine was brought to the Museum immediately after the autopsy, and a water-color drawing, representing a portion of descending colon, was made by Mr. Hermann Faber; the chromo plate is a reproduction of this drawing. The colon was moderately thickened; the general surface of its mucous membrane was pearl-gray, with greenish and bluish streaks and patches. There were also a number of reddish patches in which congested bloodvessels could be distinctly recognized by the naked eye. The cysts varied in size from $\frac{1}{10}$th of an inch or less to $\frac{1}{4}$th of an inch in diameter; for the most part they were of a bluish color, which in the larger cysts became a dark indigo-blue. At the apices of some of them the yellowish contents shone through, or protruded through tiny circular orifices; these contents could readily be expelled by pressure, and resembled drops of warm boiled

* The history of this case is also given in the first Surgical Volume, p. 568. The account there presented differs from that in the text in stating the diarrhœa to have commenced "about the middle of June," and in speaking of the solitary glands of the colon as "ulcerated." The latter statement is certainly an error, as shown by the specimen, and the former is probably so, as the case-book of the hospital explicitly says "about the beginning of June." Both errors occur in the history, sent to the Museum with the specimens, from which the account in the Surgical Volume was taken, while the history as given above was extracted from the case-book of the hospital, which is the original record.

glue. The cysts were very unequally scattered over the mucous surface; in some places they were so close as to be in contact; in others they were an inch or more apart. No ulceration was detected anywhere. The minute anatomy of these cysts will be discussed in a subsequent part of this section.

A very similar specimen to that just described is represented in the plate facing page 514, which is reproduced from a photograph of No. 602, Medical Section, and represents the specimen after it had been preserved in alcohol for some time. The following history of the case was furnished by Acting Assistant Surgeon George K. Smith:

CASE 900.—Private Thomas Kelcher, company E, 28th Massachusetts volunteers; age 29; Irish; enlisted August 1, 1864. March 25, 1865, he received a gunshot fracture of the left thigh in action near Petersburg, Virginia. He was admitted to the depot field hospital of the Second Army Corps, City Point, Virginia, and on the 31st was sent on board the steamer State of Maine for transfer to Washington. He was admitted to Armory Square hospital, Washington, D. C., April 1st. On examination it was found that the ball had entered the external surface of the left thigh at the junction of its middle and lower thirds, and passing transversely inwards comminuted the femur, and made its exit on the internal surface opposite the wound of entrance. April 2d, he was etherized, the wound of entrance enlarged, and five fragments of bone removed. When admitted to Armory Square this man had an abscess at the lower border of the left popliteal space, caused by the pressure of the end of a splint which had been applied to the posterior surface of the thigh. This caused so much pain and soreness that he could not at first bear extension, but at the end of the month of April this trouble was so much better that he was able to bear extension well. May 10th, he was attacked with dysentery, the stools containing mucus but no blood, and this continued until his death, with the exception of two or three short intervals. June 15th, he was doing remarkably well; appetite good, tongue clean and bowels regular; but, July 1st, he had a return of the dysentery, which was not subsequently benefited by treatment. July 25th, the injured limb was attacked by erysipelas, and for a little distance around the wound, not exceeding half an inch at any point, it presented the appearance of gangrene. This was treated by the application of solution of bromine. The limb was considerably swollen, and the patient felt great pain near the ankle joint. July 29th, a large patch of the epidermis over the left ankle was raised, and the space beneath filled with dark-colored serum. The true skin presented the bluish color seen in the first stage of gangrene. This appearance continued to extend up the limb until his death, on the following day. The night before his death he had a severe pain in his left side, indicative of pleurisy. *Autopsy* 8 hours after death: Rigor mortis well marked The apex of each lung was studded with tubercles. The posterior surface of the lower part of the left lung was covered with lymph, and the pleura at this point was highly inflamed. The heart was normal; the stomach and small intestine were also normal. The mucous membrane of the large intestine throughout its whole extent presented numerous ulcers about a quarter of an inch in diameter, and in the descending portion there were a large number of cysts containing lymph, some of which appeared to be undergoing ulceration, while others, already perforated, were filled with pus. The femoral and iliac veins of the injured side were completely filled with a firm fibrinous clot extending from the knee to the vena cava ascendens. The fractured femur was firmly united, with three-quarters of an inch shortening. [Specimens Nos. 602 and 603, Medical Section, are portions of the colon in this case, and No. 1105, Surgical Section, is the fractured femur.]

The large intestine from this case was brought to the Museum immediately after the post mortem examination. When received its mucous surface was of a pale cream color, with livid bluish discoloration around the cysts. These contained a semi-transparent yellowish matter resembling calves'-foot jelly, in which, with the microscope, a few delicate nucleated cells resembling the white corpuscles of the blood were observed to be imbedded. This substance was undoubtedly what is described as pus in the history of the case given below. Many of the cysts had ruptured and their contents escaped, leaving cavities resembling follicular ulcers. I found no other ulcers in any part of the specimen. The specimen, No. 602, Med. Section, represented in the photo-plate, is a portion of the transverse colon, exhibiting some fifty of the cysts described; the action of the alcohol has caused them to collapse, but their position and dimensions can still be recognized; several have so ruptured as to be converted into the cavities just described. No. 603, Medical Section, is a portion of the descending colon from the same case; it contains a small number of similar cysts, and also presents a number of small, irregular, oval cicatrices, such as result from the healing of follicular ulcers. A few of these cicatrices can also be recognized in the photo-plate by the help of a lens.

In both the cases just described the death of the patient was undoubtedly hastened by the gunshot wound. Similar specimens, however, are preserved in the Museum from two

other patients, in which this was not the case. The first is case 173,* an example of chronic flux, the exact duration of which is not recorded, but the patient was admitted to general hospital for "chronic diarrhœa" about two months before his death. He had pleurisy and limited pleuropneumonia on the left side, and was erroneously supposed to be suffering from phthisis as well as diarrhœa; he became extremely emaciated before death. In this case, besides cysts similar to those just described, follicular ulceration had taken place in the thickened colon, and the picture was still further complicated by the fact that the diphtheritic process had set in just before death, so that the lower fifteen inches of the ileum and much of the large intestine between the ulcers were plastered with pseudomembrane. Nos. 56, 57, 58 and 59, Medical Section, are portions of the colon from this case.

The remaining example of this cystic lesion is case 433,† in which the patient suffered from intermittent fever as well as a chronic flux; he died three months after admission to hospital for the treatment of his diarrhœa.‡ No. 527, Medical Section, is a portion of the colon from this case; in which, besides thickening of the colon and cysts similar to those in the previous cases, a number of follicular ulcers were found, and shreds of pseudomembrane adhered to the mucous surface between the ulcers and cysts, as if the diphtheritic process had commenced before death.

The peculiar cystic lesion exhibited in these cases was described and figured by Stark in 1766.§ A somewhat similar case is figured by Cruveilhier in his great work,‖ but the patient, although he complained of colic and digestive disorders, had no diarrhœa until a few days before death; on the contrary, he complained rather of constipated bowels: Cruveilhier believed the cysts to be seated in the solitary follicles. Still another case has been reported by Virchow,¶ which resembled Cruveilhier's in that some of the cysts were pedunculated, but the others in that the patient had suffered from a chronic flux. He found on making thin sections of the intestine in this case that the cysts were not seated in the solitary follicles, but resulted from cyst-like dilatation of the lower portion of the glands of Lieber-

---

‡ In the history of this case, on p. 186, private John Fulton, company B, 16th Pennsylvania cavalry, is reported to have been admitted to Emory hospital November 14, 1864, and died December 27th. Since printing that part of the work the following additional facts have been discovered: Private Fulton was admitted to the field hospital of the 2d division cavalry corps before Petersburg, Virginia, October 25, 1864. Diagnosis recorded "diarrhœa." October 26th, he was transferred to the depot hospital of the cavalry corps, City Point, Virginia, where he is again reported as suffering from diarrhœa. November 12th, he was transferred to general hospital.

§ WM. STARK—*Septem historiæ et dissectiones dysentericorum*, Leyden, 1766, Plate I, Fig. 2, and Plate II, Figs. 3 and 4. The patient was a woman, aged 27, who, after a quotidian remittent fever of two months' duration, was seized by a severe diarrhœa, of which she died about six weeks later. The lower part of the ileum and the whole large intestine presented considerable numbers of cysts, at the apices of which there was a pellucid point through which a translucent gelatinous matter could be expressed, [Hist. 2, p. 3.] In another case of chronic flux [Hist. 3, p. 8] in a man, aged 54, very many little round foramina with red edges, (follicular ulcers, or ruptured cysts,) and a few little hemispheres emitting a pellucid gelatine on pressure, (cysts,) were found in the colon. One of these, nearly half an inch in diameter, found near the anus, is figured in Plate II, Fig. 5.

‖ J. CRUVEILHIER—*Anat. Path. du Corps Humain*, T. II, Paris, 1835–42, Livraison 34, Plates 2 and 3. This remarkable case was originally published by BRIQUET, in the journal L'Institut Méd., July 15, 1839, under the title *Obs. d'adénite chronique avec altération spéciale des follicules muqueux du tube digestif*. The patient was a man 41 years old. The case was diagnosed during life as chronic enteritis. In the colored lithographic plates some of the cysts are bluish, and strikingly resemble those figured in the chromo plate facing p. 512, but many of them were pedunculated—an accident which was not observed in any of the cases in the text. Similar cysts were numerous throughout the whole small intestine. The patches of Peyer were thickened and of an indigo-blue color. The cysts were filled with a mucus resembling that which coats the intestines. The auther remarks: "j'ai été conduit à les considérer comme kystes muqueux, formés par le développement des follicules intestinaux." The plates illustrating this case have been copied by ALBERS—*Atlas der path. Anat.*, Abth. IV, Bonn, 1862, Tab. XI and XII.

¶ R. VIRCHOW—*Die Krankhaften Geschwülste*, Bd. I, Berlin, 1863, S. 243 and Fig. 39. The patient was a boy, aged 15, who died of chronic dysentery accompanied by liver cirrhosis and dropsy. The wood-cut is an excellent one. H. LEBERT—*Traité d'Anat. Path.*, T. II, Paris, 1861, p. 316; also Atlas, Plate 122, Figs. 1 and 2; and H. LUSCHKA—*Ueber polypöse Vegetationen der gesammten Dickdarmschleimhaut*, Virchow's Archiv, Bd. XX. 1861, S. 133; also Plate 3, have each described cases of chronic flux in which polypoid excrescences similar to those figured by CRUVEILHIER and VIRCHOW projected from the colon; but in their cases the polypi were solid, not cystic. In LEBERT'S case the little tumors were composed of a fibroid matrix in which elongated nuclei were imbedded; no glands were recognized in their substance. In LUSCHKA'S case naked roundish nuclei and nucleated cells, some of which had two nuclei, were imbedded in a partly fibrillated partly granular matrix, but a large part of each tumor was composed of the tubular glands of the intestine, (see Plate 3, Fig. 2.) VIRCHOW, *loc cit.*, speaks of these cases as *colitis polyposa*, and regards them as nearly related to his own case, which he describes as *colitis cystica polyposa*. LUSCHKA mentions that he himself has observed the cystic form in a girl 5 years old dead of chronic dysentery. VIRCHOW [*vide supra*] refers also to a case reported and figured by MENZEL—*Acta Med. Berol.*, T. IX, 1721, p. 78, and Fig. 4—which, however, I judge, from the curious etching by which it is illustrated, is rather similar to the cases of LUSCHKA and LEBERT than to the cystic forms. It is headed, "De excrescentiis verruceso cristosis copiosè in intestinis crassis dysenteriam passi observatis." The patient was a soldier who died of dysentery.

TRANSVERSE COLON WITH CYSTS.

No. 602. MEDICAL SECTION.

kühn, several of which usually coalesced to form one of the cysts seen with the naked eye. It will be shown further on that in our own cases the cysts also originated in these glands, but only after they had invaded the solitary follicles by a process which is of frequent occurrence in chronic intestinal catarrh.*

Chronic inflammation accompanied by follicular or other ulcers.—This process in its most exquisite development always involves the large intestine, but it sometimes extends for some distance into the lower part of the small. The development of the ulcers is preceded or accompanied by more or less thickening of the mucous and submucous layers, especially the latter, sometimes even of all the intestinal coats. When this thickening is considerable the colon is usually much contracted, so that its lumen is abnormally small, and when grasped by the hand during the autopsy feels hard and rigid. The contraction sometimes involves the whole length of the large intestine; in other cases it is limited to certain parts only, while others are preternaturally dilated. More or less extensive peritoneal adhesions very frequently bind the large intestine in these cases to the abdominal parietes or the adjoining viscera. In sections of such intestines cut perpendicularly to the mucous surface the several coats can be distinctly recognized by the naked eye, and the submucosa, sometimes the $\frac{1}{8}$th of an inch or more in thickness, presents a peculiar whitish translucent or lardaceous appearance which is quite characteristic. Two kinds of ulcers can usually be observed: follicular ulcers, and ulcers which originate independently of the closed follicles in the mucous membrane between them.

The *follicular ulcer* in its earliest stages may be recognized by the fact that it is seated at the apex of an enlarged follicle, where it appears as a tiny irregular excavation. At a later period the affected gland is entirely destroyed by ulceration, and the ulcer appears as a little cavity in the submucous layer which communicates with the surface by a constricted orifice. Subsequently the ulcer extends in the submucosa, undermining the mucous membrane, which perishes in proportion as its nutritive supply is cut off from beneath, and the orifice thus enlarges as well as the ulcer. Still later, adjoining follicular ulcerations often coalesce, forming large irregular excavations, by which, in extreme cases, a large portion of the mucous membrane of the colon is destroyed. These ulcers never present the beveled edges of those which result from diphtheritic sloughing, but always, unless complicated by this latter process, have overhanging edges, from the fact that they spread more rapidly in the submucosa than in the mucous membrane. Seen from the surface in their earlier stages the follicular ulcers appear as rounded or oval orifices $\frac{1}{10}$th to $\frac{1}{4}$th of an inch or more in diameter, which look almost as though they had been cut into the thickened intestine by a shoemaker's punch; and this abrupt character is observed also in the larger and more irregular ulcers which are found at a later stage of the process. Both these ulcers and those next to be described may be spoken of as catarrhal ulcers, to distinguish them from those resulting from the diphtheritic process.

Intestines invaded by follicular ulceration usually present a certain number of other *ulcers unconnected with the follicles.* These appear at first as superficial erosions by which more or less of the thickness of the mucous membrane is destroyed; ultimately, however, they invade the submucous connective tissue. They are generally quite small, but sometimes cover a considerable area. These larger ulcers are so similar to those which result from the separation of diphtheritic sloughs that it is sometimes quite difficult to distinguish

* See pp. 328 and 465, *supra*.

between them. There is a curious and by no means frequent variety of the smaller ones, in which they appear as superficial circular erosions around the solitary follicles, which remain intact as central eminences. No. 406, Medical Section, Army Medical Museum, is an example of this lesion. The specimen was obtained from case 310;* its microscopical characters will be commented upon hereafter.

Both the forms of colon ulcers described may invade the muscular coat, and, penetrating more and more towards the peritoneal surface, may finally perforate it, giving rise to fæcal extravasation. Both forms may also be observed in the lower part of the small intestine in some of the cases of chronic flux in which they exist in the colon. The follicular ulcers, which are usually associated with more or less thickening of the submucous layer and clavate hypertrophy of the villi, appear as small, rounded or oval punched-out depressions. Sometimes one or more of the follicles in a Peyer's patch are destroyed without material thickening of the rest of the same patch, which, however, is generally the seat of pigment-deposits, [see the plate facing page 302, which represents No. 600, Medical Section.] The non-follicular ulcers appear as irregular erosions of the mucous surface, of variable dimensions, by which the villi and a part or the whole of the glandular layer are destroyed.

In cases of chronic inflammation of the intestine, accompanied by follicular ulceration, the diphtheritic process frequently supervenes and complicates the pathological picture. We may thus see all stages of diphtheritic inflammation between the characteristic follicular ulcers. In very many instances this complication proves so promptly fatal that on post mortem examination only pseudomembranous frosting or patches can be seen, or at most a somewhat extensive pseudomembranous layer on the mucous surface between the ulcers; but occasionally the patient survives until sloughing occurs, and then it is almost impossible to distinguish the nature of the primary lesion. Finally, under favorable circumstances the catarrhal ulcers readily cicatrize, giving rise, when the ulcers are small, to peculiar stellate cicatrices, which are found not only, when opportunity occurs, after recovery from chronic fluxes, but also in fatal cases between the unhealed ulcers.

From the material at my disposal I have selected several specimens to illustrate the characteristic appearances of follicular ulceration of the colon.† The plate facing this page is reproduced from a photograph of No. 206, Medical Section, which is an exceedingly well marked specimen of uncomplicated follicular ulceration of the colon. The original memo-

* Page 151, *supra*.

† The earliest plates representing the follicular ulceration of the intestines of chronic fluxes that I have seen are those of WM. STARK, [*op. cit.*, p. 444, *supra*,] who has figured follicular ulcers of the colon in Plate I, Fig. 6, from a case (Hist. 5) of chronic flux in a soldier 50 years old, who had contracted the disease in the East Indies. Plate I, Figs. 7 and 8, of the same work, represents small follicular ulcerations of the ileum, some affecting individual follicles in a Peyer's patch, others the solitary follicles. The specimen was taken from the body of a sailor, 46 years old, (Hist. 7,) who had long suffered from a chronic flux; many similar ulcers and some large ones existed in the cæcum. Death was caused in this case not by the flux, but by obstruction of the bowels due to the development of a fungous growth in the rectum, the nature of which can only be conjectured. BAILLIE, [*op. cit.*, p. 444, *supra*,] Fasc. IV, Plate II, Fig. 4, gives a good representation of follicular ulcers of the colon from Mr. Hunter's museum—no history. ANNESLEY [*op. cit.*, p. 444, *supra*] gives two colored lithographs, which, I judge, represent follicular ulcers of the colon. Plate XXXII represents acute catarrhal dysentery with small follicular ulcers, and Plate XXXVIII represents a characteristic thickened colon with follicular ulcers from a case of chronic flux. CARSWELL [*op. cit.*, p. 444, *supra*] gives two colored lithographs, which illustrate follicular ulceration of the colon. The first—Softening, Plate II, Fig. 4—is a pale anæmic-looking piece with small ulcers, very similar to that from the case of J. Leonard, [see p. 517, *infra*.] No history of the case is given. The second—Melanoma. Plate IV, Fig. 3—I judge to represent large follicular ulcers with hæmorrhage into the cavities of the ulcers and the substance of the mucosa. The specimen is said to have been taken from a person who had long suffered with dysentery. GLUGE, [*op. cit.*, p. 444, *supra*.] Bd. II, Lief 18, Taf. 3, Fig. 4, gives a colored lithograph representing follicular ulceration of the colon, and LEBERT [*op. cit.*, p. 444, *supra*] gives in his beautiful Atlas six copperplate figures, two of them colored, which are, on the whole, the best of the representations enumerated. They are, Plate 116, Fig. 5, large intestine of a tuberculous woman, who also had Bright's disease; Plate 117, Fig. 7, colon from a case of chronic dysentery; Plate 118, Figs. 1 and 2, colon showing enlarged solitary follicles, as well as follicular ulcers, from a case of chronic dysentery; Plate 118, Figs. 3 and 4, described as dysenteric intestine, without stating whether the disease was acute or chronic. Observe the remarks at the conclusion of the note to p. 444, *supra*. I may add to the foregoing, two lithographic plates prepared to illustrate the Catalogue of the Medical Section of the Army Medical Museum, Washington, 1867. The first, facing p. 72, represents small follicular ulcers in the descending colon, from No. 64, Medical Section, [see case 134, p. 111, *supra*.] The second, facing p. 80, represents a portion of the colon, No. 224, Medical Section, [see case 266, p. 143, *supra*,] in which there are numerous minute follicular ulcers and five large irregular erosions formed by their extension. The mucous membrane between the ulcers is plastered with pseudomembrane.

Am. Photo-Relief Printing Co., 1002 *Arch St., Phila.*

FOLLICULAR ULCERATION OF THE COLON.

No. 206 MEDICAL SECTION.

randum has unfortunately been mislaid, and it is only known that the specimen was taken from the body of a soldier said to have died of "chronic diarrhœa" in one of the hospitals in Washington during 1863. The colon in this specimen is much thickened, and numerous follicular ulcers exist, which appear in the plate as round or oval orifices leading to dark cavities; they vary in size from mere points to the tenth of an inch in diameter, or larger. Near the centre of the piece some of them have coalesced, forming ulcers of greater size, the largest nearly half an inch in diameter; at the bottom of these larger ulcers the circular muscular coat of the intestine is laid bare.

The chromo plate facing page 518 represents a thickened anæmic-looking portion of colon, on the surface of which there are a great number of small follicular ulcers. The following is a memorandum of the case from which the specimen was taken:

CASE 901.—Private Jacob Leonard, 27th New York battery, while doing duty with his regiment in the army of the Potomac, was attacked with chronic diarrhœa, which was treated with variable success for several months. He finally broke down, and was admitted, August 28, 1864, to the field hospital of the first division, 9th army corps, where the diagnosis recorded was "dropsy," which had by this time become a prominent feature of the case, for, when the patient was transferred, August 31st, to the depot hospital of the 9th corps, City Point, Virginia, the diagnosis there entered on the register was "ascites and anasarca." September 8th, Leonard was sent north, and next day was admitted to Douglas hospital, Washington, D. C., where the diagnosis recorded was "scorbutic diarrhœa." He died September 16th. No further details of the case, or of the appearances observed during the autopsy, have been recorded.

The plate is a reproduction of a water-color drawing made at the Museum by Mr. H. Faber immediately after the autopsy. The mucous surface of the colon is of a pale cream color, with pale-bluish and reddish patches. The ulcers are numerous, and vary in size from mere points to the tenth of an inch in diameter. Nearly the whole of the colon was brought to the Museum, and the piece fairly represents the condition of all parts of it.

The chromo plate facing page 520 represents follicular ulcers of the colon fringed with pseudomembrane. The following is an account of the case:

CASE 902.—Corporal Ephraim Campbell, company D, 150th Pennsylvania Volunteers; age 24; was admitted to the field hospital of the first division, fifth army corps, near Petersburg, Virginia, September 12, 1864. Diarrhœa: for which he had been treated in his regimental hospital. September 14th, he was transferred to the hospital of the 3d division, fifth corps, and September 29th, to the depot hospital of the fifth corps, at City Point, Virginia, where the diagnosis recorded was fever. Thence he was transferred to Columbian College hospital, Washington, D. C., where he was admitted, October 30th, suffering from all the symptoms of chronic diarrhœa. He was extremely emaciated, pulse 110 and small; had five or six loose dejections daily, and no appetite. Ordered hot fomentations to be applied to the abdomen, with rest in bed, and a diet of boiled milk and beef tea. November 2d, he reports that he feels better than on admission, and begins to relish his food a little, but the diarrhœa continues unabated. ℞. Chalk mixture three ounces, fluid extract of ginger half an ounce, tincture of cinchona one ounce; take a tablespoonful three times a day; continue the hot fomentations; extra diet. November 6th: Since the last note the patient has been better, but to-day is worse again. His bowels are moved every hour, and the dejections are mixed with blood; pulse 110 and thread-like; abdomen tympanitic. His strength is less than yesterday; no appetite. Continue diet and treatment, with the addition of laudanum enemata. November 7th: The bowels are moved less frequently. The patient rested well last night, and has some appetite. Continue treatment. November 9th: Pulse 100; bowels again very loose, the dejections contain mucus and blood; appetite poor. Continue treatment. November 11th: The symptoms continue with little change, except that the patient complains of a dry cough at night; there is, however, no pain in the chest, and the respiration appears to be normal. Continue treatment, with the addition of a cough mixture containing syrup of senega and paregoric. November 14th: Pulse 96, skin dry and harsh, respiration 20 per minute, cough not so dry. The bowels were only moved twice since yesterday morning; appetite very poor. Continue treatment. November 15th: Pulse 108, respiration 32, bowels moved twelve times since yesterday morning; the dejections are bloody, strength failing, no appetite. ℞. Brandy four ounces, carbonate of ammonia two scruples; take a tablespoonful every three hours; beef tea. November 16th: Pulse 100, respiration 32, bowels very loose, strength failing fast. Continue treatment and diet. Died November 18th. *Autopsy* nine hours after death: Body very much emaciated. The right pleural cavity contained one gallon of sero-purulent fluid. The right lung was collapsed, coated with lymph and carnified. The left lung was normal. There was a large abscess in the upper portion of the liver which communicated with the pleural cavity through an opening in the diaphragm three by four inches in diameter. The fifth, sixth and seventh ribs were denuded of periosteum and bathed in pus. The omentum was quite devoid of fat. The mesenteric glands were enlarged. The spleen was normal. The mucous membrane of the lower portion of the ileum was coated with pseudomembrane and presented a number of small follicular ulcers. Peyer's patches were slightly thickened. The cæcum and colon were thickly studded with follicular ulcers, the edges of many of which were covered with pseudomembrane.—Acting Assistant Surgeon A. H. Wilson, U. S. A. [Nos. 433–437, Medical Section, Army Medical Museum, are from this case.]

The specimens from this case were brought to the Museum immediately after the autopsy, and a drawing in water colors representing a portion of the descending colon was made by Mr. Hermann Faber. The plate is a reproduction of this drawing. The mucous surface is seen to be generally reddened, with grayish streaks and patches. There are a considerable number of follicular ulcers, the smallest of which are rounded and very minute, while the larger ones, varying from $\frac{1}{10}$th to $\frac{1}{4}$th of an inch in long diameter, are usually oval; the edges of most of these ulcers are fringed with curdy yellow pseudomembrane. The submucous tissue was considerably thickened, as is well shown on the left hand of the piece near the bottom where its edge comes into view. This specimen has been preserved in the Museum, No. 437, Medical Section. The other specimens from the same case are: No. 436, the appendix vermiformis and a part of the cæcum, showing similar ulcers; No. 433, the collapsed right lung, thickly coated with pseudomembrane; No. 435, a portion of the liver, showing a large abscess cavity on its upper surface; and No. 434, the seventh rib, showing the effects of the burrowing of the pus from the abscess in its efforts to escape; the pulmonary surface of the bone is denuded of periosteum, and presents several flat new-formations of bony tissue. It would appear that in this case the large hepatic abscess entirely escaped observation during life, and the remark in the history of the case, on the 11th of November, only a week before death, that "the respiration appears to be normal," is worthy of note in connection with the considerable pleuritic effusion and collapse of the right lung, both of which undoubtedly existed before that time.

The plate facing page 522 is a reproduction of a photograph representing No. 279, Medical Section. The following is an account of the case:

CASE 903.—Private Frederick Wirth, company G, 72d Pennsylvania volunteers; enlisted August 10, 1861. According to the muster-roll of his company he was excused from duty on account of sickness after the 30th of April, 1862. He appears on the hospital record of his regiment admitted June 19, 1862; disease not stated; returned to duty June 23d. July 26th, he was admitted to Satterlee hospital, West Philadelphia; diagnosis chronic dysentery. Died August 3d. *Autopsy* next day, by Dr. Joseph Leidy: The organs of the chest were healthy. The liver, stomach and spleen appeared normal. The mucous membrane of the ileum and the agminated glands were inflamed and thickened, but not ulcerated. The mucous membrane of the colon was inflamed, especially towards the two extremities; the middle portion was mottled, red, gray and slate-colored; the extremities were dark red. Throughout its entire extent there were innumerable ulcers about the size of peas, many of them extending to the muscular coat. [No. 279, Medical Section, Army Medical Museum, is from this case.]

The plate shows, besides numerous follicular ulcers of characteristic form and appearance, many small patches of firmly adherent pseudomembrane on the mucous surface of the intestine between the ulcers.

A somewhat similar condition, except that the follicular ulcers are less numerous and some of them larger, is represented in the chromo plate facing page 524. The patient was a soldier who died in Judiciary Square hospital during the summer of 1863. His disease was recorded as chronic diarrhœa. The specimen represents a portion of the descending colon, and is reproduced from a drawing made at the Museum by Mr. Hermann Faber. The colon was much thickened ($\frac{1}{5}$th to $\frac{1}{4}$th of an inch in thickness) and considerably contracted. The mucous surface was of a bright red color, not unlike that of a granulating wound. It presented a number of small follicular ulcers, some of them round, others stellate, and some larger ulcers apparently resulting from the extension of the smaller ones; these ulcers for the most part had blackened bases. Thin patches of yellowish pseudomembrane adhered in places to the mucous surface between the ulcers, the expression of a diphtheritic inflammation by which the original follicular ulceration has been considerably obscured. Unfortunately no history of the case was preserved.

The extreme dimensions of the erosions, which occasionally result from the extension of follicular ulcers, are well illustrated by the plate facing page 526, which is a reproduction of a photograph of No. 195, Medical Section. The following is an account of the case:

CASE 904.—Sergeant A. L. Manchester, company E, 152d New York volunteers; age 23; was enlisted September 27, 1862, and continued to do duty with his company until March, 1863. During much of this time he had diarrhœa, which, however, did not prevent him from remaining on duty. March 2d, being then on duty as one of the guard at Douglas hospital, Washington, D. C., he was attacked by measles, with dry skin, pulse 110, and dark tongue. At the time of this attack he was a good deal broken down by the disorder of his bowels, and when, on the 5th of March, he was transferred to a bed in the hospital, the entry in the register was "measles and enteritis." The stools had been comparatively painless, but, March 7th, tormina and tenesmus supervened and they became bloody; they did not, however, exceed ten in twelve hours. These symptoms gradually abated under the use of a chalk mixture with opiate suppositories, and by the 12th of March the stools were reduced to four in the twenty-four hours, and were no longer bloody; skin moist; tongue cleaner; pulse 70, but quite feeble; the patient began to eat, and was now free from tenesmus and abdominal pain. March 20th: Is much better; pulse 84 and stronger; he sits up; has milk and eggs for diet; the remedies employed seem to control the tendency to pain and straining; the latter symptom appears to be kept in check by the use of the suppositories mentioned above. March 22d: Appetite better; only three painless passages in the last twenty-four hours; pulse 84; skin natural; tongue coated; slight tenderness on pressure in the left inguinal region. March 28th: Not so well; pulse 110; skin natural; has had about four stools daily for the last few days; they are dark-colored and stringy; tongue coated with a brownish fur; increased tenderness in left inguinal and lumbar regions. March 29th: Pulse 125; skin dry; tongue coated, but not so thickly as yesterday. Ordered quinia and milk punch. March 30th: Continual bilious vomiting set in, which was somewhat relieved by creasote, but it recurred from time to time, and death ensued April 1st. Stimulants, beef tea, &c., had been freely used during the last week of life. *Autopsy:* The small intestine near the ileo-cæcal valve was inflamed; higher up it was healthy. The large intestine was extensively inflamed and ulcerated.—Acting Assistant Surgeon Henry L. W. Burritt. [Nos. 194 and 195, Medical Section, Army Medical Museum, are from this case.]

The plate represents a portion of descending colon, which exhibits a number of the small, oval, characteristic follicular ulcers, but shows besides a number of large irregular ulcers with overhanging edges. The largest of these are more than an inch in diameter. It is probable that follicular ulceration had existed in this case for some time before the patient was attacked by measles, and that in consequence of the adynamic condition induced by that disease the ulcers rapidly extended. This seems to have been effected by a simple ulcerative process quite independent of any diphtheritic inflammation, and the specimens afford an excellent illustration of the great size to which catarrhal ulcers sometimes extend. No. 194, Medical Section, is taken from higher up the same colon, and exhibits similar lesions but in a less marked degree.

As already mentioned, under favorable conditions catarrhal ulcers readily cicatrize. Where great loss of substance has taken place I know of no well ascertained peculiarities by which the resulting cicatrices can be distinguished from those of the diphtheritic ulcer. But in the case of small oval follicular ulcers the cicatrices are quite characteristic. The process of cicatrization appears to begin at the bottom and sides of the ulcer by the development of a delicate vascular granulation tissue, by which the space beneath the overhanging edges is first filled up and the cavity of the ulcer gradually becomes diminished in depth. With the first contraction of the cicatricial tissue the edges are approximated to the muscular coat and afterwards to each other, so that the resulting cicatrix would be much smaller than the original ulcer but for the fact that a similar cicatricial tissue is generally developed simultaneously between the tubular glands of the adjacent inflamed mucous membrane, by which numerous radiating, anastomosing ridges are formed, giving a stellate figure to the cicatrix. Including the space occupied by these ridges the area of the cicatrix remains finally quite as large, or even larger, than that of the original ulcer; but with the aid of a lens it is easy to make out the orifices of the glands of Leiberkühn between the ridges, and thus to recognize that this portion of the scar is not mere cicatricial tissue, but a peculiar modified condition of the mucous membrane.

The plate facing page 528 gives an excellent idea of the appearances presented by these characteristic cicatrices. It is reproduced from a photograph of a portion of No. 603, Medical Section. The specimen represented is from the case of Thomas Kelcher, related on page 513. In that case the patient, while under treatment for a gunshot fracture of the thigh, suffered an attack of acute catarrhal dysentery which passed into a chronic flux. His colon presented a number of cysts, containing a jelly-like substance; these were fully described in the place referred to, and are represented in the plate facing page 514, which is reproduced from a photograph of No. 602, Medical Section. But between these cysts and the ulcer-like cavities formed here and there by their rupture there were a considerable number of stellate cicatrices. Several of these cicatrices can be recognized in the plate just mentioned as representing No. 602, Medical Section. The photograph of a portion of No. 603, reproduced in the plate now described, was taken one-half larger than nature in order that the surface details might be better seen. In the portion reproduced there are several small, deep, oval cavities which represent the ruptured cysts just referred to. The surface of the intestine exhibits, besides, rather more than a dozen stellate cicatrices, some four or five of which form a conspicuous group near the centre of the plate. Each cicatrix consists of a central smooth area, oval or almost linear in shape, and varying in the specimen from one-twentieth to one-fifth of an inch in long diameter. From this central smooth portion radiate numerous delicate sinuous ridges, which sometimes branch and sometimes anastomose. In the plate, almost as well as in the specimen, the orifices of the glands of Lieberkühn can readily be recognized with a lens in the interspaces of the network formed by these radiating ridges.

Cicatrices quite like these are occasionally seen in cases of follicular ulceration of the colon that must be regarded as steadily progressing. Some of the ulcers cicatrize while others are still spreading, or new crops of ulcers make their appearance while those formed first are healing. The colon in case 543* afforded a striking illustration of this possibility. The patient died of a chronic flux in the course of which he became exceedingly emaciated. His colon was studded with follicular ulcers from the ileo-cæcal valve to the anus. A portion of this colon was preserved in the Museum, No. 673, Medical Section. It presents numerous punched-out follicular ulcers very similar to those represented in the plate facing page 522. There are also some larger erosions, and here and there some little pseudomembranous frosting. Everywhere between the ulcers, except where the pseudomembrane obscures the surface, there were numerous cicatrices exactly similar to those shown in the plate just described. Extensive puckering of the mucous surface, resulting in a diminution of the lumen of the intestine or even in intestinal stricture, occurring from the cicatrices of catarrhal ulcers, has been described by Rokitansky,† but I have never witnessed it.

Extensive ulceration of the large intestine, the result of sloughing during a previous attack of acute diphtheritic dysentery.—This condition is very often encountered in subjects dead of a chronic flux. I can add nothing to the descriptions already given‡ of the lesions found in such cases. Ulcers of the most various size and depth, some or all of which may exhibit different degrees of the process of cicatrization,§ may be met with. Nothing more need be done in this place than to refer the reader to what has been already said in describing the morbid anatomy of diphtheritic dysentery.

ANALYSIS OF AUTOPSIES REPORTED IN PREVIOUS SECTIONS.—A brief analysis of the cases reported in the previous Sections, in which the intestines were ulcerated, exclusive of those grouped above under the head of diphtheritic dysentery, and of those to be discussed hereafter under the head of tubercular diarrhœa, will here be presented. In the first place, I note that in cases 163, 164, 174, 210, 531 and 854, although the disease is reported as diarrhœa or chronic diarrhœa, it was really some form of continued fever in which the typhoid affection of Peyer's patches was the prominent lesion, as is clearly shown by the record of the autopsies, and in cases 163 and 210, by specimens preserved in the Army Medical Museum. Cases 836 and 837, reported as chronic diarrhœa, and case 838, reported as typhoid dysentery, although much more imperfectly recorded, were probably of the same nature. These cases might have been postponed to the chapter on fever, but they have been allowed to remain as reported, in order to illustrate a class of errors of diagnosis which were no doubt of frequent occurrence.

Case 854 is particularly instructive. The patient was attacked, September 10, 1863, by intermittent fever, the symptoms of which were replaced after about a week by those of acute dysentery, after which the symptoms of diarrhœa and dysentery alternated. Death took place November 10th. The autopsy, which is reported in considerable detail by a careful observer, shows that characteristic typhoid ulceration of Peyer's patches was present in the ileum, associated, as is so often the case, with catarrhal inflammation and a moderate degree of follicular ulceration of the colon. I cannot attach much importance to the remark that the disease of Peyer's patches was "not so extensive near the cæcum as is usual in typhoid fever," in view of the extent to which they actually appear to have been diseased in the rest of the ileum, and must regard the case as one of those hybrid cases of fever, beginning as intermittent and ending as typhoid, to which I have given the name typho-malarial. The dysenteric phenomena which chiefly attracted the attention of the medical attendant are explained by the intensity of the accompanying catarrhal ulceration of the colon. The contrary error of mistaking diarrhœa or dysentery during life for typhoid fever was at least equally common.

Passing by these erroneously reported histories, the cases here to be discussed may be divided into two classes, viz: A, Those in which the descriptions, or specimens preserved in the Army Medical Museum, show either positively or with a reasonable degree of probability that the ulcers were of simple inflammatory or catarrhal origin; on account of the prominent form of ulceration these may be designated simply as *cases of follicular ulceration.* B, Those in which the descriptions are too imperfect to permit the nature of the ulcers to be positively diagnosticated. Undoubtedly in many of these cases the ulcers were of diphtheritic origin, but on account of the uncertainty in which they are involved they will be designated *undetermined cases.*

A. *Cases of follicular ulceration.*—A few of these cases probably belong to acute diarrhœa or acute dysentery. Thus, in case 871 the patient was killed by lightning, and had never been on sick report: Pin-head enlargement of the solitary follicles of the ileum and minute follicular ulcers of the colon were found after death; but if, as is possible, diarrhœa previously existed, it was not probably severe or of long duration. In case 402 the patient was only sick about fifteen days. His disease is reported as acute gastro-enteritis. His stomach was so irritable that little could be retained, and considerable griping attended the stools; but there does not appear to have been any tenesmus. The large intestine was

found thickly studded with small ulcers, very few of which exceeded a pin's head in size. In case 855 the disease was acute catarrhal dysentery, as is quite clearly shown by the history. The patient died after an illness of but sixteen days. The attack began as diarrhœa, but assumed the dysenteric characters on the fourth day. The stools were mucous and bloody, at first very frequent, and there was great tenesmus. On the autopsy, evidences of intense catarrhal inflammation were observed throughout the intestines, especially in the lower part of the ileum and in the large intestine; in the rectum follicular ulceration was just commencing. Case 839 was possibly of the same nature, being recorded as acute dysentery, but the clinical history is too imperfect to warrant a judgment.

In the great majority of cases belonging to this class, however, the history is either unmistakably that of a chronic flux of from two to more months' duration, or, although the clinical history is imperfect, the length of treatment in the last hospital only being recorded, the cases are reported as "chronic diarrhœa" or "chronic dysentery." It is possible that some of these also may really have been acute cases, but I cannot regard this as very probable. In eleven of these cases, viz: 248, 329, 343, 378, 421, 451, 468, 490, 545, 569 and 826, more or less marked evidences of chronic catarrhal inflammation of both small and large intestines, such as has been described in a previous portion of this section,* were found, but ulceration had taken place in the small intestine only. In all these cases the descriptions are sufficiently clear to make it very probable, and in most of them to make it certain, that the ulceration was of catarrhal, generally of follicular, nature, similar to that which often occurs in the small intestine when there is follicular ulceration of the colon. Case 332 probably also belongs to this group.† I feel by no means sure that the colon was entirely free from ulcers in all these cases; the bias in the minds of certain medical officers leading them to seek the lesions of "chronic diarrhœa" as well as of the acute form of the disease in the small intestine,‡ must not be forgotten. Nevertheless I do not doubt that in chronic intestinal catarrh the small intestine sometimes ulcerates before the large, though this happens comparatively seldom.

But in most of these cases of follicular ulceration the process was either exclusively or chiefly seated in the large intestine. I find ninety-nine autopsies of this kind, which may be divided into two groups, the first embracing those in which the intestine was affected merely by simple chronic inflammation with the follicular and other ulcers dependent upon it; the second those in which, at some time during the disease, usually just before death, diphtheritic inflammation of the mucous membrane between the ulcers had supervened. To the first group belong fifty-nine autopsies, viz: cases 86, 134, 138, 139, 140, 142, 145, 166, 194, 195, 196, 198, 201, 207, 208, 223, 225, 234, 263, 264, 267, 281, 293, 295, 301, 310, 320, 339, 350, 351, 355, 363, 370, 374, 381, 387, 389, 401, 414, 426, 458, 461, 505, 518, 564, 575, 598, 645, 687, 697, 714, 715, 732, 746, 819, 823, 844, 860 and 873. To the second group belong forty autopsies, viz: cases 167, 191, 227, 262, 265, 266, 277, 300, 314, 316, 318, 333, 336, 368, 371, 379, 395, 398, 427, 428, 431, 432, 454,§ 500, 542, 543, 573, 574, 801, 814, 853, 856, 858, 859, 868, 869, 870, 872, 877 and 878.

---

* Page 296, *supra*.

† In case 332 the soldier died of pneumonia. He had previously suffered from what was diagnosticated typhoid fever; the typhoid lesion, however, was not found in the small intestine, but only "ulcerations in the transverse rugæ of the jejunum;" all that is said of the colon is that it was "contracted." Whether the case was simply one of intestinal catarrh or one of continued fever (not typhoid) must remain uncertain. To the cases enumerated above I might also add case 342, see note to p. 310, *supra*.

‡ Page 266, *supra*.

§ Case 454 was reported as one of "cholera morbus." From the autopsy, I presume it to have been a case in which the diphtheritic process supervened comparatively early in the course of a chronic flux, (*i.e.*, before much emaciation had occurred,) and suppose the vomiting, which often accompanies such cases, to have led to the diagnosis recorded.

Am. Photo-Relief Printing Co., 1002 *Arch St., Philadelphia.*

COLON WITH FOLLICULAR ULCERS AND PATCHES OF PSEUDO-MEMBRANE.

No. 279. MEDICAL SECTION.

These two groups are to be regarded as really constituting but a single morbid category, the second group differing from the first less in the essential nature of the cases than in their mode of termination. A number of the cases in each group are imperfectly observed and recorded, but others are given with satisfactory detail and fairly represent the morbid conditions present. As of the latter character, eight cases recorded by Dr. J. Leidy, eleven by Assistant Surgeon McGill, ten by Assistant Surgeon Allen and four by Surgeon French, may be particularly commended. Moreover, specimens from fourteen cases of the first group and thirty-three of the second are preserved in the Army Medical Museum; [the Museum numbers are in each instance attached to the account of the case in the previous sections.] These specimens, taken in connection with those described and figured above, furnish tolerably complete material for the study of the lesions under consideration, which has been used in drawing up the general account of these lesions already presented.* It only remains to make a few brief additional comments with regard to the cases just enumerated.

In these cases the *large intestine* presented all the phases of follicular ulceration, thickening of the submucosa and changes of color, which have already been sufficiently dwelt upon. In some of them those solitary follicles which were not ulcerated are spoken of as enlarged, or the seat of pigment deposits, or both. In others the coats of the intestine are described as softened or hardened, gelatinous, lardaceous, &c. In some of the cases the ulcers in the large intestine were few in number or slight in character, indicating that the ulcerative process had just commenced, as in cases 138, 140, 142 and 145, which are examples of the so-called Chickahominy diarrhœa, and differed from the non-ulcerative cases of the same group already described† only in the presence of a few incipient follicular ulcers. Cases 86, 293, 339, 363, 645 and 687 are examples of the same condition occurring under other circumstances. Between these cases and those in which the large intestine was riddled with numerous punched-out ulcers, and in which there was great thickening of the submucous connective tissue, every transition existed.

In the cases in which the diphtheritic process had supervened it varied in intensity from a mere pseudomembranous frosting of the affected mucous membrane to deep and extensive diphtheritic sloughing. Cases 300, 316, 870 and 877 are examples of the latter occurrence, which was comparatively rare, probably because when the diphtheritic process attacked the intestine of a patient already exhausted by a chronic flux he usually succumbed before the new lesion had time to make much progress.

Perforation of the colon by the ulcers was observed in but two instances, viz: case 801, in which two perforations occurred in the transverse colon, leading to extravasation of the intestinal contents and fatal peritonitis; and case 872, in which there were several perforations just above the sigmoid flexure. Both of these were cases in which the diphtheritic complication had supervened. No instance has been brought to my notice in which perforation occurred in a case of flux resulting from uncomplicated follicular ulceration.‡ In case 878 an hepatic abscess had opened into the colon. In cases 140 and 401 it is stated that some of the ulcers appeared to be cicatrizing; in cases 293 and 398 that some of them had actually cicatrized; in three other cases, although no mention is made of cicatrices in the reports, well marked ones were found between the unhealed follicular ulcers in the specimens received at the Museum. These were case 196, [Med. Sect. 616,] case 543

* See p. 515 *et seq.*, *supra*. † See p. 310, *supra*.

‡ Of course I do not overlook the occurrence of perforation in typhlitis, which is not embraced in my statement.

[Med. Sect. 673] and case 872, [Med. Sect. 971.] Similar cicatrices are shown in No. 466, Medical Section, from a case related in Circular No. 6.* With regard to the characters of the cicatrices of follicular ulcers see the account given on page 519.

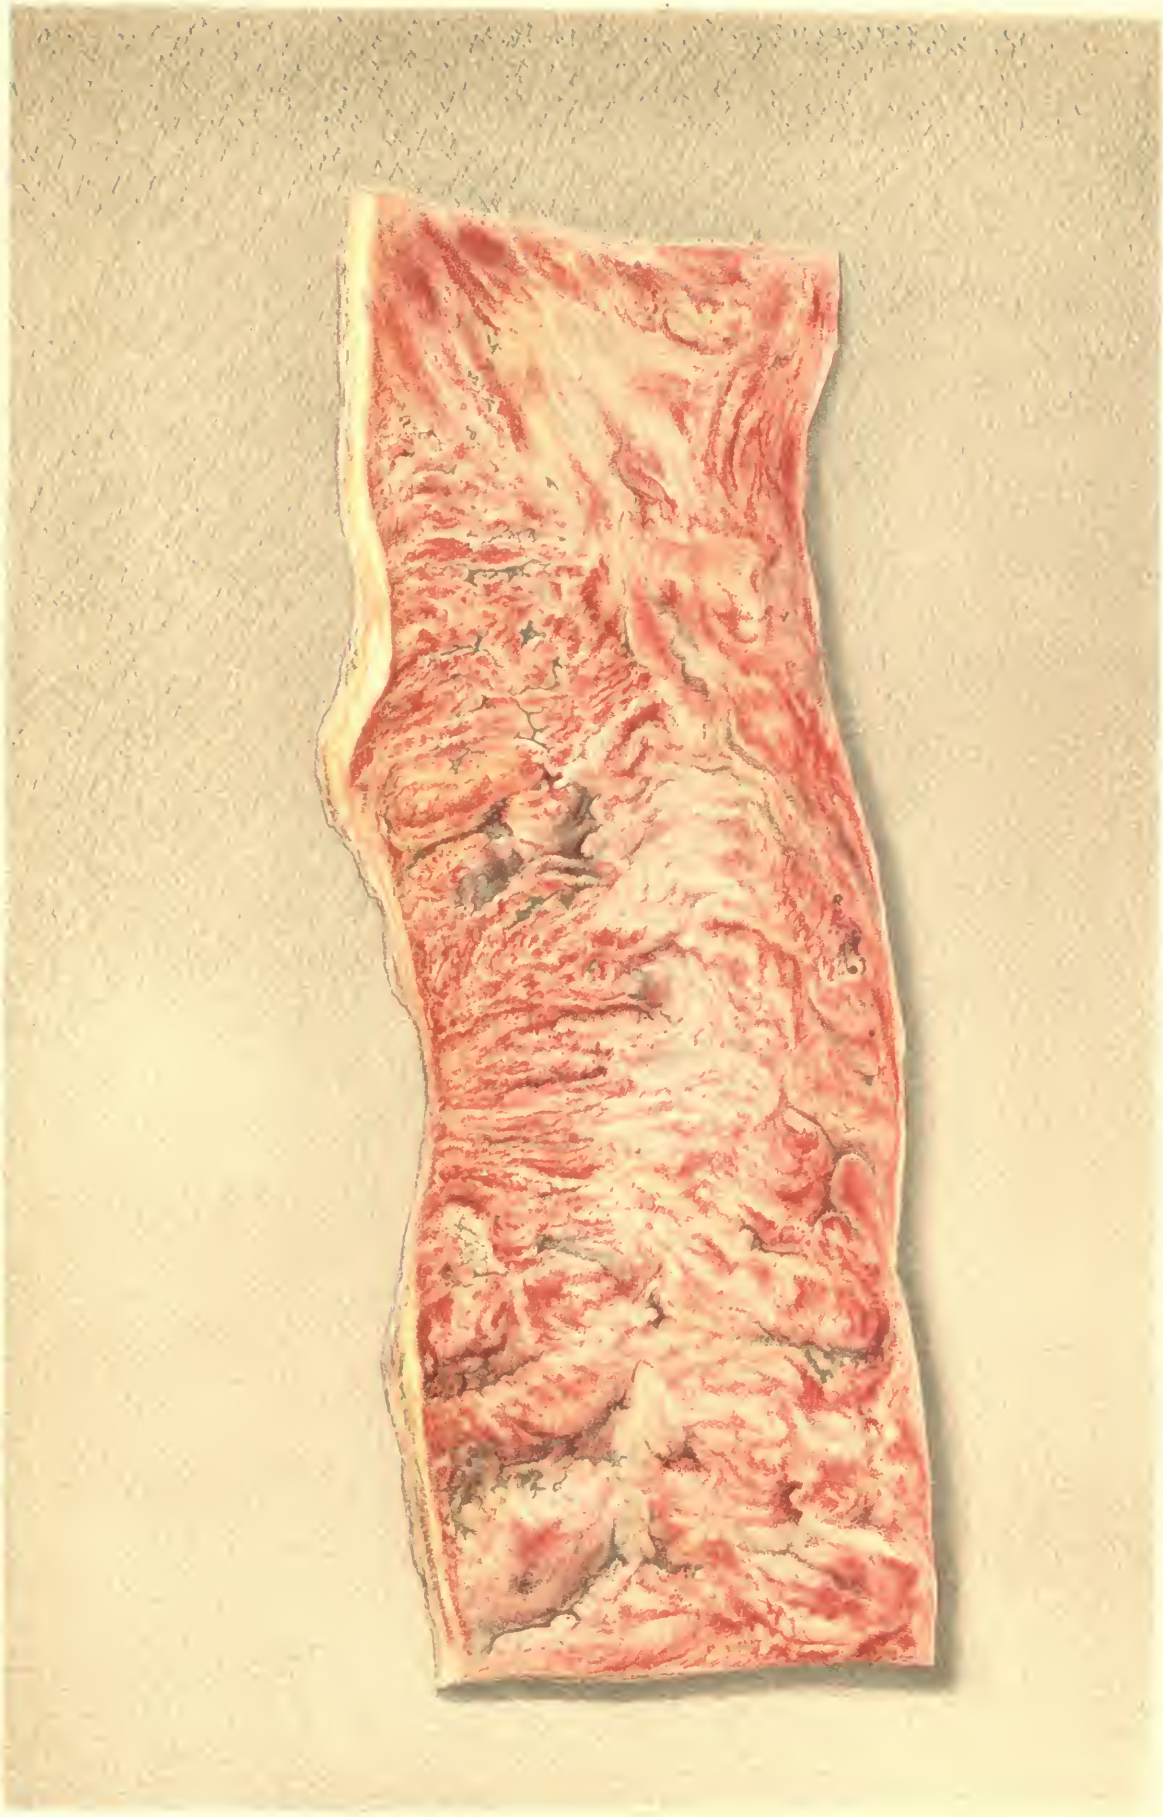
In a few of the cases under consideration, viz: cases 167, 196, 263, 314, 316, 368, 500, 732 and 877, the mucous membrane of the *small intestine* is stated to have been healthy; in case 379, it is recorded that the small intestine was healthy, except that its walls were thin; in case 878 an abscess of the liver opened into the duodenum, but the small intestine is said to have been otherwise healthy; in cases 543 and 687 no lesion of importance was observed except in the large intestine; and in fifteen cases no mention is made of the condition of the small intestine. In all the other cases, seventy-one in number, congestion of the mucous membrane, enlargement of the solitary follicles, hypertrophy of the villi, thickening or softening of the mucous membrane or other evidences of inflammation are recorded as having been observed in the small intestine.

In several cases this condition was associated with more or less ulceration quite similar to that described above as sometimes existing in the small intestine only. Thus, in cases 201, 266, 301 and 414, from one to three small ulcers were observed in the ileum. In case 374 Peyer's patches were slightly elevated, and one of them near the cæcum ulcerated; the solitary glands in the same region were enlarged and slightly ulcerated. In case 401 there were in the last two feet of the ileum several ulcers in process of cicatrization. In case 853 one or two of Peyer's patches were studded with minute ulcers. In these cases the ulcers were undoubtedly catarrhal in their nature, whether follicular or not, and the same was probably the nature of the more numerous ulcers at the lower extremity of the small intestine in cases 195, 208, 262, 363 and 844. In cases 461, 715 and 869 ulcers existed in the small intestine, which, from the descriptions, would appear to be undoubtedly of typhoid origin, and those mentioned in cases 505 and 860 were possibly of the same nature. Peyer's patches are spoken of as thickened or congested in about a dozen other cases, and in about as many pigment deposits were observed in them, in the solitary follicles or in the extremities of the villi. I do not believe that this represents the frequency with which pigment deposits actually occurred in these situations, and think their presence frequently failed to attract attention.

In several of the cases in which the diphtheritic process had supervened between the follicular ulcers in the large intestine, it also extended into the lower portion of the small intestine. This occurred in cases 333, 371 and 801, and a similar condition, associated with ulceration of the small intestine, was observed in cases 277, 431 and 870; case 454, in which the mucous membrane of the ileum for twelve inches from the ileo-cæcal valve was thickened, inflamed, ulcerated and "almost gangrenous in many places," was probably of the same nature.

Assistant Surgeons McGill and Allen in several of their autopsies speak of the small intestine as being thin, extremely thin, or dilated and thin: cases 333, 350, 351, 355 and 381 are examples. In case 387 Assistant Surgeon Allen remarks that the small intestine, which was anæmic, with conspicuous solitary follicles, "had an ironed-out appearance." In case 86 there was an intussusception about eight inches long in the small intestine; in case 505 there were two intussusceptions in the ileum. In case 316 a cul-de-sac projected

* Circular No. 6, S. G. O., Nov. 1, 1865, p. 146. A portion of the ileum of the patient is represented in a chromo plate facing the page cited; he is said to have died of typhoid fever.



from the ileum opposite its mesenteric attachment and sixteen inches above the ileo-cæcal valve. In case 398 it is stated that Brunner's glands in the duodenum were enlarged, and in case 869 that the follicles of the duodenum were prominent.

The presence of *gas in the intestinal canal* appears seldom to have attracted attention. In cases 145, 281 and 645 it is stated that the intestines were distended with gas; in case 363 that the intestines, especially the colon, were so distended; in case 134 that the transverse colon was distended with gas; in case 355 that the ileum and cæcum were "dilated;" in case 350 that a small portion of the jejunum was dilated. Of course, the intestines were much more frequently distended than this would indicate, but the circumstance does not appear to have been thought worthy of record.

In many of the cases the condition of the *stomach* is not recorded. It is spoken of as congested or inflamed in about a dozen and a half cases. In a few instances it is said to have been pale or softened. In cases 281, 398, 426 and 870 its mucous membrane is said to have been slightly thickened, or thickened. In cases 301 and 427 it is stated that the walls of the stomach were thin. In case 134 the pyloric half of the stomach was contracted to an inch in diameter, and to a corresponding degree in the cardiac half, [No. 63, Med. Sec.] A similar contraction of the stomach existed in cases 428 and 844. In cases 139, 145, 363 and 645 the stomach was distended with gas.

I note, also, that in seven of the cases included in the foregoing groups, viz: 234, 263, 264, 266, 267, 398 and 870, the diagnosis typhoid fever was recorded at some time during the progress of the case, although the typhoid lesion was not found after death in the glands of Peyer; also that some form of malarial fever is said to have preceded the flux or occurred during its progress in eleven cases, viz: intermittent fever in cases 191, 194, 196, 316, 389, 401 and 859; remittent fever in cases 167 and 320; typhoid remittent fever in case 363; and typho-malarial fever in case 518. I must think that had all the cases been recorded with completeness, these complications would have been found of still more frequent occurrence.

B. *Undetermined cases.*—I have included under this heading all those cases in which the language used in the reports implies that a large part of the mucous membrane of the large intestine was destroyed by ulceration, such as those in which it "presented numerous large ulcers," was "extensively ulcerated," "a mass of ulceration," "much ulcerated throughout," &c., &c., as well as those in which it is simply recorded that the intestine was "ulcerated," without defining the extent of the ulcers any better than their other characters. Cases of the first kind undoubtedly very often represent the large ulcers left after the separation of diphtheritic sloughs, while those of the second very often represent follicular ulcers. But the cases here included are so imperfectly recorded, both as to their clinical history and the post mortem appearances, that it would hardly be safe to affirm positively of any one of them to which of these two categories it properly belongs.

I find altogether two hundred and ninety-three cases of this character, viz: cases 78, 79, 80, 83, 84, 85, 87, 88, 89, 90, 91, 96, 99, 100, 101, 106, 108, 112, 117, 119, 120, 122, 123, 178, 183, 186, 189, 193, 211, 213, 214, 219, 220, 228, 229, 231, 233, 237, 240, 247, 249, 250, 254, 255, 258, 260, 261, 268, 269, 272, 273, 274, 275, 276, 279, 283, 285, 289, 290, 292, 296, 297, 298, 304, 307, 308, 311, 312, 319, 322, 326, 327, 334, 356, 365, 375, 380, 383, 384, 388, 391, 393, 394, 396, 405, 406, 407, 408, 409, 410, 411, 417, 418, 420, 422, 423, 440, 441, 443, 447, 448, 449, 450, 452, 453, 456, 457, 459, 464, 469, 471,

486, 487, 501, 504, 506, 507, 509, 510, 511, 513, 519, 520, 521, 522, 523, 526, 527, 528, 533, 536, 541, 549, 550, 552, 555, 557, 559, 563, 565, 568, 571, 572, 576, 577, 578, 580, 588, 593, 601, 602, 604, 607, 609, 610, 614, 615, 617, 618, 619, 620, 621, 622, 623, 624, 626, 629, 631, 632, 634, 636, 637, 638, 640, 641, 643, 646, 647, 648, 649, 650, 651, 653, 654, 655, 656, 658, 659, 660, 661, 662, 663, 665, 670, 671, 673, 674, 675, 676, 678, 680, 681, 686, 688, 691, 695, 696, 698, 700, 703, 704, 705, 706, 707, 708, 709, 713, 717, 718, 719, 720, 721, 722, 724, 726, 727, 728, 731, 733, 734, 735, 736, 737, 738, 739, 741, 742, 743, 744, 745, 747, 753, 754, 755, 756, 757, 758, 759, 762, 764, 765, 766, 767, 768, 771, 772, 773, 775, 777, 778, 781, 782, 786, 787, 791, 792, 794, 802, 803, 804, 806, 807, 808, 810, 812, 813, 815, 820, 825, 828, 830, 833, 834, 835, 840, 842, 843, 846, 847, 848, 849, 850 and 851.

In most of these cases the duration of the disease is not reported with precision; but in eighty-four of them, chiefly recorded as chronic diarrhœa or dysentery, the record extends over a period ranging between two months and two years or even longer. In the remaining cases, in which the duration of treatment in the hospital where the patient died was less than two months, and the previous duration of the disease quite unknown, the same diagnosis is generally recorded. There are, however, a few exceptions. Thus, cases 193 and 440 are recorded "diarrhœa," and case 213 "dysentery," without specifying whether acute or chronic. Cases 423, 507 and 522 are recorded "acute diarrhœa," and case 835 "enteritis." In eight cases the intercurrent disease, which was the immediate cause of death, only is recorded, viz: cases 656 and 722, "acute bronchitis;" case 840, "pleurisy;" cases 620, 624 and 631, "typhoid pneumonia;" and cases 405 and 673, "pleuropneumonia." In cases 501, 510, 513, 536 and 834 the disease was diagnosticated "typhoid fever;" in case 825, "typhoid remittent fever;" and in case 411, "remittent fever." In case 279 no diagnosis is recorded. In case 406 the diagnosis recorded is rheumatism and phthisis, but no tubercular disease of the lungs was found on the autopsy. In case 521 the diagnosis recorded is consumption, and on the autopsy tubercular disease of the lung was actually found. In case 409 the patient had a gunshot wound of the left hand, and is said to have died of "purpura and exhaustion." Notwithstanding these diversities of diagnosis, I presume the majority of the cases specified were actually examples of chronic dysentery; that some of them may have really been men admitted in the later stages of acute diphtheritic dysentery I do not doubt, but the same remark applies also to those cases in the foregoing list in which the diagnosis chronic diarrhœa or dysentery was recorded.

From several of these cases specimens were sent to the Army Medical Museum, but only in four instances is any portion of the alimentary canal represented, and in these the specimens do not suffice to solve the doubt with regard to the nature of the disease. The cases in question are 193, 440, 578 and 721. In case 193 the specimen [No. 618, Medical Section] is a small portion of the cæcum, with the ileo-cæcal valve and two inches of the ileum. There are several ulcers in the cæcum, one of which has perforated. From the characters of these ulcers I incline to the opinion that they are of diphtheritic origin; but the rest of the colon not having been sent to the Museum, and the descriptions being imperfect, I am uncertain whether the case was one of acute diphtheritic dysentery or whether the diphtheritic process supervened upon a chronic flux. In case 440 the specimen [No. 44, Medical Section] is a portion of the jejunum showing an invagination. In case 578 the specimen [No. 478, Medical Section] is a portion of the greater curvature of the

Am. Photo-Relief Printing Co. *1002 Arch St., Philadelphia.*

COLON WITH IRREGULAR ULCERS.

No. 195. MEDICAL SECTION.

stomach, showing a number of minute ulcers. In case 721 the specimen [No. 53, Medical Section] is a pedunculated connective-tissue tumor attached to the peritoneal surface of a small fragment of the ileum.

In very many of these cases the *large intestine* is spoken of as thickened, softened, congested or inflamed. In all of them ulceration is affirmed to have existed except five, in which it may reasonably be inferred to have been present from the language used, viz: in case 255 "the mucous membrane of the intestines was extensively disorganized;" in case 471 the mucous membrane of the colon was "very much disorganized;" in case 614 the mucous membrane of the colon was "disorganized by inflammation;" in case 88 the mucous membrane of the intestines, especially of the large intestine and rectum, was "very much diseased;" and in case 394 the intestines presented "the usual lesions of chronic diarrhœa." In a few instances, viz: cases 83, 89, 250, 459, 626, 781, 782, 786 and 787, besides the fact of ulceration, the ulcers themselves or other parts of the mucous membrane of the large intestine are spoken of as "gangrenous," or "almost gangrenous," or as having a "gangrenous appearance;" epithets no doubt suggested by some of the phases of the diphtheritic process.

Besides case 557, in which it is left uncertain whether the perforations recorded existed in the small intestine or the large, the large intestine is said to have been *perforated* in nine instances, viz: case 193, a perforation in the cæcum; case 559 one perforation, and case 213 two, in the ascending colon; case 211 one perforation, and case 728 several, in the transverse colon; case 269, numerous perforations in the descending colon; cases 296 and 449, each a perforation in the sigmoid flexure; and in case 327 one just below the sigmoid flexure. In the first of these cases [193] fæcal extravasation was prevented by previous adhesions, and the perforation communicated with a circumscribed abscess containing about two ounces of offensive pus, which burrowed between the iliacus internus and psoas magnus muscles; in cases 211, 296, 327, 449 and 557 evidences of fæcal extravasation or of more or less extensive peritonitis were observed; in the remaining cases no mention is made of these consequences, and I am therefore disposed to regard them with some reserve, since undoubtedly the rents made during the unskilful removal of extensively ulcerated dysenteric intestines are occasionally mistaken for perforations.

Some of the ulcers were thought to be healing in cases 247, 268, 272, 273, 734, 772, 810 and 813. Fully formed cicatrices, or what were supposed to be such, were observed between the still open ulcers in cases 79, 308, 522, 528, 602 and 847; only in the first and last of these cases is any description given of the character of these cicatrices; in case 79 the flux appears to have been kept up by rectal ulcers the exact nature of which remains uncertain; "between them were puckered cicatrices of various dimensions, the largest the size of a five-cent piece;" in case 847 some of the ulcers in the rectum "had cicatrized, in consequence of which the calibre of the gut was diminished." To these may be added case 585, which was not included in the list under discussion, because the patient appears to have recovered from the flux some time before death. He was admitted to hospital suffering with jaundice, and died of peritonitis complicated with pleurisy of the right side, which set in a few weeks before death. He does not appear to have had diarrhœa during the six weeks he was in hospital except for a few days from taking cod-liver oil. "Traces of former ulcers" were found in the sigmoid flexure and transverse colon.

In sixty-one of the cases included in this class the condition of the *small intestine* is not recorded. In twenty-eight cases it is said to have been healthy. In almost all the others

the small intestine, or some part of it, is spoken of as congested, inflamed, thickened, softened, abraded or ulcerated. Ulceration of the small intestine is recorded in seventy-five cases, in nine of which Peyer's patches are said to have been ulcerated, viz: 240, 308, 311, 365, 456, 559, 709, 743 and 777. Most of these were probably complications with the typhoid process. In case 456 the ulcers are said to have been healing. In about half a dozen other cases Peyer's patches are said to have been thickened; in case 356 they are said to have presented a mammillated appearance. *Perforation* of the small intestine is said to have existed in case 237. According to the record, the solitary glands throughout the ileum were ulcerated, and it was one of these ulcers which had perforated; fæcal extravasation and general peritonitis resulted. In case 557 it is stated that "there were a number of perforations," but the record does not make it clear whether they were in the ileum or large intestine, both of which are said to have been "extensively ulcerated."

In two cases *cicatrices* were observed in the small intestine, viz: case 88, in which the cicatrices are said to have been "numerous," and case 231, in which simply "some cicatrices" were observed; whether these cicatrices corresponded in position to Peyer's patches or not does not appear from the record. A single *intussusception* of the small intestine was observed in cases 78, 84, 99, 269, 580, 623, 636, 660, 665, 680 and 686; two intussusceptions in cases 440, 671 and 673; three in cases 521 and 658; four in case 602, and seven in case 618. These probably all occurred shortly before death, or during the agony, as in none of them did any inflammatory condition about the seat of the invagination attract attention, except perhaps in case 78, in which it is recorded that the bowel adjoining the invagination was greatly congested. In case 418 a *divérticulum* two inches long and half an inch in diameter was found five feet and a half above the ileo-cæcal valve. In case 708 a similar diverticulum about two inches long and of nearly the same diameter as the ileum was found about twelve inches above the ileo-cæcal valve.

In very many of these autopsies the condition of the *stomach* is not mentioned. In about forty cases it is spoken of as congested, inflamed or thickened; in case 786 it is said to have presented "many excoriations;" in cases 78 and 258 it was "ulcerated;" in case 807, ulcerated at the pyloric extremity; in case 247 there were two ulcers near the pylorus, and one of considerable extent in the greater curvature; several other ulcers had existed, but were healed. In case 578 the mucous membrane presented a number of minute ulcers. A portion of this stomach has been preserved in the Museum, [No. 478, Medical Section.] The ulcers are quite numerous, very small, and resemble the minute follicular ulcers of the colon seen in certain cases of chronic dysentery.

These conditions represent the various stages of catarrhal inflammation of the gastric mucous membrane, which, it would appear, were observed in somewhat more than one-sixth of all the undetermined cases. Similar conditions were observed in nearly one-fourth of the cases of follicular ulceration;* in about one-sixth of the cases of acute diphtheritic dysentery;† and in about one-fourth of the cases in which the intestinal mucous membrane was inflamed without being ulcerated.‡ It would not be safe to infer that gastric catarrh is a more frequent complication of catarrhal than of diphtheritic dysentery from these figures, because there are so many cases in which the stomach was not examined, or in which its appearances are not recorded. Nor should I be willing, in view of the inexperience of many of those who made the autopsies under discussion, to admit that gastric

COLON, WITH CICATRICES OF FOLLICULAR ULCERS.

No. 603. MEDICAL SECTION.

[ENLARGED ONE-HALF.]

LIBRARY
UNIVERSITY OF
CALIFORNIA.

catarrh had actually existed in every one of those instances in which the stomach is spoken of as congested or inflamed; but after making every allowance for errors of this sort, the figures will, I think, serve to show, in spite of their incompleteness, that gastric catarrh is a very frequent concomitant of all the varieties of intestinal flux.* In case 791 we are told that "on opening the stomach, a firm tumor, the size of a hazel-nut, with a central opening, from which pus flowed, was seen near the pylorus."

The presence of *gas in the alimentary canal* is referred to in but few instances. In cases 258, 272, 296, 624, 632, 634 and 777 the stomach was distended with gas; in cases 255 and 735 the stomach and intestines; in cases 456, 676 and 759 the intestines; in case 808 the small intestine; in case 577 the ascending and transverse colon; in case 659 "the small intestine was a succession of abnormally large pouches alternating with constrictions."

LESIONS OBSERVED IN OTHER ORGANS.—In this place the lesions observed in other organs, in both the cases of follicular ulceration and in the undetermined cases, will be discussed.† In the majority of the cases of both classes in which the appearance of the body at the time of the autopsy is recorded it is spoken of as emaciated, much emaciated or extremely emaciated. In a few cases of each class the emaciation is said to have been slight; and in one only of the cases of follicular ulceration, viz: 454, and two of the undetermined cases, viz: 407 and 408, the body is said to have been stout, well nourished or well supplied with fat.

Besides the characteristic posterior suggillation, mentioned in a number of the autopsies, discolored spots, resembling ecchymoses or the spots of purpura, were observed on the anterior parts of the trunk and abdomen in a few instances. These are mentioned in six of the cases of follicular ulceration, viz: cases 134, 138, 139, 140, 142 and 310—all except the last recorded by Dr. J. Leidy; and in seven of the undetermined cases, viz: cases 406, 409, 471, 638, 640, 681 and 778. I doubt not similar conditions existed in other cases, although not recorded, apparently because little importance was attached to this circumstance by most of those by whom the post mortem examinations were made. Such purpura-like stains may originate in several ways: They may result from some undefined alteration of the blood, such as exists in purpura; they may express a febrile condition analogous to that which exists in typhus or typhoid fevers, or they may be the consequence of scurvy. The latter condition was actually recognized in a few of the cases just enumerated. Thus, in

* I know of no trustworthy statistical appreciation of the frequency of gastric complications in dysentery. ANNESLEY—*Diseases of India*, London, 1828, Vol. II, p. 271—thought they occurred only in "the cases of dysentery occurring during the progress of, or upon convalescence from, fevers," and even then regarded them as merely contingent affections. On the other hand, HAUFF—*Zur Lehre von der Ruhr*, Tubingen, 1836, S. 318 *et. seq.*—on the basis of the dissections of the Wurtemberg physicians during the epidemic of 1834, regarded gastric inflammation as a part of the dysenteric process, which involved the whole length of the alimentary canal from the stomach to the anus, most intense, indeed, in its lower portion, but not sparing the rest. He describes redness, thickening, pseudomembranes and even ulceration as usual appearances in the gastric mucous membrane. PARKES—*Dysentery and Hepatitis of India*, London, 1846, p. 49—declared, on the basis of his own dissections, that "in all cases of simple dysentery the alterations in the canal are circumscribed by the ileo-colic valve;" but admitted that "gastro-enteritis is at certain times an accompaniment of dysentery, and is a dangerous complication, on account of the obstinate exhausting vomiting which may attend it." FINGER—*Die epidemische Ruhr*, Prager Vierteljahrschrift, Bd. IV, 1849, S. 140, and GRIESINGER—*Krankheiten von Egypten*, Abschnitt X, Cap. 2, Vierordt's Archiv für Phys. Heilk., Bd. XIII, 1854, S. 539—both observed gastric catarrh in a small number of their cases, erosions or ulcerations of the mucous membrane of the stomach still more rarely. GRIESINGER observed hæmorrhagic erosions even more frequently than catarrh. MACPHERSON—*Bengal Dysentery*, Calcutta, 1850, pp. 34 and 44—in 160 dissections of acute dysentery, found the mucous membrane of the stomach over-vascular or softened in 4 cases, and ulcerated in 1. In 55 dissections of chronic dysentery the gastric mucous membrane showed chronic inflammation and softening in 2 cases, increased vascularity in 2, and abrasion of the pylorus in 3. MOREHEAD—*Disease in India*, London, 1860, p. 271—reports two cases in which circular ulcers of the stomach were associated with similar ulcers in the colon, but does not discuss the question of the frequency of gastric catarrh in dysentery. JULIEN—*La dyssenterie en Cochinchine*. Montpellier Thesis, No. 62, 1864, p. 49—from the study of 108 autopsies of Cochin China dysentery, came to the conclusion that the lesions of the stomach were as rare as unimportant. HEUBNER—*Dysenterie*, in Ziemssen's Handb., Bd. II, Th. 1, Leipsic, 1871, S. 527—declares in a general way that in dysentery the stomach, duodenum and upper part of the small intestine are either normal or in a condition of catarrh, which is especially frequent in tropical dysentery. For the latter statement I know no authority.

† The remarks which follow are based upon an analysis of 396 cases, viz: 103 of follicular ulceration, including cases 901 to 904 and the 99 cases enumerated on p. 522, as well as 293 undetermined cases enumerated on pp. 525 and 526.

case 640 "the lower limbs were œdematous and discolored, the gums in a sloughing condition;" in case 681 "scorbutic stains were observed on both lower extremities;" and the same condition, in a higher degree probably, existed in case 638, in which it is recorded that "the inner side of the left leg, from the thigh to the ankle, was purplish, and on being cut into the tissue beneath the discolored portion appeared to be disorganized."

In three of the cases of follicular ulceration, viz: 167, 281 and 310, the lower extremities were œdematous; the same condition was observed in six of the undetermined cases, viz: 100, 319, 610, 640, 738 and 786; in a seventh case, 365, œdema of the lower extremities coexisted with abdominal distension, and in two other cases, 621 and 735, with general anasarca. In one of the cases of follicular ulceration, case 310, an abscess formed over the left parotid gland a little more than a month before death, followed by a number of subcutaneous abscesses in various parts of the body.

The following anomalies were observed in some of the undetermined cases: In case 250 the skin had a brownish tint; in case 815 the whole surface of the body was of a dark lead color, the result of the excessive use of nitrate of silver; in case 326 there was a large abscess in the anterior portion of the left thigh; in case 680 suppuration of the cervical lymphatic glands had occurred on the right side; in case 681 a small abscess and several ulcers were observed over the left knee; in case 555 there was double inguinal hernia; in case 842 an anomalous condition of the generative organs was observed; and in case 593 there was a general transposition of the thoracic and abdominal viscera from left to right. In case 601 the existence of bed-sores is recorded; this accident must certainly have existed in some of the other cases, but it seems to have been regarded as undeserving mention.

The brain and its membranes.—In a considerable number of the cases of both classes the condition of these parts was not recorded. In a few instances the membranes or the brain substance, or both, are said to have been congested, and in a few the brain substance is said to have been soft or flaccid. In a small number of cases congestion of the brain or its membranes was accompanied by an abnormal quantity of fluid in the subarachnoid space or the ventricles. Thus, among the cases of follicular ulceration, in case 198 there was a considerable quantity of fluid in the subarachnoid space and in the ventricles of the brain, and numerous puncta vasculosa were observed on section of the cerebrum; in case 201 "the substance of the brain was soft; a quantity of reddish fluid was found in the left lateral ventricle; in the left choroid plexus, about an inch from the foramen of Monro, was a mass of white, granular, caseous material resembling tubercle;" in case 223 about four ounces of liquid were found in the lateral ventricles, the floor and roof of which are said to have been "soft and pultaceous;" in case 350 the brain substance was injected with blood and the ventricles full of serum; in case 870 the membranes of the brain were congested, and on removing it about three ounces of pinkish serum were found in the posterior fossæ of the cranium.

So, among the undetermined cases, in case 417 the meninges were opaque, and there was a much larger quantity of subarachnoid fluid than normal; in case 255 the membranes were congested, and from four to six ounces of serum were found at the base of the brain and in the ventricles, [this was one of the cases of sudden death referred to on page 502;] in case 411 the membranes were congested, the brain substance softened, six ounces of fluid escaped on opening the membranes, and two ounces were found in each ventricle; the patient is said to have died of "tetanus from internal irritation;" in case 820 there was a large quantity of serum beneath the arachnoid, and one or two small patches of organized

lymph on the superior surface of the cerebrum. These results do not differ materially from those found in the autopsies of the cases in which the intestines were inflamed but not ulcerated,* or those of acute diphtheritic dysentery.† In each group meningeal congestion and serous subarachnoid or ventricular effusion were found in a small number of instances. No notion of the comparative frequency of these lesions can be formed from the record, because an examination of the cranial cavity was so often omitted. I suspect, however, that in a portion of the cases in which they were observed the normal cerebro-spinal fluid, stained by post mortem transudation of the coloring matter of the blood, has been mistaken for a pathological appearance; moreover, variations in the quantity of blood found after death in the veins of the brain and its membranes are by no means certain indications of morbid conditions existing during life. Still less importance can be attached to the statement that the brain is softened, except when made by an expert, for softening is an early post mortem change in the normal brain. But these considerations will not, I think, dispose of all the observations in question, some of which seem to indicate without doubt that subarachnoid effusion, with or without meningeal congestion, is an occasional complication of all the forms of intestinal flux, and that even, though in rare instances, meningeal inflammation may be developed.‡ To the foregoing I may add that calcareous matter in the pineal gland was noticed in cases 351 and 870; in case 356 the pineal gland is said to have been absent; in case 196 the middle commissure of the brain was absent.

Respiratory organs.—These were almost always examined, and were frequently the seat of serious lesions.

The *larynx* was seriously diseased in three of the undetermined cases, viz: in case 420 it was œdematous; in case 522 the immediate cause of death was throat diphtheria extending into the larynx, trachea and bronchial tubes; in case 409 an ulcer in the larynx had exposed the surface of the hyoid bone, which was roughened as if carious.

Bronchitis, unconnected with tubercular disease or pneumonia, appears to have been present in two of the cases of follicular ulceration, viz: 363 and 819, and in sixteen of the undetermined cases, viz: 123, 240, 255, 304, 356, 406, 407, 408, 409, 418, 526, 757, 759, 773, 775 and 803. Perhaps the same condition was also present, though not recognized, in some of the cases in which the lungs are said to have been merely congested, for the bronchial tubes were by no means systematically examined in these autopsies.

Congestion, occasionally limited to one lung, but usually involving both, was the only pulmonary lesion recognized in about a dozen of the cases of follicular ulceration, and about half as many more of the undetermined cases. In several of these cases the congestion is said to have been hypostatic, and it was probably of the same character in some of the others; in a few it may have represented incipient pneumonia.

---

* Page 314, *supra*. † Page 457, *supra*.

‡ These complications, in consequence of their rarity, have escaped the consideration of most of the writers on dysentery, who have either passed them over or, like JULIEN—*La dyssenterie en Cochinchine*, Montpellier Thesis, No. 62, 1864, p. 23—declared them to be of little importance. They particularly attracted the attention of the Wurtemberg physicians during the epidemic of 1834. According to G. C. F. HAUFF—*Zur Lehre von der Ruhr*, Tubingen, 1836, S. 314—during that epidemic HEIM found subarachnoid effusions in 22 out of 25 post mortem examinations; SPÄTH in 17 out of 20; and RAMPOLD in 4 out of 5. The effusion consisted in most cases of clear or bloody serum, but sometimes was gelatinous, (*i. e.*, contained coagulated fibrin,) and sometimes even the convolutions were coated with pseudomembranes. Similar effusions were found in the ventricles of the brain, and in two instances in the spinal canal. The substance of the brain was softened and rich in blood. These lesions were found in the bodies even of those who remained conscious to the last. These statements are undoubtedly open to the criticism made in the text on our own autopsies. HEUBNER—S. 528, *op. cit.*, *supra*, p. 529—takes a very similar view, saying that the Wurtemberg physicians were misled by false interpretation of "œdema of the subarachnoid lymph spaces." VOGT—*Monographie der Ruhr*, Giessen, 1856, S. 66—in speaking of the Wurtemberg observations, declared that in numerous autopsies in his own practice he had met these lesions but rarely except in those cases in which brain symptoms had been present during life. LYONS—*Report on the Pathology of the Diseases of the Army in the East*, London, 1856, p. 50—appears to have observed similar lesions, but gives no precise data as to their frequency: "In the Arachnoid, the changes have been confined to opacity, associated with fluid effusion over the convolutions and in the ventricles of the Brain. Congestion of the Pia Mater has been also observed to a morbid degree."

Pneumonia was a very frequent complication, and often proved the immediate cause of death. Not including those cases in which the disease supervened upon tubercles of the lungs, pneumonia or pleuropneumonia of one or both lungs was observed in rather more than one-fifth of all the autopsies. Thus, among the cases of follicular ulceration eighteen instances of pneumonic complication were observed. In four cases the lung lesion is described as lobular pneumonia, affecting the right lung in case 140, the left in case 167, both lungs in cases 339 and 351. In twelve cases the lesion is either described as red or gray hepatization, or simply as pneumonia, or hepatization, or inflammation, affecting the right lung in cases 86, 227, 389, 395 and 505; the left lung in cases 198, 265, 387 and 746; both lungs in cases 458, 732 and 858. Pleuropneumonia was observed on the right side, with pneumonia on the left, in cases 414 and 714.

Among the undetermined cases sixty-four instances of pneumonic complication were observed. In six cases the lesion is described as lobular pneumonia, affecting the left lung in cases 297 and 393; both lungs in cases 229, 705, 758 and 765. In forty-five cases it is described either as red or gray hepatization, hepatization, pneumonia or inflammation; affecting the right lung in cases 254, 283, 319, 384, 388, 391, 447, 448, 449, 527, 614, 618, 626, 631, 655, 656, 658, 698, 733, 735, 737, 738, 739, 755, 762, 791 and 792; the left lung in cases 84, 292, 453, 456, 601, 671, 736, 767, 804 and 834; both lungs in cases 193, 311, 604, 742, 745, 747, 768 and 813. Pleuropneumonia was observed in thirteen cases: on the right side in cases 405, 507, 673 and 678; on the left side in cases 509, 654, 681 and 753; on both sides in cases 420, 504, 649, 653 and 661. There are, besides, in each class several cases in which either no disease of the lung tissue is specified, or it is merely said to have been congested, but in which the recorded weight of one or both lungs is so great as to create a suspicion of the existence of pneumonia, so that it is highly probable that the frequency of this complication was even greater than would be indicated by a literal interpretation of the record.

The time of year at which these pneumonic cases died points significantly to the probable causes of the chest affection. I find that of the eighty-two instances of pneumonic complication mentioned above, sixty-nine died between the first of October and the last of March, and but thirteen between the first of April and the last of September.* A similar observation may be made with regard to the pneumonic complications observed in the other forms of flux discussed in previous portions of this chapter. Of forty-two such cases occurring in connection with non-ulcerative inflammation of the intestinal mucous membrane, twenty-seven died between the first of October and the last of March, and fifteen during the rest of the year;† and of twenty occurring in connection with acute diphtheritic dysentery, eighteen died between the first of October and the last of March, and but two during the rest of the year.‡

A comparison of these figures with the number of autopsies of each of the several forms of flux shows that pneumonia was observed rather more frequently than once in every four autopsies in which non-ulcerative inflammation of the intestine was found; rather less frequently than once in every five autopsies of acute diphtheritic dysentery; somewhat oftener than once in every six autopsies of chronic follicular ulceration, and once

* Viz: April, 2; May, 3; July, 2; August, 3; September, 3: total, 13. October, 4; November, 11; December, 14; January, 22; February, 12; March, 6: total, 69.

† Viz April 2; May, 6; July, 1; August, 3; September, 3: total, 15. October, 6; November, 3; December, 7; January, 2; February, 5; March, 4: total, 27.

‡ Viz: May, 1; September, 1: total, 2. October, 3; November, 3: December, 2; January, 1; February, 4; March, 5: total, 18.

in every four of the undetermined cases.* It will be observed that the difference in the frequency of pneumonic complications in the several groups of cases was not very great; and the fact that they were quite as common in the non-ulcerative cases as in the diphtheritic or ulcerative ones, confirms the view that their development was not dependent upon the character of the intestinal lesion.

The occurrence of *metastatic foci* in the lungs† does not appear to have been recognized in any of the autopsies. I note, however, among the cases of follicular ulceration three in which this lesion probably existed, viz: in case 139, "isolated nodular masses of effused blood about the size of shell-barks, some of which had a white central nucleus," were found in both lungs; in case 195 both lungs contained a number of small abscesses, there being also an abscess of the liver in this case; and in case 333 the right lung contained a number of "circumscribed condensations of tissue" which presented "the features of red and gray hepatization," and varied in size from that of a pea to that of a large walnut, a similar nodule being also found in the left lung. Among the undetermined cases there are at least two which probably require the same interpretation, viz: case 247, in which numerous small abscesses were found in both lungs; and case 787, in which circumscribed elevated spots, hard at their peripheries, soft in their centres, were observed on the surfaces of both lungs. Here too probably belongs case 393, mentioned above as one of lobular pneumonia; the lobules are said to have been hepatized gray.

To the foregoing I may add that the pneumonic process in case 460, mentioned on page 315, was probably of the same nature; "several of the lobules in all the lobes" of the right lung "were hepatized, some of them having advanced to the stage of gray hepatization;" in this case "no ulcers could be detected in the ileum," but there were one or two "abraded" spots in the cæcum. It has also been mentioned on page 457 that in case 160, one of the diphtheritic cases, a multitude of purulent foci were found in the lower part of the superior lobe of the left lung. These are the only autopsies I find among those hitherto recorded in which I feel warranted in interpreting the appearances observed as resulting from embolic pneumonia.‡ Possibly some few more of the cases recorded as lobular pneumonia were of the same nature, but I suspect that many of these were really examples of lobular collapse occurring during bronchitis, and not pneumonia at all.

Pleurisy or pleuritic effusion, uncomplicated with tubercular deposits or pneumonia, was observed in thirteen instances. Among the cases of follicular ulceration, in case 196 both pleural sacs contained "much serum;" in case 263 the right lung was compressed by two quarts of pus, and the pleura costalis was coated with pseudomembrane; in case 363 the pleural sacs contained six and three-quarter ounces of bloody serum; in case 426 the right pleural sac was about half-full of fluid; in case 697 it contained a large quantity of serum; in case 398 the left pleural sac contained two ounces of bloody serum; in case 645 "there were evidences of pleurisy on the left side;" in case 819 the right pleural sac contained sixteen ounces of serum, the left eight, and the surfaces of both lungs were coated with "unorganized lymph," bronchitis also existing in this case; in case 902 a hepatic abscess had discharged into the right pleural sac. Among the undetermined cases, in case 89 "evidences of recent pleurisy" were observed on both sides; in case 120 the thoracic

* The figures are as follows: Of 156 autopsies of non-ulcerative intestinal inflammation, (see note † to p. 314, *supra.*) pneumonic complications were recorded in 42, (see p. 315;) of 115 autopsies of diphtheritic dysentery, (see note to p. 456, *supra,*) they were recorded in 20, (see p. 457, *supra;*) of 103 autopsies of follicular ulceration, (see note † to p. 529, *supra.*) in 18; and of 293 undetermined cases, (see p. 525, *supra.*) in 64.

† See JUERGENSEN—*Embolische Pneumonie*, Ziemssen's Handb., Bd. V, Th. 2, Leipsic, 1874, S. 242, or Amer. Ed., Vol. V, New York, 1875, p. 245.

‡ In all, seven cases out of 667 autopsies, or rather more than one per cent.

cavity contained about three pints of fluid; in case 610 the left pleural cavity contained twelve ounces of purulent serum, (in this case the pericardium contained four ounces of serum and the abdominal cavity about twenty ounces;) in case 620 the right lung was coated with a large quantity of pus-like lymph; and in case 704 the right side of the chest contained fifty-four ounces of purulent serum.

If the foregoing summary account of the inflammatory affections of the respiratory organs observed in the chronic ulcerative cases be compared with the account given on page 315 of the similar complications in the non-ulcerative cases, and that given on page 457 of those observed in diphtheritic dysentery, the reader will not fail to be struck with the very great frequency with which these lesions accompanied the fluxes observed during the civil war. It must be remembered that in each instance the cases in which the inflammatory affection was a mere concomitant of phthisis have been rigorously excluded, such cases being separately enumerated under the head of tubercular disease of the lungs. I know of no other recorded statistics, except those of Griesinger, in which these inflammatory affections of the thoracic organs have played so conspicuous a role in the post mortem appearances of dysenteric subjects.*

Pleuritic adhesions of greater or less extent, and for the most part of ancient date, existed in many of the cases. Exclusive of those which were observed in connection with pneumonia and phthisis, they were noted, among the cases of follicular ulceration, on the right side in three instances; on the left in seven; on both sides in seven. Among the undetermined cases, on the right side in seventeen; on the left side in thirteen; on both

* It is not surprising that the occurrence of intercurrent pneumonia or other inflammatory affections of the respiratory organs should have failed to attract the attention of those who have studied dysentery in tropical lands. Thus, ANNESLEY—*Diseases of India*, London, 1828, Vol. II, p. 271—does not even mention them among the complications, and the same may be said of PARKES—*Dysentery and Hepatitis of India*, London, 1846, p. 38 *et seq.*—and MOREHEAD—*Disease in India*, 2d Ed., London, 1860, p. 271 *et seq.* JULIEN—*La dyssenterie en Cochinchine*, Montpellier Thesis, No. 62, 1864, p. 24—in his 108 autopsies seldom found any lung lesions. Occasionally some hypostatic congestion was observed in the posterior portion of the lungs; more rarely there was general pulmonary congestion. In one case pleurisy existed with considerable effusion. In the chronic cases complicated with dropsy, he sometimes found effusions of liquid in the pleural sacs and the pericardium as well as in the abdominal cavity. CATTELOUP—*Recherches sur la dyssenterie du nord de L'Afrique*, Recueil de Mém. de Méd., de Chir., et de Pharm. Militaires, T. VII, 1851, p. 87—went so far as to express the opinion that thoracic inflammations and dysentery are incompatible. He declared that in Algeria he had observed "a great number of cases of bronchitis and pneumonia, which are frequent during the winter, to be so favorably modified on the appearance of bloody alvine evacuations that the thoracic symptoms disappeared as by metastasis." GRIESINGER—*Krankheiten von Egypten*, Abschnitt X, Cap. 2, Archiv für Phys. Heilk., Bd. XIII, 1854, S. 539—alone, of the writers on the diseases of hot climates, appears to have found pneumonia a frequent complication. He relates with surprise that he found it more common in the dysentery of Egypt than in that of Germany. In 96 autopsies of primary dysentery he found lobar croupous pneumonia 7 times, and 12 times lobular scattered (not pyæmic) infiltrations associated with catarrh and œdema of the lung; 10 times he found considerable bronchitis, 4 times little apoplectic foci, and 7 times gangrene of the lungs. These results, which rival our own, must have been due to different causes. In the colder climates of Europe these chest complications might be expected to be, and undoubtedly are, more frequent than is usual in hot lands, but they do not attain the importance indicated by our own experience. According to HAUFF—*Zur Lehre von der Ruhr*, Tubingen, 1836, S. 315—serous effusions into the cavities of the pleura were occasionally observed by the Wurtemberg physicians; the lungs were often adherent to the pleura, partly congested—(theilweise infarcirt, blutreich; was this lobular pneumonia?)—usually of an ash-gray color. In seven cases HEIM observed a peculiar cinnabar-red color of a part or the whole of the lungs, which was sometimes superficial, sometimes penetrated more or less deeply into the parenchyma—S. 88. VOGT—*Monographie der Ruhr*, Giessen, 1856, S. 66—declared that all possible diseases of the bronchi, the lungs and the pleura may complicate dysentery, either being present before it begins or arising during its progress. He says, speaking of the cinnabar-red color of the lungs observed by the Wurtemberg physicians: "The observation is quite correct, and this cinnabar-red color is the same that STOKES regarded as the hyperæmia preceding pneumonia." ROKITANSKY—*Der dysenterische Prozess*, Oester. Jahrb., Bd. XX, 1839, S. 93—declared that in dysentery of an adynamic character, hypostasis of the lungs, sometimes developing into hepatization, is of frequent occurrence, but gives no figures to show how frequent. FINGER—*Die epidemische Ruhr*, Prager Vierteljahrschrift, 1849, Bd. IV, S. 143—in 231 autopsies of dysenterics found lobular pneumonia in 16, in 5 of which the affected lobules showed an inclination to sphacelus; croupous pneumonia he found in but 2 of the autopsies; pleurisy was noted in 6 instances, in 3 of which it was associated with lobular pneumonia. This makes altogether 24 instances of chest inflammations, or rather more than one in ten autopsies of dysentery. LYONS—*Report on the Pathology of the Diseases of the Army in the East*, London, 1856, p. 51—declares in a general way the lungs to have been the organs which "exhibited the greatest tendency to secondary engagements in dysenteric cases," and during the Crimean war regarded this as the more remarkable, because "idiopathic affections of these organs have been of great rarity," (p. 87.) Two forms of pulmonary complication were observed: 1, bronchitis, usually accompanied by well marked spots of lobular pneumonia; and 2, "engorgements or actual exudations into the pulmonary parenchyma." To the description given of these latter lesions he adds, in a subsequent part of his report: "In some cases of chronic Dysentery, consolidation existed with small abscesses, varying in size from that of a pea to a considerably larger mass of broken down exudation, while some were nearly as large as a walnut, and not limited by any margin, but they were gradually broken up in the centre, while the friable edges mingled with congested and healthy parenchyma," (p. 88.) SAVIGNAC—*Traité de la Dysentérie*, Paris, 1863, p. 111—declares that phlegmasias of the respiratory organs are not common in the course of acute dysentery, but that chronic dysentery singularly predisposes to them. He points out as one cause of the complication in acute cases that patients who incessantly get out of bed in inclement weather without precaution are apt to catch cold. HEUBNER—S. 528, *op. cit.*, *supra*, p. 529—says merely of this complication: "Die Lungen bieten nach längerem Krankenlager die Zustände der Atelektase und lobulären Pneumonie." This remark, taken in connection with the report of his own dissections and those of SEITZ—both cited in note † to p. 438, *supra*—seems to show that intercurrent pneumonia was not frequent in the dysentery of the Franco-German war.

sides in twenty-four. Local thickenings of the pleura, generally supposed to be *cicatrices*, were observed in five cases, viz: in case 138 an "old stellate cicatrix," about two inches in diameter, was found on the convex surface of the lower lobe of the left lung; in case 316 "several dense fibrinous bands resembling cicatrices" were observed at the apices of the lungs; in case 717 a cicatrix was observed at the apex of the left lung; in case 856 there were "a few" cicatrices at the apex of each lung; in case 370 "the lower lobe of the right lung presented posteriorly a hard spot about two inches in diameter, which extended into the parenchyma about half an inch, and was apparently the result of former inflammation."

Tubercular disease of the lungs in various stages, with or without vomicæ or intercurrent inflammations, was observed in fourteen of the cases of follicular ulceration, viz: in the right lung in case 336; the left lung in cases 225 and 870; in both lungs in cases 142, 223, 266, 310, 316, 355, 379, 381, 500, 518 and 869. Similar conditions were observed in fifty-seven of the undetermined cases, viz: in the right lung in cases 80, 322, 450, 457, 510, 520, 624, 676, 707 and 720; in the left lung in cases 79, 275, 577, 623, 778 and 847; in both lungs in cases 78, 85, 88, 90, 91, 96, 189, 260, 289, 290, 307, 365, 487, 521, 550, 568, 578, 607, 609, 629, 647, 650, 651, 660, 662, 663, 670, 674, 703, 709, 717, 718, 719, 721, 722, 727, 734, 756, 794, 807 and 851. A single nodule, supposed to be of tubercular nature, was observed in the left lung in case 380, in the right lung in case 713. One or more calcareous nodules, probably obsolete tubercles, were found in the lungs in four of the cases of follicular ulceration, 196, 281, 853 and 856, and in five of the undetermined cases, 459, 622, 724, 728 and 743.

If to the cases of tubercular disease enumerated above, not including the single or obsolete tubercles just mentioned, we add those enumerated on page 458 as having been observed in the autopsies of diphtheritic dysentery, and on page 315 as observed in those of non-ulcerative intestinal inflammation, it will be found that tubercular disease of the lungs was observed in nearly one-sixth of all the autopsies of fatal cases of the forms of flux hitherto described;* a circumstance almost as remarkable as the frequency of acute inflammations of the respiratory organs commented upon above. This complication was undoubtedly most frequent in the chronic cases, but was observed also in the acute. In the first instance the chest affection appears to have been developed, in many cases, during the progress of the flux; in the second the dysenteric attack occurred in patients already laboring under phthisis, which exhibits no such antagonism to dysentery as Rokitansky was led to believe existed.†

---

* Viz: out of 156 autopsies of non-ulcerative intestinal inflammation, tubercular disease of one or both lungs was found in 24, p. 315, *supra*; out of 115 of diphtheritic dysentery, in 11, p. 458, *supra*; out of 103 of follicular ulceration, in 14; and out of 233 undetermined cases, in 57; total tubercular complication in 106 of 667 cases.

† ROKITANSKY—*Über Combination und wechselseitige Ausschliessung verschiedener Krankheitsprozesse, nach Beobachtungen an der Leiche*, Oesterreich. Jahrb., Bd. XVII, 1838, S. 220: "Es gehört zu den seltensten Fällen, entwickelte Dysenterie neben Lungentuberkulose zu sehen, wohl nie kommt sie neben Darmtuberkulose zur Entwicklung," S. 232. One of the earliest protests against this too exclusive view was made by BALY—*Gulstonian lectures on dysentery*, London Med. Gazette, Vol. IV, 1847, p. 489—who declared that "in the Millbank penitentiary, as well as in several other prisons, both dysentery and tubercular disease have prevailed together during many successive years," and that "amongst 27 cases during the last six years in which death was caused principally by tubercular disease of the lungs, there have been 10 in which that disease was combined during the last few days or weeks of life with active dysenteric disease of the large intestines;" in three of the 10 the form of disease was "gangrenous inflammation of the colon." FINGER—S. 134, *op. cit.*, *supra*. p. 534—in 231 subjects dead of dysentery found tubercular disease 48 times. He states the fact also in another way: of 320 subjects dead of tubercular disease, dysentery was found 48 times; and he relates that he not merely found lung tuberculosis thus complicated, but also that in cases in which the tubercular disease of the lung was complicated by intestinal tubercle he saw the tubercular ulcers of the ileum coexist with the true dysenteric process in the colon, and also saw cases in which old tubercular girdle-ulcers of both small and large intestine coexisted with recent croupous exudates or small follicular ulcers. LYONS—p. 53, *op. cit.*, *supra*, on p. 534—found tubercular disease a frequent complication, especially of the chronic cases of dysentery during the Crimean war. He remarks: "The clinical and pathological relations of Dysentery and Tubercle were obscure in the highest degree. From the great chronicity which the Dysenteric process assumed in the cases presented to our observation, marked constitutional effects were induced. It is not improbable that the cachectic state thus brought about was highly favourable to the development of Tubercle, in systems naturally predisposed to it. Some of the cases were undoubtedly of a Scrofulous type of constitution, and perhaps only required the stimulus of a chronic disease like Dysentery to call the latent process into action."

In addition to the foregoing lung lesions it may be mentioned that in case 868 the lungs are said to have contained "melanotic nodules;" and that in case 833 a neoplasm of undetermined nature, but of "cartilaginous hardness," was observed on the surface of the left lung, and masses of a similar character existed in the liver.

The condition of the *bronchial glands* is very often not mentioned in these autopsies. In a few instances they are spoken of as dark, or pigmented; in others as large, or enlarged; in some they are said to have contained calcareous matter; but their condition is so rarely reported as to make it probable that they were seldom systematically examined.

Circulatory organs.—Well marked *pericarditis*, characterized by the formation of lymph or pus as well as serum in the pericardial sac, was observed in one of the cases of follicular ulceration, 858, and in three of the undetermined cases, 614, 653 and 678; in all these cases pneumonia coexisted. In three others of the undetermined cases, 673, 742 and 743, slight pericarditis is said to have existed. The pericardium contained two ounces or more of *effused serum* in seven of the cases of follicular ulceration, viz: in case 86, ten ounces; in case 426, three; in cases 194, 387, 401, 428 and 870, two. Similar conditions existed in thirty of the undetermined cases, viz: in cases 228 and 618 the pericardium was "distended" with serum; in cases 254 and 655 it contained twenty ounces; in case 681, sixteen; in case 634, twelve; in cases 388 and 671, ten; in cases 80 and 676, eight; in cases 85, 648 and 792, six; in case 717, five or six; in case 601, five; in cases 84, 383, 572, 610, 636 and 680, four; in cases 604, 782 and 851, three; in cases 120, 250, 285, 448, 450 and 520, two. Besides these cases, quantities of serum, less than two ounces, were found in the pericardium, or it is simply said to have contained serum, without specifying the quantity, in seventeen of the cases of follicular ulceration and thirty-five of the undetermined cases. *Adhesions*, probably of ancient date, existed between the heart and pericardium in cases 319, 351, 523, 638 and 697; in cases 277, 509 and 663 the heart and pericardium were universally interadherent.

The *heart* is spoken of in a number of cases as pale, or soft or flabby, or thin-walled, or as having no fat or but little fat upon its surface; in a few instances its muscular tissue is said to have been fatty. In ten of the cases of follicular ulceration the heart is said to have been *small*, and in seven others this is shown by its weight, viz: in cases 379 and 414 the heart weighed six ounces and a half; in case 196, six ounces; in cases 198, 336, 350 and 398, five and a half ounces. Among the undetermined cases the heart is said to have been small in about a dozen cases, and in eighteen others this is indicated by its weight, viz: in cases 334, 356, 411, 418, 721, 742 and 767 it weighed six ounces and a half; in case 396, six and a quarter; in cases 292, 739, 759, 765 and 772, six; in cases 406,* 756, 802 and 803, five and a half, and in case 448 about four ounces.

Valvular disease of the heart was observed in two of the cases of follicular ulceration, affecting the aortic valves in case 746, the aortic, mitral and tricuspid in case 870; and in eight of the undetermined cases, affecting the aortic valves in case 835; the mitral in cases 319, 735 and 786; the mitral and tricuspid in case 787, and probably case 509; in cases 743 and 745 the particular valves affected are not specified. In case 746 the valvular disease was associated with exquisite calcareous atheroma of the aorta;† atheroma of the aorta, in a less marked degree, was also observed in case 869. In cases 458, 461 and 541

* This heart is preserved in the Museum, Med. Sect., No. 403.

† The specimens are preserved in the Museum, Nos. 310, 311 and 312, Medical Section.

the foramen ovale still remained patulous. In case 454 the left pulmonary veins opened into the auricle by but a single opening.

If the cardiac lesions just enumerated be compared with those observed in the cases of non-ulcerative intestinal inflammation* and diphtheritic dysentery,† it will be noticed that the most significant lesions were very similar in each case. These were the occasional occurrence of acute pericarditis, which, as a rule, coexisted with pneumonia or pleurisy, the frequent presence of more or less effused serum in the pericardial sac, and a few examples of chronic valvular disease, which probably antedated the dysentery. To these must be added the small, pale, flabby, or even fatty condition of the heart, which was very often observed, particularly in the chronic cases; a condition I suspect to have existed more frequently in this group of cases than is indicated by the record, and which results from the protracted inefficiency of the nutritive processes in these cases.‡

Heart-clots.—Whitish or yellowish fibrinous coagula, either alone or associated with black clots, are recorded to have been observed in the cardiac cavities of one or both sides in a considerable number of instances. Among the cases of follicular ulceration such clots were observed on the right side in cases 140, 142, 145, 293, 368, 371, 381, 426, 427 and 428; on the left side in cases 227, 336 and 363; on both sides in cases 194, 198, 201, 223, 333, 370, 379, 389, 454 and 870. These clots extended both into the pulmonary artery and aorta in cases 194, 198, 201 and 870; into the pulmonary artery in cases 368, 370 and 371; into the pulmonary veins in case 454, and into the superior vena cava in case 370. In several other cases clots are said to have existed in the cardiac cavities, but their characters are not specified; in about half a dozen more, black clots only were found.

Among the undetermined cases fibrinous or mixed clots were observed in the right side in cases 89, 384, 388, 410, 620, 621, 738, 755, 802 and 810; in the left side in cases 228, 304, 396, 722 and 778; and in both sides in cases 275, 356, 375, 383, 407, 417, 418, 420, 448, 449, 452, 610, 614, 721, 724 and 768. The clots extended into the aorta in case 356; the pulmonary artery in cases 375, 620 and 621; the vena cava in case 375. There were also about a dozen cases in which clots are said to have existed, but their character is not specified, and about half as many more in which black clots only were found. There were also a few cases in which clots are mentioned without specifying either their character or the side on which they were found. If the foregoing observations be compared with those made in connection with the non-ulcerative and diphtheritic cases,§ it will be seen that fibrinous heart-clots are recorded to have been observed in more than one hundred of the autopsies, and it must be borne in mind, too, that in the majority of the autopsies no mention is made of the character of the cardiac contents, so that the percentage of cases in which this accident occurred is understated rather than exaggerated by the record.

Fibrinous concretions in the cavities of the heart began to attract the attention of pathologists soon after dissection was revived in Europe. Towards the close of the fifteenth

---

* *Supra*, p. 315. † *Supra*, p. 458.

‡ According to HAUFF—S. 315, *op. cit.*, *supra*, p. 534—the Wurtemberg physicians noticed the occasional occurrence of serum in the pericardium, and that the heart was sometimes small, sometimes flabby (bald welk und schlapp, einen häutigen Sacke ähnlich) during the epidemic of 1834. VOGT—S. 66, *op. cit.*, *supra*, p. 534—observed the complication with pericarditis, and remarked that dysentery may coexist with any organic disease of the heart. FINGER—S. 143, *op. cit.*, *supra*, p. 534—does not appear to have noticed these lesions. He mentions only that in 231 autopsies he saw moderate endocarditis twice, and a few instances of coagulation of the blood of certain veins, viz: 3 times in the sinuses of the brain, 3 times in the veins of the lower extremities, and once in the portal vein. The case in which the portal vein was involved was a woman 54 years old, and the lesion is said to have been diagnosticated during life by Prof. OPPOLZER. LYONS—p. 50, *op. cit.*, *supra*, p. 534—occasionally observed serous and sero-purulent accumulations in the pericardial sac in Crimean dysentery. HEUBNER—S. 528, *op. cit.*, *supra*, p. 534—remarks: "The heart is flabby, (schlaff.) The blood mass is considerably diminished, therefore all the organs are very anæmic."

§ Pages 316 and 458, *supra*.

century Benivenius* observed a blackish fleshy body in the left ventricle of a woman, and supposed it to have caused her death. During the sixteenth century whitish or yellowish fibrinous clots were found in the cardiac ventricles by a number of observers. Similar clots, seen in the sinuses of the brain by the barber-surgeons who accompanied the Hungarian campaigns, were supposed to be worms, and this notion having been extended to the cardiac coagula, was accepted by some as late as the seventeenth century, as is illustrated by the celebrated case observed by Edward May in 1637.† But from a very early period, less credulous observers, such as Helidæus, Coiter and Erastus, described the cardiac coagula as composed of concreted phlegm,‡ and Coiter sharply ridiculed for their credulity the barber-surgeons who supposed them to be worms.

I note that according to Morgagni,§ Fabricius Bartoletus (1633) first spoke of these concretions as "polypoid." I note also that Tulpius,‖ in 1641, described a concretion found

* BENIVENIUS—*De qbditis nonnullis ac mirandis morb. et san. causis*, Cap. 35; I cite the Paris Ed. of 1529, fol. 9—described the substance found as "frustulum nigrioris carnis in sinistro cordis ventriculo supra arteriam, quod mespilii formam haberet." I suppose this to have been merely a firm black blood clot, and put the same interpretation upon the mass of glandular but blackish flesh, almost two pounds in weight, ("carnis libras propemodum duas reperimus, corde instar uteri,") which VESALIUS found, some fifty years later, in the left ventricle of a man who for some time had been troubled by a very irregular pulse, which at times beat as if the heart were endeavoring to expel something—*De Humani Corp. Fabr.*, Lib. I, Cap. 5; I cite the Venice Ed. of 1568, p. 15: this case is not related in the Basel Ed. of 1543, but was introduced in the edition of 1555.

† According to COITER—*Extern. et intern. princip. humani corporis partium tabulæ, atque anatomicæ exercit. observationesque*, etc., Nuremberg, 1573, p. 110—many physicians, but especially the barber-surgeons, ("barbi tonsores,") had observed the conditions referred to in the text. They supposed that in the Hungarian fever the brain putrefied, and that worms were thence generated; and interpreted the concretions they sometimes saw in the hearts of these patients in the same way, calling them heart-worms, ("die hertz würme.") COITER ridicules these notions, and declares that the vermiform concretions found by him in the cerebral sinuses and heart of a woman, who died of a phrenzy supervening upon an ardent fever in 1567, were composed of white phlegm, ("alba pituita conflata,") and states that he had observed similar appearances in the brain sinuses of persons dead by hanging. HOLLERIUS—*De Morb. Intern.*, Venice, 1572, Lib. I, Cap. 27, scholia, fol. 79—attributed the notion that worms in the heart were the cause of cardiac palpitations to MESUE, ("vermibus cor vellicantibus, ut vult Mesue,") who wrote in the eleventh century; but this was not an opinion based upon anatomical observation, but a notion suggested by the analogy of intestinal worms, as may be seen in the passage referred to. MESUE—*Grabadin, id est compend. secret. medicament.*, Lib. II. Partic. 2, Summa IV, Cap. 1, Opera, Venetiis, apud Juntas, 1581, fol. 272—"Et sunt ex vermibus habentes aculeos pungentes orificium stomachi punctione vehementi, donec faciant cadere in dolorem acutum causam ad syncopim, et aliquando ad mortem; et sunt quandoque ex penetrantibus usque ad cor, et sunt causa mortis festinæ." On the other hand VIDUS VIDIUS (died 1569)—*De curatione membratim*, Lib. VIII, Cap. I; I cite Opera, Frankfort, 1626, T. II, p. 271—evidently had in view observations such as those criticized by COITER, though he regarded them with greater credulity, when, speaking of the anomalous contents of the cardiac ventricles in disease, he wrote "ad quas potissimum vermes referuntur, ques aliquando in pestiferis febribus, in ventriculis cordis fuisse genitos, audivimus ab hominibus fide dignis, qui ejusmodi aegrotantium cadavera secuere, quamvis verisimile sit raro admodum istud contingere." Several other observations of cases in which worms were supposed to have existed in the heart were collected by SCHENCKIUS—*Obs. Med.*, Frankfort, 1609, Lib. II, p. 296—under the heading "Vermes cordis." BONETUS—*Sepulchretum*, Geneva, 1679—repeated some of these cases, and added others in which cardiac worms were supposed to be the cause of syncope, Lib. II, Sect. 10, Obs. 7, p. 681; and even of sudden death, Lib. II, Sect. 11, Obs. 3, p. 695. The observation of MAY, mentioned in the text, has recently been reprinted by RICHARDSON (p. 67, *op. cit.*, *infra*) from a "quaint paper" in the library of the "Medical Society," which I have never seen. I find the case, however, related by ZACUTUS LUSITANUS—*De praxi med. admir.*, Lib. II, Obs. 140, p. 37, in Opera, T. II, Lyons, 1649—and by MARCUS AURELIUS SEVERINUS—*De recondita abscessuum natura*, Ed. secunda, Frankfort, 1643. Lib. IV, ad fin., p. 281—under the title "Historia mirabilis anguis bifidi flagellosi in lævo cordis sinu reperti," illustrated by two figures etched on copper, one of which, representing the supposed worm, has been copied by RICHARDSON, (*loc. cit.*) It had a bloody head and a straight cylindrical body which divided into two crura or thighs, and these again each into several smaller branches. MAY thought it had a central intestine or bloodvessel, which opened between the thighs by an orifice capable of receiving a probe. The other figure, representing the heart with the worm coiled up in it, is evidently, from the manner in which the heart is represented, drawn from memory rather than from the object; and I suspect that the clot never had the position shown, but that its trunk passed through the semilunar valves and bifurcated at the junction of the aorta and innominate artery, forming the crura, while the secondary branches were formed further on, as in the very similar clot in specimen No. 638, Medical Section, Army Medical Museum.

‡ According to SPIGELIUS—*De semitertiana* (1624) Lib. I, Cap. 15; I cite Opera, Amsterdam, 1645, *De semitert.*, p. 10—HELIDÆUS of Padua, some time during the previous century ("præterito seculo") dissected, in the hospital at Bologna, the body of a subject dead of a protracted quartan in whose heart and veins long white fragments of phlegm were found, ("frusta magna, longa, alba, pituitosa.") MORGAGNI—*De Sed. et Causis Morb.*, Lib. II, Epist. 24, § 22—gives HELIDÆUS the credit of being next after BENIVENIUS to observe cardiac coagula; but he does not state when he made the observation recorded by SPIGELIUS, or, indeed, when he lived, relating only, in order to approximate the period, that he was the preceptor of FORESTUS. Now FORESTUS commenced the study of medicine about the year 1539 at Louvain, went into Italy about four years later, where first probably he could have studied with HELIDÆUS; this can hardly fix the date of the observation in question. The observations of COITER are mentioned in the last note. ERASTUS—*Disp. de feb. putrid.*, Basel, 1580, Part 5; I cite from SCHENCKIUS, *Obs. Med.*, Frankfort, 1609, Lib. II, p. 298—found a concretion of pituitous humor, "concretio quædam humoris pituitosi," which resembled the marrow of cooked beef bones, in the hearts of two subjects dead of fever and pleurisy. I may add that SCHENCKIUS also relates (*loc. cit.*) that NERETUS NERETIUS, a physician of Florence, observed a "whitish fleshy substance" in the left ventricles of four subjects dead of pleuropneumonia, and also in the right ventricle of a woman dead of the same disease, in whom it extended a long distance into the vena cava.

§ MORGAGNI—*De Sed. et Causis Morb.*, Lib. II, Epist. 24, § 24—the word used by BARTOLETUS was "polypodi."

‖ TULPIUS—*Obs. Med.*, (1641;) I cite the Amsterdam Ed. of 1652, Lib. I, Cap. 27, polypus cordis, p. 55. The concretion in this case is represented by an admirable etching on copper. "It lay in the left ventricle, adhering by many branching roots to the columnæ carneæ of the heart, thence it stretched through the aortic orifice, and shortly after branched. TULPIUS falls into the palpable error of supposing one of these branches to lie in the aorta, the other in the pulmonary artery, (arteria venosa;) for, of course, the branches were formed, one in the aorta, the other in the innominate artery. He says the name polypus was given partly from its many feet, (*i. e.*, filaments adhering between the columnæ carneæ and chordæ tendineæ,) partly from its similitude in form and material to polypus of the nose, a case of which he had described in the previous chapter, (Cap. 26, Polypus narium,) in which he says the name polypus is derived either from the marine creature so-called, (à pisce marino,) or from the number of feet, (*i. e.*, roots.) He supposed the cardiac concretion he described to have caused death by preventing the closure of the aortic valves and otherwise interfering with the functions of the heart.

in the left cardiac ventricle, which the physicians who witnessed the dissection, with one consent, called a polypus of the heart, so that Schroetter* is certainly in error when he declares that these coagula were first so designated by Sebastian Pissinius,† whose essay, De Polypo Cordis, was not published until 1654. A few years later Thomas Bartholinus‡ published, (1657,) under the title Polypus Cordis, an observation made by Michael Kirstenius in 1651, which, like that of Tulpius, is illustrated by an excellent etching on copper. After this, observations and essays multiplied.§ It was generally agreed that the polypi were composed of concreted phlegm; that they were formed during life, and the most various symptoms were attributed to them, such as irregularities of the pulse, palpitation of the heart, embarrassed respiration, suffocative catarrh and sudden death.

Kerckringius|| appears to have been the first to have raised his voice against this popular opinion, declaring that the so-called polypi were merely coagula formed from the blood after death, and that the symptoms attributed to them were really due to other causes. Similar views were maintained by Pasta,¶ 1737, in a dissertation which appears to have convinced Morgagni,** in whose work the subject is treated in the most elaborate manner. Morgagni concluded that cardiac polypi were composed of the very same substance as the buffy coat that forms on blood drawn from a vein, and that while they might possibly sometimes form during the last moments of life, or during protracted syncope, yet that in most instances they were of post mortem origin.

On the other hand, Haller,†† while he admitted that cardiac coagula were so common that a dead body is seldom dissected in which they are not found, especially on the right side, declared that he was by no means willing to strike polypus of the heart from the number of diseases. True polypi, as he called them, firm, white coagula, formed of many concentric laminæ, more or less fibrous in texture and adherent to the interior of the heart, were so often observed in individuals whose death had been preceded by cardiac palpitations, irregular pulse, difficult respiration and the like, that he held fast to the belief that these

* SCHROETTER—*Gerinnungen im Herzen*, Ziemssen's Handb., Bd. VI, Leipsic, 1876, S. 268; or Amer. transl., Vol. VI, New York, 1876, p. 292. In most respects an excellent, though brief, article.

† S. PISSINIUS—*De diabete et polypo cordis*, Milan, 1654; I have not seen this essay, and cite the title from HALLER—*Bibl. Med. Pract.*, T. II, Basel, 1777, p. 406. MORGAGNI *(loc. cit.)* assigns it to the same date.

‡ BARTHOLINUS—*Hist. Anat. Rar. Cent. III*, Copenhagen, 1657—Hist. 17, *Polypus cordis*, p. 39. In this case there were fibrinous clots in both sides of the heart, extending from the right ventricle into the pulmonary artery and its branches, and from the left ventricle into the arch of the aorta and its branches. Fibrinous clots were also found in the cerebral sinuses. The copper etching is very graphic, although less artistic in its execution than that published by TULPIUS. BARTHOLINUS expressly states that this observation was made in 1651.

§ As, for example, MALPIGHIUS—*Diss. de polypo cordis*, Amsterdam, 1669; I cite Opera, Leyden, 1687, T. II, p. 311; GERARD BLASIUS—*Obs. Med. Rar.*, Amsterdam, 1677, Pars 6, Obs. 1, p. 73, *Polypus cordis*, illustrated by two figures, Tab. VIII, Figs. 1 and 2; and the cases collected by BONETUS—*Sepulchretum*, Geneva, 1679, viz: Lib. II, Sect. 1, Obs. 92, 93, 94 and 95, pp. 430–31, and Lib. III, Sect. 21, Obs. 3, p. 1037 *et seq.*, which contains a number of observations with interesting scholia on pp. 1046–47, &c.

|| TH. KERCKRINGIUS—*Spicilegium Anatomicum*, (1670;) I cite Opera, Leyden, 1717, p. 145. He called them "pseudopolypi," and declares "nihil enim aliud sunt, quam sanguis, qui post animalium mortem refrigeratus et grumosus, durâsque redditus," &c., adding further the notable statement that he had been able to produce them in animals as often as he pleased. Rough etchings are subjoined in Tab. 23, showing various pseudopolypi.

¶ ANDREA PASTA—*Epist. ad Alethophilum duæ*, Bergamo, 1737, Epist. 2, *De Cordis polypo in dubium revocato*, p. 9 *et seq.* A most interesting essay, in which abstracts of almost all the previously published observations are given, and the objections of the author to the generally accepted view supported by admirable arguments. The same opinions had previously had the support of the observations of LOUIS PETIT—*Second mémoire sur la manière d'arrêter les hémorrhagies*, p. 388 of Mémoires appended to Hist. de L'Acad. Royale des Sci., 1732, Paris, 1735—who, after stating that the "lymphatic part" of the blood only coagulates, and that in doing so it sometimes, but not always, entangles the "globulous or red part" with it, remarked that ordinarily on opening cadavers the blood is found coagulated in the heart and vessels, but not always in the same way; sometimes the red part is exactly mingled with the lymphatic, forming a red firm clot, while at other times the clot is composed of two parts, one white, composed of lymph, and the other red. Moreover, since the lymphatic part is the lightest it will be uppermost, provided the cadaver has grown cold in the horizontal position, as is usually the case.

** MORGAGNI—*Op. cit.*, Epist. 24, § 22–31; also Epist. 4, § 22; Epist. 17, § 29; Epist. 18, § 9; Epist. 52, § 34; and Epist. 64, § 9.

†† ALBERT V. HALLER—*Elementa Physiologiæ*, Lib. V, Sect. 1, § 11, T. II, Lausanne, 1760, p. 23—while emphasizing the firmness, laminated or even fibrous character, &c., of what he called "polypi veri," nevertheless denied that they are ever enveloped in true membranes, or that these membranes are ever vascular, as some had asserted: they are simply blood coagula, often formed after death, but very often also during life. Similar coagula had been observed also in the lower animals, as in the elephant, the lion and the horse. I may add that the discussion is enriched with a bibliography worthy of all praise. Indeed, I may say that the works of MORGAGNI (cited last note) and HALLER are the best guides for the modern student to the early literature of this subject. I may also mention in this connection the essay of JOSEPH PASTA—*De sanguine et de sanguineis concretionibus*, &c., Bergamo, 1786—a work of 157 pp., 8vo, in which the opinions of ANDREA PASTA are maintained and copious references to the literature given.

symptoms were actually produced by the concretions found after death. Whatever impeded the motion of the blood through the heart might give rise to coagula, as in aneurisms or after arteries are ligated. Hence polypi were so frequently found in patients who have suffered from asthma, pneumonia and phthisis. The credit of having first proposed the distinctions just mentioned between true polypi, or those formed during life, and mere post mortem coagula, has been erroneously attributed to Corvisart,* who, however, did nothing in this respect but follow in the footsteps of the great physiologist.

Kreysig† advanced the opinion that these polypi were products of an inflammation of the endocardium, and asserted the existence of a genuine carditis polyposa. This opinion was widely accepted as an explanation of a portion of the cases, at least, notwithstanding the objections urged against it by Laennec.‡ To Laennec belongs the credit of having directed attention to those cyst-like formations, which he called "*végétations globuleuses*," and the contents of which he supposed in some cases to be altered blood or decomposing fibrin; in others true pus. This latter opinion was shared by Legroux § and several subsequent writers. Even Cruveilhier,‖ who earnestly combated the suggestion of Legroux that the cardiac concretions might be themselves the seat of a suppurative inflammation, does not appear to have doubted that these cysts sometimes actually contain pus; a belief which, in the present condition of pathological histology, is no longer tenable.

The opinion that certain varieties of fibrinous concretions might form in the heart at variable periods before death was now fixed upon a firm foundation. Babington ¶ vainly protested against it. It was sustained by Bouillaud, Hughes and Rokitansky, who agreed as to the general proposition, though differing somewhat in matters of detail. The same

* J. N. CORVISART—*Essai sur les maladies et les lésions organiques du cœur et des gros vaisseaux*, 1806; I cite the 2d Édit., Paris, 1811, p. 458, *Des concrétions polypiformes.* Among those who have fallen into the error referred to in the text, I may mention BOUILLAUD—cited note *, p. 541, *infra*—and COPLAND—cited note ‖ on the same page.

† KREYSIG—*Die Krankheiten des Herzens*, Th. 2, Abth. 1, Berlin, 1815, S. 90 und 396; I have not been able to see this work, and cite from FRIEDREICH—*Herzkrankheiten*, in Virchow's Handb. der Spec. Path. u. Ther., Bd. V, Abth. 2, S. 401 u. 404.

‡ LAENNEC—*Traité de L'Auscultation Médiate*, (1819;) I cite the 4me Edit., Paris, 1837, T. III, Ch. 18, p. 289 *et seq.* He agreed substantially with HALLER and CORVISART in the distinction between recent and old coagula. In the first or recent concretions there is a thin fibrinous layer around clots of cruor, which resembles the buffy coat, or, if denser masses are formed, they are not usually adherent to the heart; sometimes they are jelly-like and semi-transparent, but not firm nor distinctly fibrinous. The second or more ancient concretions are firm, sometimes almost as tough as muscular tissue, and are more or less strongly adherent to the internal surface of the heart. They are more opaque than the others, and their fibrinous character is better marked. He even supposed that in some cases he saw rudimentary bloodvessels, the organization of which proceeded as in the fœtus, ("l'organisation vasculaire se développe à peu près comme chez le fœtus.") He found such concretions most frequently in the right cavities of the heart. While combating the opinion of KREYSIG, (p. 313 *et seq.*,) he admitted that the adhesions between the polypi and the cardiac walls may be due to inflammation of the latter, but if so, thought the inflammation was probably a secondary process due to the irritating action of the clot itself, ("l'action irritante du caillot lui-même sur les parois du cœur, qui peut déterminer l'exsudation d'une lymphe plastique," p. 315.) On the other hand, he held that the polypoid concretions are themselves living and capable of organization, and that the adhesions may depend on this. The chief merit of LAENNEC in this connection, however, is his admirable description of what he called "végétations globuleuses," p. 344 *et seq.* These were spheroidal or oval cysts, varying in size from that of a pea to that of a pigeon-egg, whitish and smooth on the exterior, their walls opaque and seldom more than half a line in thickness. The contents resembled half-liquid blood of turbid appearance, as if an insoluble powder had been stirred in; or was more pultaceous, resembling the lees of wine; or, finally, yellowish and opaque, resembling thick pus, or evidently formed of decomposed fibrine, such as is sometimes observed in aneurismal sacs. Such cysts are found adherent to the parietes of the ventricles or the sinuses of the auricles, and are as frequent in the right side of the heart as in the left. The pus-like contents of some of these cysts he held to be really pus, and endeavored to distinguish it from decomposed fibrine, ("dans les plus anciennes une matière qui paraît être du pus, car il en a la couleur jaune citron, et non la couleur jaune fauve de la fibrine décomposée," p. 348;) but since pus was not always present, he would not admit that the cysts owed their origin to inflammation, and thought it wiser to leave the question of their causation an open one, p. 350. I may add that ALLAN BURNS—*Obs. on some of the most frequent and important Diseases of the Heart, etc.*, Edinburgh, 1809, p. 200—had previously described a polypus "more than one inch in length in the left ventricle" attached to the septum of the heart, in the centre of which he found an abscess which, "when opened, discharged above a teaspoonful of perfectly formed purulent matter."

§ C. J. LEGROUX—*Rech. sur les concrétions sanguines dites polypiformes, développées pendant la vie*, Paris Thesis, No. 215, 1827—held also that these concretions were in some cases connected to the cardiac parietes by vessels of new formation, (p. 35.) He believed that in some cases an inflammatory process was set up in the concretion, resulting in the formation of pus.

‖ J. CRUVEILHIER—*Anat. Path. du Corps Humain*, T. II, Paris, 1835-42, Livraison 28. He, too, held that some concretions were merely mechanically adherent, others organically united to the walls of the heart. Purulent cysts belonged to the latter category, and are united by inflammation to the cardiac walls whence the pus is derived, ("le pus central de ces caillots a sa source dans la membrane interne du cœur.") In Plate 4, Fig. 1′ and 1″, he gives colored representations of such a pus-containing clot.

¶ B. G. BABINGTON—*Blood, morbid conditions of*, in Todd's Cyclopædia of Anatomy and Physiology, Vol. I, London, 1835-6, p. 421: "That such congulation may take place during life I am willing to admit, but I am by no means led to the conviction that such an event often occurs. To the formation of a firm coagulum I am persuaded that rest is absolutely necessary, and I must consider it as a very rare occurrence that the contents of the cavities of the heart should be at rest during life." The usual appearance of the concretions "is such as would take place in blood that coagulated very slowly, whether in or out of the body."

view has been maintained in the most recent times, especially by Gerhardt and Richardson,* who have once more revived the attempt to diagnosticate the presence of these concretions during the life of the patient. The chief symptoms relied upon by Richardson for this purpose are the sudden occurrence during an acute inflammatory attack, or during the puerperal state, of a peculiar and distressing dyspnœa, small intermittent pulse, venous congestion of the lips and cheeks accompanied by coldness and whiteness of the general surface, muscular prostration with constant restless motion of the limbs, involuntary discharge of the excretions, and death. This train of symptoms is supposed to indicate the formation of fibrinous concretions in the right side of the heart; if the patient does not speedily perish, the venous obstruction produced by the foreign body in the right cardiac cavities may even lead to general anasarca. When the concretion forms in the left side of the heart the symptoms are somewhat different; congestion of the lungs and suffocative dyspnœa are then prominent phenomena; the muscular perturbation lapses into violent convulsions, and coma precedes dissolution.†

These symptoms are not materially different from those relied upon for the same purpose by previous writers, particularly by Senac, Laennec and by Bouillaud.‡ In addition to these, Gerhardt§ has pointed out that heart-clots, especially in the cavities of the left side, may become the source of emboli, and endeavored to trace some connection of diagnostic worth between their seat and number and the seat of the original concretion in the right or left heart, but, as he himself confesses, with slender results. I must, however, certainly agree with Schroetter,‖ that all the symptoms brought forward may also result from other causes than cardiac concretions, and cannot therefore be regarded as characteristic; and I may add that Richardson himself admits that there are no reliable physical signs by which the concretions can be detected.¶

The proposition that certain cardiac concretions are formed during life would appear, then, to rest exclusively upon the anatomical characters of the concretions found. It is

* BOUILLAUD—*Nouvelles rech. clin. sur les concrétions sanguines formées pendant la vie*, &c., L'Expérience, T. III, 1839. pp. 273 and 337. H. M. HUGHES—*Obs. on fibrinous concretions in the heart*, Guy's Hospital Reports, Vol. IV, 1839, p. 146. ROKITANSKY—*Bemerkungen und Zusätze, betreffend die faserstoffigen Gerinnungen in den Herzhöhlen*, etc., Oesterreich. Med. Jahrb., Bd. 24, 1841, S. 53. According to this observer, the conditions which determine the development of heart polypi during life may be divided into two groups: 1, A preternatural inclination to coagulation on the part of the fibrin of the blood, either from idiopathic disease or the admixture of foreign matters. Such an anomalous condition of the blood occurs in ordinary inflammation, in croup, rheumatism, and in blood-poisoning by the absorption of the products of inflammation. 2, Conditions favoring an unnatural delay or even stasis of the blood-mass in the cardiac cavities, such as (a) depression of the heart's function, as in hypertrophy with dilatation, and during the agony if the heart gradually becomes paralyzed; or (b) stenosis of the cardiac orifices. As to their form he distinguished three kinds of fibrinous concretions in the heart: 1, Lumpy or stringy-like coagula, which are the more entangled with the trabeculæ of the ventricles the longer before death they were formed; 2, vegetations on the cardiac valves; 3, spherical vegetations, (*végétations globuleuses* of LAENNEC.) The fluid contained in these, as GULLIVER had previously pointed out, is not pus, but a mass of molecular debris derived from the decomposition of the fibrin, in which only here and there a pus corpuscle (*!*) swims. In his *Lehrb. der Path. Anat.*, Bd. II, 3te Aufl., Vienna, 1856, S. 283, he makes the spherical vegetations a mere variety of the first kind, but otherwise holds substantially the same views as in his original paper. C. GERHARDT—*Ueber Blutgerinnung im linken Herzohre*, Würzburger Med. Zeitschrift, Bd. IV, 1863, S. 151. BENJ. W. RICHARDSON—*On fibrinous deposition in the heart*, British Med. Jour., Jan. 1860, pp. 21, 45 and 65; *On treatment in extremis of acute cases of fibrinous deposition in the heart*, abstract of a paper read before the Medical Society of London, Med. Times and Gazette, June, 1873, p. 636; and *The cause of the coagulation of the blood*, &c., London, 1858.

† RICHARDSON, p. 423 *et seq.*, work last cited. With regard to the symptom of anasarca, I may cite the following passage: "In one instance which I observed, the symptoms of dyspnœa extended over many days, and anasarca supervened as a result of the obstruction."

‡ SENAC—*Traité de la Structure du Cœur, de son action et de ses Maladies*, Paris, 1749, T. II, Liv. IV, Ch. 10, p. 442 *et seq.* Note particularly his remarks on the symptoms produced, pp. 470–77. LAENNEC, *loc. cit.* in note ‡, p. 540, *supra*. BOUILLAUD, *loc. cit.* in note *, *supra*.

§ GERHARDT—*loc cit.* in note *, *supra*.

‖ SCHROETTER—*loc. cit.* in note * to p. 539, *supra*. The reader desirous of investigating this interesting subject for himself will find, prefixed to the article of SCHROETTER cited, references to a number of the more important modern papers. Brief bibliographies are also given by COPLAND—*Of polypous concretions in the cavities of the heart*, Art. *Heart and pericardium*, Dict. of Pract. Med., Vol. II, London, 1844, p. 228, (the article itself contains several historical inaccuracies on p. 220,) and FRIEDREICH—*Gerinnungen im Herzen*, in Virchow's Handb. der Spec. Path. u. Ther., Bd. V, Abth. 2, Erlangen, 1855, S. 401. From these references, and those given by MORGAGNI and HALLER, a good survey of the subject may be obtained. There are, moreover, a number of reports of single cases scattered through the medical journals, which it would be profitable to collect.

¶ BOUILLAUD—p. 277, *op. cit.*, *supra*—spoke of a characteristic whispering murmur, "un bruit de piaulement, * * un bruit de sifflement aigu," but admits that he has also heard these sounds in cases in which no concretions were found after death in the cardiac cavities. RICHARDSON—*op. cit.*, p. 429—speaks of "a peculiar rumbling, fidgety, jog-trot motion, with which the two sounds are heard in natural sequence as regards each other, but irregularly and lispingly." But this able observer did not attach undue importance to such uncertain signs, and cautiously adds: "The diagnosis must therefore rest on the general symptoms, rather than on the physical."

now admitted on all hands that mixed clots, in which the upper surface consists of a layer of fibrin, shading more or less gradually into a soft mass of cruor below, are formed after death, and that clots composed of completely separated fibrin must have been formed either during the death agony or at some previous period. A distinctly laminated or fibrillated texture of the clot and its firm adhesion to the cardiac parietes have been regarded by many, ever since the time of Haller, as proof that it was formed some time before death. But the texture of the clot varies quite as much with the varying qualities of the blood-fibrin in different individuals as with the time that has elapsed since the coagulum began to form. The variations in the buffy coat of blood drawn from a vein illustrate this proposition. If the fibrin of the blood were simply whipped out by the projecting irregularities of the cardiac cavities during the last moments of life, and allowed to repose for a variable period after death before it was examined, it is not unreasonable to believe that all the various degrees of lamination, fibrillation, firmness or softness, commonly found, would be observed; the variations depending rather upon the composition of the blood-fibrin than upon the circumstances under which the clot was formed.

The degree of adhesion to the cardiac parietes likewise depends, so long as this adhesion is purely mechanical, merely on the varying composition of the blood-fibrin. Nor can I regard the circumstance that a clot is grooved externally by the blood current, or hollow, as if it had formed around a blood stream, or deeply indented by surrounding structures, or that long branches proceed from it into the great vessels that open into the heart, as proof that it was formed at any considerable period before death. All these conditions might be expected to occur, in favorable conditions of the blood-fibrin, during the few minutes of the death agony, while the vitality of the blood was gradually diminishing and the heart still feebly acting. Even if the clot completely fills one of the cavities of the heart, for example the right auricle,* there is no reason to conclude from that circumstance that it was formed otherwise than during the agony; and the same may be said with regard to the disproportion between the weight of the heart-clot and the quantity of blood found along with it in the cardiac cavities, which has been insisted upon by Richardson† as proof of the ante mortem formation of such clots. Finally, I may remark of the ingenious experiments in which Richardson has artificially developed heart-clots in living animals, that the evidence does not satisfactorily show that the clots found were actually formed at any earlier period than during the agony.‡

* Thus ROKITANSKY—*Lehrb. der Path. Anat.*, 3te Aufl., Bd. II, Vienna, 1856, S. 284—records a case in which the whole left ventricle was stuffed with what he calls leukæmic clots, (leukämische Gerinnungen.) The patient was a woman, 42 years old, who had a splenic tumor and dysentery. RICHARDSON—*op. cit.*, p. 403—reports three cases in which the right auricle was completely filled with fibrinous clots; one a child who died of acute laryngitis, the second a child who died of pneumonia, the third an infant who suffered from hypertrophy of the spleen and purpura. C. HOUSLEY—*Death from fibrinous concretions in the right side of the heart*, Med. Times and Gazette, Vol. XVI, 1858, p. 425—reports a similar coagulum in the right auricle of a child 2 years old, who had pneumonia of a part of the right lung. According to SCHROETTER, *loc. cit.*, VIRCHOW observed a similar coagulum in the left auricle. Now it seems self-evident to me that the last increments of such bulky concretions could only have been formed during the agony, and I see no reason to suppose that the whole mass might not be separated from the blood in a very few minutes, especially when we consider the disposition to coagulation which exists in inflammatory blood.

† RICHARDSON—Brit. Med. Jour., Jan., 1860, p. 65—has laid great stress upon this argument, which certainly shows that the large clots in question must be formed while the heart is still beating; but, as during the death agony the whole blood of the body must pass at least several times through the heart, this argument is of no force if used to favor the belief that the clots antedate the agony.

‡ RICHARDSON—*Op. cit.*, p. 67—says that the best way of performing these experiments is to place a carnivorous animal in a chamber supplied with a current of pure freshly-made oxygen: "When the animal begins to fail, or, in other words, to sink, there is manifested in all his movements the signs of obstruction of the heart—signs which will hereafter be more carefully indicated. The sinking fully set in, (for, before the sinking, there is no concretion, the prostration being the mere result of the obstruction,) narcotic vapour is introduced into the chamber, and, insensibility complete, the vivisection is made. I have extracted large concretions from six animals under this condition." Now this language seems to show pretty conclusively that the concretions were not found if the animal was opened before it was actually dying. Indeed, I may point out that in what appears to be the most successful experiment of this kind performed by RICHARDSON—p. 73 of *The cause of the coagulation*, &c., cited *supra*, p. 541—in which, after death from exposure to an atmosphere of oxygen, the right auricle of a cat was found "literally choked with a tough fibrinous mass, which was firmly adherent to the wall of the auricula." The animal was not opened until "about two hours after death," so that the experiment really affords no proof whatever that the clot was formed before the agony. FAURE—*Recherches exp. sur les caillots fibrineux et sur les produits d'inflammation du cœur*, Archives Gén.

But, although none of the foregoing circumstances can be regarded as affording satisfactory proof that the fibrin-clots found in the heart were formed before the agony, I do not doubt in the least that, under favorable conditions, such clots are actually formed at various periods before death. This belief is based upon the fact that clots are occasionally found which have undergone central softening or other degenerative metamorphoses that require considerable periods of time to effect them. To this category belong not merely globular or oval cysts, like those described by Laennec, but adherent coagula of the most diverse position and size,* whose central portion has undergone softening into a pap-like fluid of diverse appearance, in which the microscope detects nothing but granular debris and a variable number of white blood corpuscles. The time necessary to effect such changes cannot be definitely fixed, but it is probably never less than several days, and may even occupy weeks or months.

Such coagula are, however, quite rare if contrasted with the exceeding frequency of clots of recent fibrin. Still rarer must be those cases, if any such really exist, in which the clots are not merely mechanically adherent but actually united by bloodvessels to the cardiac walls. The existence of this condition would of course prove the clot to have been formed some time before death, but the observations which have been recorded invite criticism. For example, the one reported by Richardson † was probably not a mere fibrin-clot, but a true connective-tissue polypus of the heart, a rare morbid condition, which, however, occasionally occurs. I will not digress here to discuss the so-called vegetations that form upon the diseased cardiac valves, and occasionally upon other portions of the interior of the heart in certain forms of endocarditis; these are undoubtedly in many cases composed merely of fibrin, and may form at any time during the life of the patient. But the more or less bulky and firm whitish or yellowish fibrin-clots, observed so often after death from diarrhœa and dysentery, and, indeed, as will be shown hereafter, during the dissection of those dead of fever, consumption, pneumonia and other diseases, during the civil war, I am disposed to regard as having been formed in the vast majority of cases during the death agony. I am not prepared to deny that the formation of such clots may sometimes take place suddenly as a primary condition, and cause the agony instead of being caused by it; but the grounds which support the doctrine that this is a frequent accident are so far from conclusive that it must be regarded rather as an ingenious speculation than as a logical deduction from the observed phenomena.

It has more than once happened that the heart-clots found in those dead of various epidemic and endemic diseases have been supposed to be the immediate cause both of the

---

de Méd., Feb., 1864, p. 129—found that fibrinous heart-clots are often formed in animals killed by an injury to the brain that does not prove immediately fatal, but if the animal was opened at the moment of death they were never so dense as when the examination was postponed to some time later. He mentions also that TARDIEU related to him that he had frequently found heart-clots in individuals dead in consequence of injuries of the head. I may add that it has long been known that heart-clots are occasionally found in those who have died a violent death in the midst of apparent health. MORGAGNI—Lib. II, Epist. XXIV, § 27—relates that before his time it sometimes happened that polypi were found in the hearts of persons killed by the sword, by clubs or by poison, and that, on judicial inquiry, the accused escaped because the polypi were affirmed by the physicians to have caused death.

* These changes in cardiac coagula have been well studied by BRISTOWE—*Softening clots in the heart*, &c., Trans. of the Path. Soc. of London, Vol. VII, 1855-6, p. 134, with an analysis of 23 cases, and *Further report on softening clots in the heart*, same Trans., Vol. XIV, 1862-3, p. 71, with an analysis of 41 additional cases. See also JOHN OGLE—*Fibrinous coagula of old standing within the cavities of the heart, which had undergone a process of softening*, &c., same Volume, p. 65, with particulars of 8 cases, in several of which the coagula were quite large.

† RICHARDSON—p. 89 of *The cause of the coagulation*, &c., cited *supra*. p. 541. A large, pear-shaped, white, movable body was found in the left ventricle of an old lady. It was adherent to a point between the segments of the mitral valve by "a fine peduncle." "The growth in question was unmistakeably, for I examined it minutely, fibrinous. It was connected with the heart at its peduncular part by a vessel, and, throughout its structure, vessels could be distinctly traced." A wood-cut is annexed. I hope this specimen has been preserved, and that it will be again examined by some histological specialist. I suspect that it was rather fibrous than fibrinous, and suggest in comparison the cases observed by KOTTMEIER—*Fibröse Neubildung im Herzen, (Wahrer Herzpolyp.)* Virchow's Archiv, Bd. XXIII, 1862, S. 434, also Taf. IV, Fig. 3; PROUST—*Obs. d'un polype de l'oreillette droite*, &c., Gaz. Méd. de Paris, December, 1864, p. 789—who relates one case well observed by himself, and gives abstracts of five others collected from literature; and DUROZIEZ—*Mém. sur les anévrysmes du cœur*, &c., Gaz. des Hôpitaux, August, 1872, p. 804, Obs. 3—one well observed case.

morbid phenomena and the fatal issue by those who made the autopsies. To this cause Lancisius* attributed the epidemic which prevailed among horses in the vicinity of Rome in the year 1712; Huxham† explained in the same way an outbreak of suffocative catarrh which carried off some twenty sailors at Plymouth in 1742; and Chisholm‡ went so far as to name an epidemic of malignant malarial fever, which he observed at Grenada in 1790, "The Epidemic Polypus." Accordingly, it is by no means surprising that the heart-clots so often observed during the civil war were sometimes supposed to be the cause of the fatal issue. Surgeon J. R. Black§ explained in this way the cases of sudden death that sometimes occurred in the course of chronic dysentery, and Surgeon George G. Shumard,‖ applied the same interpretation to the cases of sudden death which happened in the course

* LANCISIUS—*Hist. etc., de equorum epidemia quæ Romæ grassata est toto Vere anni* 1712, Opera, Geneva, 1718, T. II, p. 171 *et seq.*—declares the "fons mali" of this epidemic to have been an excess in the lymph of the blood, "sanguinem, lymphaticis fervidisque particulis abundantem," and the consequent tendency of that fluid to coagulate, as manifested on the one hand by the buffy coat in blood drawn from a vein, on the other by the polypi found in the heart on dissection, "plurima polyporum instar concreta corpora in cordis sinubus," p. 174. I understand LANCISIUS, therefore, to have sought the cause of this disease rather in the condition of the blood that produced the polypi than in the polypi themselves. I would point out that in one of the two autopsies appended to this essay the animal was opened four hours after death and two polypi were found in the right side of the heart: the other horse was opened while yet breathing, "altera sectio equi adhuc spirantis, * * peracta fuit," and no cardiac polypi were found, "nullum omnino in pulmonum lobis, atque in corde, cujus sinus et sanguine, et polypis vacui erant, vitium deteximus," p. 183.

† J. HUXHAM—*Diss. de polypis*, &c., in Opera Phys.-Med., Leipsic, 1773, T. III, p. 50, and Phil. Trans., abridged, Vol. IX, London, 1747, p. 135. The patients "were seized with short, importunate, asthmatic coughs, without any expectoration. Violent and almost continual palpitation of the heart, with a perpetual intermitting, trembling, fluttering pulse, and a constant anxiety, pain, and sinking of the heart." They breathed with excessive difficulty: some had pains in the side, but very little fever. Three autopsies only were made, in all of which the "polypi" were found.

‡ C. CHISHOLM—*An Essay on the Malignant Pestilential Fever, introduced into The West Indian Islands from Boullam, on the coast of Guinea, as it appeared in* 1793, 1794, 1795, *and* 1796, 2d Ed., Vol. II, London, 1801, Appendix, No. 6, "A short Account of the Epidemic Polypus at Grenada in 1790," p. 454. This disease occurred among the negroes of the plantation Grand-mal, about the end of September or beginning of October, and disappeared in November. About 40 were taken sick, of whom 7 died. It began with pain in the pit of the stomach and head, difficult respiration, depressed spirits and anxious countenance, but without fever. After about three days fever set in; pulse 120 to 140, with a penetrating, pungent heat and aggravation of all the former symptoms. The fever was intermittent, with intermissions of eight or nine hours. During the paroxysm the struggle for breath, the palpitation of the heart and other symptoms "produced a scene of uncommon horror;" death occurred chiefly during the second paroxysm. The paroxysms were each succeeded by a clammy sweat, and in several of those who recovered subcutaneous abscesses occurred. In four of the dead, polypi were found in both sides of the heart, and in one in the right ventricle only, and extending thence into the pulmonary artery. I may add that this narrative seems to have made a great impression on JOSEPH JONES—*Heart-clot*, a clinical lecture, The New Orleans Jour. of Med., Vol. 22, 1869, p. 469—who has himself "observed, carefully noted, and recorded a number of cases of malarial fever, in which heart-clots were formed before death," and arrived at the conclusion that the "formation of heart-clots during life, is very common in malarial fever."

§ Surgeon J. R. BLACK, 113th Ohio vols.—Letter to the Cincinnati Lancet and Observer, Vol. VI, 1863, p. 424—says, in speaking of the diarrhœa which prevailed in General Granger's corps during the early part of 1863: "Sudden deaths from the disease are no uncommon occurrence, and they are so sudden as to imply death from heart, or brain lesion. Post mortems have shown that the lesion is in the heart, involving deposits of fibrin on the columnæ carneæ and chordæ tendineæ. They are remarkable depositions, in some instances being from two to three inches in length, about the size of a goose quill, and larger at the free extremity than in the attached. There is no evidence in any whom I have examined, of endocarditis, and its formation is somewhat mystical. It appears from the statements of others not to be confined to diarrhœa, but to be found in nearly all classes of cases in army life. Surgeon VARIAN, U. S. V., tells me that he invariably finds it in deaths from diarrhœa." Again, Surgeon BLACK—*Camp diarrhœa*, same Jour., Vol. VII, 1864, p. 273—after relating that he had found fibrinous clots in five autopsies, "two in the left ventricle, two in the right, and one in both right and left," and describing the appearances presented with some care, adds: "Surgeon W. VARIAN, U. S. V., informed me that in a large number that he examined who died with the disease, but few were found without it. In fact he looked upon them as one of the determined pathological states of chronic diarrhœa of camp life." Surgeon BLACK adds: "I never had opportunity to examine one who died with surprising suddenness, but there is little doubt but that the death is owing to the sudden detachment of these emboli."

‖ Surgeon GEORGE G. SHUMARD, U. S. Vols.—*Heart clots in typhoid fever*, The Med. and Surg. Reporter, Vol. IX, 1862-3, p. 381—relates that "while acting as Medical Director of Huntsville, Alabama," during the summer of 1862, "a number of sudden deaths, occurring in persons considered convalescent from typhoid fever, were from time to time reported to me." "They usually fell while taking exercise, and would die in from one to five minutes after falling." No post mortem examinations were made, but after Surgeon SHUMARD became "Medical Director of the Danville District" he had several similar cases reported to him, "and they continued to recur one or more of them every week." The coagula found were "unusually tough, elastic, of a straw tint, and unmixed with coloring matter of the blood. Most of them appear to be semi-organized, though I have not thus far been able to detect vessels in them with the naked eye; but with a good glass I believe such vessels may be detected. They all appear to be composed of distinct layers, and in several of the cases I have examined, they were found attached by one or more points to the lining membrane of the heart." Surgeon SHUMARD adds: "From my own observations I am of the opinion that the formation of these coagula in the heart and arteries is of common occurrence in typhoid fever, and that in many cases they exist long before death takes place. What is known as the '*double elastic pulse*' in that disease, and which I believe is usually regarded as an unfavorable symptom, I have but little doubt is owing to this condition of the circulating system. At any rate all the cases of heart coagula that have fallen under my notice were characterized by that condition of pulse long before death." The writer speaks of "making up a box of heart specimens, with the coagula in them, for the Surgeon General U. S. A., who will, I presume, place them in the government collection." These, however, were never received at the Museum. It is somewhat amusing, in view of the experiments of RICHARDSON, (see note ‡ to p. 542, *supra*,) who found the inhalation of oxygen the surest method of producing heart-clots in animals, to learn that Surgeon SHUMARD imagined it to be the surest method of curing them in man: "I believe we have in oxygen-gas a remedy *that will prevent* the formation of coagula in typhoid fever, if administered sufficiently early in the disease." This belief was based upon experiments in which "the gas was administered to the greater number of the patients in the form *(sic!)* of *nitrous oxide*. In twelve of the cases pure oxygen was given." Surgeon SHUMARD reports that he found this treatment "most beneficial in diseases of an asthenic character, and more especially in typhoid fever, typhoid pneumonia, diphtheria, congestive measles, and erysipelas." See also, in this connection, a paper by the same author on *The inhalation of nitrous oxide gas in severe cases of fever*, Amer. Med. Times, Vol. VI, 1863, pp. 28 and 38. The views widely accepted in the army with regard to the significance of heart-clots are well illustrated by the paper of Acting Assistant Surgeon W. M. DORRAN, (Gayoso hospital, Memphis, Tenn.)—*Thrombi in cardiac cavities*, same Jour., Vol. VIII, 1864, p. 62—who groups together eight cases representing several very different pathological conditions simply because heart-clots were found in each case.

of typhoid fever. So far as I have been able to learn, these opinions were shared by very many medical officers, but I must point out that no facts were collected to show that the clots were found more frequently in the cases of sudden death than in those who died from the same diseases in the usual way, and without any symptoms pointing to the heart; nor is there any evidence that the clots in the one group of cases differed from those that occurred in the other either as to size, texture, adhesions or any other characteristics. I must, therefore, regard this supposition as a mere conjecture which is not supported by any observations actually made during the civil war.

Yet another conjecture was advanced by Salisbury, who supposed the heart-clots to be the consequence of a scorbutic taint resulting from the too exclusive use of amylaceous diet.* There is not a particle of evidence in favor of this assumption. The autopsies reported do not show that heart-clots were found during the war at all more frequently than they are in similar diseases occurring in civil life under circumstances which put the suspicion of a scorbutic taint out of the question. Nor is the assumption supported by what is known of the phenomena of scurvy, in the course of which, as we shall see hereafter, a diminution in the quantity and coagulability of the blood-fibrin is much more frequent than the opposite conditions.† It is perhaps excusable for the inexperienced observer, who for the first time enjoys the opportunity of observing numerous post mortem examinations, to indulge in speculations such as these; but the conscientious student who endeavors to acquaint himself with all the facts of the case, before forming an opinion, will regard such hasty generalizations with distrust or disapproval.

Chemical analyses of the blood in dysentery have been made by Masselot and Follet, Lehmann, Leonard and Foley, Artigues and Oesterlen.‡ They agree pretty well in showing a diminution in the albumen of the blood and the blood corpuscles, as might be expected from the character and quantity of the stools. With regard to the blood-fibrin the results are not accordant, in consequence probably of the circumstance that the quantity of this ingredient varies in different cases, both with variations in the character of the disease and its accompanying complications. *Microscopical examinations* of the blood, undertaken especially with reference to the presence of low vegetable organisms, have produced as yet no satisfactory result in connection with the subject of dysentery.

---

* J. H. SALISBURY—*Chronic diarrhœa*, &c., cited p. 373, *supra*—expresses the opinion that all the characteristic army diseases "belong to abnormal states excited by insufficient or imperfect alimentation and fermentative conditions and to a peculiar scorbutic taint, developed by the too exclusive use of an amylaceous diet. In this group of army diseases may be placed chronic diarrhœa; paralytic conditions; fibrinous depositions in the heart (Thrombosis); the clogging up of the pulmonary vessels with fibrinous clots (Embolia); the tendency to tuberculosis; loss of voice; the so called muscular rheumatism, and the majority of the diseases of the eye and ear," *op. cit.*, p. 25.

† Indeed, so frequent is the diminution of fibrin, especially in chronic scurvy, that BECQUEREL and RODIER—*Hématologie*, Gaz. Méd. de Paris, T. VII, 1852, p. 474—proposed to designate the constitutional conditions which result from this diminution by the term "état scorbutique," without reference to the causes from which it may arise in any particular case. In acute scurvy they admitted that the fibrin might oscillate between the normal limits, or even in some cases be increased; but in chronic scurvy the fibrin is constantly diminished in quantity, *e. g.*, to 1.85, 1.32, or even 1.14, per 1,000 parts, the normal proportion being from 2 to 3 per 1,000 parts.

‡ MASSELOT et FOLLET—*Mémoire sur l'épidémie dysentérique*, etc., Arch. Gén. de Méd., T. II, 1843, p. 167—concluded, from eight analyses of the blood of dysenteric subjects, that both the globules and the fibrin are diminished. The following is the mean of their observations: water, 840.288; fibrin, 1.715; globules, 99.103; albumen and fixed matters, 58.894. If a febrile reaction supervenes, however, they say the quantity of fibrin and albumen increases while the globules diminish. LEHMANN—*Physiological Chemistry*, Transl. of Cavendish Society, Vol. II, London, 1853, p. 264—says that "in dysentery the blood is poor in corpuscles. The fibrin is generally, although not always, somewhat increased. All the solid constituents of the serum are decreased, but especially the albumen. The salts, on the other hand, are considerably increased in quantity." LEONARD et FOLEY—*Rech. sur l'état du sang dans les maladies endémiques de L'Algérie*, Rec. de Mém. de Méd., de Chir., etc., Militaires, T. LX, 1846, p. 202—analyzed the blood in six cases of dysentery, in four of which they found the fibrin increased in quantity, while in two it was normal. The globules were somewhat diminished, except in one case, in which they were increased in quantity. The albumen was diminished in three cases; in the others it was not determined. They mention that during an epidemic of dysentery in September, 1841, at the military hospital at Versailles, ARTIGUES analyzed the blood in several cases, and concluded that there is in dysentery a diminution of the fibrin, albumen and globules, with a corresponding augmentation of the water. OESTERLEN—*Zur Chemie der Ruhr*, Henle's Zeitschr. für Rat. Med., Bd. VII, 1849, S. 253—concludes that in consequence of the loss of albumen, &c., by the stools in dysentery, the blood becomes "poorer in albumen, fibrin and blood corpuscles, while its proportion of water increases," S. 274. But so far as the fibrin is concerned this conclusion is not sustained by the only analysis he reports, in which the result was, (S. 262,) water, 831.6; fibrin, 7.2; blood corpuscles 96.9; serum-albumen, 56.2; serum-salts, 8.1.

Abdominal organs.—Besides the cases already mentioned in which peritonitis resulted from perforation of the bowel, evidences of *general peritonitis* were observed in four of the cases of follicular ulceration, viz: 281, 316, 395 and 868; and in eleven of the undetermined cases, viz: 233, 258, 275, 409, 533, 653, 719, 735, 737, 772 and 851, to which may be added case 304, in which the peritonæum and omentum were "much injected," as representing an early stage of the same process. In one of the follicular cases, 374, a small quantity of straw-colored serum was found in the abdominal cavity. Various quantities of serous fluid were observed in nine of the undetermined cases, viz: in case 91, a "considerable quantity;" in case 80, two gallons; in case 843, half a gallon; in case 273, twenty-four ounces; in case 610, twenty ounces; in case 804, twelve ounces; in case 527, eight ounces; in case 808, five ounces; and in case 297, four ounces. In several of the foregoing cases of peritoneal inflammation and effusion a similar process coexisted in the pleural sacs and the pericardium, as, for example, in case 653. In case 781 "some peritoneal adhesions existed;" in cases 274, 389, 555 and 557 the adhesions were extensive, binding the intestines to each other, to the viscera, or to the abdominal parietes; in case 629 similar adhesions were associated with a deposit of tubercles on the peritonæum.

The *omentum* is said to have been congested in a few instances; in a few others devoid of fat; in cases 274, 646 and 727 it was almost entirely absorbed; in case 648, "completely absorbed;" in case 870 it was "contracted into a band;" in case 365, contracted and doubled up under the stomach; in case 449, adherent to the small intestine; in cases 247 and 254, adherent to the colon; in case 201, "thickened and studded with tubercles;" in case 601, transformed into "a soft gelatinous mass."

The *mesenteric glands* are very generally not mentioned. They are recorded to have been enlarged in about one-fourth of the cases. In case 647 they were "enormously enlarged and filled with a pus-like fluid;" in cases 258 and 521 they are said to have been cheesy; in cases 167, 247, 520, 771 and 778 they are said to have been tuberculous, or to have contained tuberculous deposits, by which expressions the cheesy condition was probably indicated; in cases 459 and 853 they contained calcareous deposits; in case 557 it is said that "there was an extensive deposit of tubercle in the mesentery." In case 851 a morbid growth, the nature of which was not determined, was found in the transverse mesocolon.

The *liver* is said to have been "congested" in some eight or nine of the cases of follicular ulceration and about thirty of the undetermined cases. In about half a dozen of the former and twenty of the latter class it is said to have been "soft" or "flabby." It is described as "pale" in five of the cases of follicular ulceration and rather more than a dozen of the undetermined cases; in some of these the organ was probably *fatty*. This latter condition is said to have existed in eight of the cases of follicular ulceration, viz: 145, 167, 293, 426, 505, 564, 714 and 746; and seventeen of the undetermined cases, viz: 289, 290, 308, 326, 380, 459, 568, 623, 696, 705, 736, 738, 744, 745, 747, 758 and 835. The liver is said to have presented the "nutmeg appearance" in two of the cases of follicular ulceration, 381 and 389; and six of the undetermined cases, viz: 79, 365, 441, 519, 523 and 526. In two of the cases of follicular ulceration, 138 and 139, both observed by Dr. J. Leidy, the organ is described as "rat liver," a term which, in case 139, is explained as follows: "The liver, rather small, presented the minutely mottled appearance of red and brown, which I denominate 'rat liver;' the tissue of the organ exhibited some fatty degeneration." It will be remembered that Dr. Leidy also employed the term "rat liver" in two

of the Chickahominy cases, viz: 131 and 153, in which chronic intestinal catarrh existed without ulceration.*

The liver is said to have been *large* or "enlarged," without, however, specifying its weight or any morbid appearance of its substance, in four of the cases of follicular ulceration and nineteen of the undetermined cases; in two other cases of the former class the large size of the organ is shown by its weight, which was seventy-five and a half ounces in case 401, and eighty-six ounces in case 295. So also in thirteen of the undetermined cases the organ weighed more than usual, ranging from seventy to eighty ounces in cases 228, 289, 408, 720, 737, 738, 747, 753, 810 and 842; between eighty and ninety in cases 298, 420 and 577. The liver is said to have been *small*, or its recorded weight was less than forty ounces, without any other abnormity being mentioned, in four of the cases of follicular ulceration and four of the undetermined cases; in some of these cases it was possibly cirrhosed. In one of the cases of follicular ulceration, case 196, it is said to have been cirrhosed, and weighed only twenty-seven ounces. *Cirrhosis* probably existed also in case 198, in which the organ was "firm," bronzed, and weighed only twenty-eight ounces; in case 333, in which it was firm and had a granular appearance; in case 370, in which it was of a yellowish-chocolate color internally, had well marked acini, and weighed forty-seven ounces; in case 387, in which it was firm and had well marked acini; and case 194, in which it was small and hard. Among the undetermined cases cirrhosis is said to have existed in case 794, and the liver presented a granular appearance in case 828. In one of the cases of follicular ulceration, 870, the liver was large and of a "dark bronze color."

Abscess of the liver was observed in five of the cases of follicular ulceration, viz: in case 195 the right lobe of the liver was adherent to the diaphragm and contained a large single abscess which held about a quart of gray odorless pus; in this case there were also a number of small metastatic abscesses in the lungs; in case 872 there was a large single abscess in the right lobe of the liver, and hard nodules, probably metastatic foci, existed in the spleen, [Nos. 971 and 972, Med. Sect., Army Med. Museum, are from this case;] in case 878 there was also a large single abscess in the right lobe of the liver, which had discharged into the intestinal canal by two openings, one in the duodenum, the other in the ascending colon; extravasation of the intestinal contents was prevented by previously formed adhesions, [Nos. 1149 and 1150, Med. Sect., Army Med. Museum, are from this case;] in case 902 there was a large abscess in the right lobe of the liver, which communicated with the pleural cavity through an opening in the diaphragm; in case 201 the liver was bound by peritoneal adhesions to the abdominal parietes; on section it was dark-red, and "contained a large number of saccules, which varied from the size of a grape-seed to that of a bean, and contained a semi-fluid granular matter."

Abscesses were also observed in eleven of the undetermined cases, viz: in case 405 a single abscess the size of a large hen-egg in the right lobe; and in case 578 a large single abscess, (probably in the right lobe,) which contained about a quart of pus and projected on the under surface of the liver; multiple abscess or metastatic foci were observed in case 375, in which the liver contained a number of purulent deposits; in case 393 "the liver was hard and presented a number of whitish lardaceous spots," and "a number of lobules in the left lung were hepatized gray," I interpret these expressions as descriptions of metastatic foci; in case 407 the left lobe of the liver "was entirely destroyed by abscesses,"

* See p. 316, *supra*.

and its right lobe contained two others, "one about the size of a goose-egg, the other about the size of a hen-egg;" in case 449 the liver contained about twenty small abscesses varying in size from that of a pea to that of a walnut; in case 619 the liver contained twelve distinct abscesses varying from the size of a walnut to that of a goose-egg: one of them had discharged through the diaphragm and adherent right lung into the bronchial tubes; in case 727 "the lungs, liver and spleen were filled and covered over with small light-yellow masses about the size of mustard-seeds or rather larger; these had the appearance of tubercles, were of firm consistence, and were closely adherent to the adjacent tissue; they were more abundant in the liver and spleen than in the lungs, and were more numerous on the surface than through the substance of the organs;" these, I doubt not, were really metastatic foci; in case 728 the liver contained a few small purulent collections; in case 762 it contained numerous small circumscribed collections of a pus-like fluid; finally in case 781 the liver was large, and presented on its upper surface "a number of yellowish spots the size of a dime," which were probably metastatic foci.

Including the cases of both classes, we have six instances of single hepatic abscess and ten of multiple or metastatic abscesses out of three hundred and ninety-six cases of chronic intestinal ulceration, so that hepatic abscess can be said to have existed in only about four per cent. of these cases.

Reviewing now the facts previously given with regard to the occurrence of hepatic abscess in other forms of flux, it will be remembered that of 156 cases of acute or chronic catarrhal inflammation of the intestinal mucous membrane without ulceration, there was but one case of this complication, viz: case 171, in which two large multilocular abscesses were found in the liver,* while in 115 cases of diphtheritic dysentery there were three of single abscess and four of multiple metastatic foci.† Adding together these figures, we shall have fourteen cases of multiple abscess and nine of large single abscess occurring in five hundred and eleven cases of flux in which the intestine was ulcerated, and but a single case of (large) hepatic abscess occurring in one hundred and fifty-six cases of flux in which the intestine was not ulcerated. There is one other case of multiple abscess of the liver reported in the previous section, viz: case 822, in which the patient is said to have died of "chronic diarrhœa," but no evidences of disease were discovered in the intestines.‡ It will hence be seen that our experience on this subject corresponds rather with that of medical observers in Great Britain and continental Europe than with that of Europeans in tropical countries.

---

* See p. 316, *supra*. † See p. 459, *supra*.

‡ In addition to the cases thus summarized, two specimens of abscess of the liver from dysenteric subjects, which are preserved in the Army Medical Museum, may be mentioned. The first is No. 668, Medical Section: The patient was a soldier, 41 years old, who had suffered from "chronic diarrhœa" for several months, and died at Fort McHenry, Maryland, October 21, 1865; three abscesses, each containing about 4 ounces of pus, were found in the right lobe of the liver; the colon was ulcerated throughout; some of the ulcers were very large and had penetrated to the muscular coat. The second is No. 1294, Medical Section: The patient was a citizen, 63 years old, recently convalescent from dysentery, who died at San Antonio, Texas, November 23, 1874; an abscess containing a quart of pus was found in the right lobe of the liver, and the cicatrices of dysenteric ulcers were detected in the ascending and transverse colon. There is still a third specimen in the Museum, No. 447, Medical Section, from a colored corporal, who is said to have suffered from diarrhœa several times during the six months preceding his death, and who died at L'Ouverture hospital, Alexandria, October 8, 1864; the right lobe of the liver contained a number of small abscess-cavities, but no appearance of ulceration could be detected in either the large or small intestine; in the catalogue—*Catalogue of Medical Section*, Washington, 1867, p. 92—it is erroneously stated that "the condition of the intestinal mucous membrane was, unfortunately, not recorded;" the letter of transmittal contains the statement made above, which was overlooked in preparing the catalogue. It may be added that this man was admitted to L'Ouverture hospital, August 9, 1864, with slight flesh wounds on the hand, side and hip, received from fragments of shell; we are told, however, that by September 12th his wounds had "healed without difficulty." It seems improbable, therefore, that the liver abscess was due to the wounds. The Museum also contains nine other specimens of abscess of the liver in which this lesion was unconnected with dysentery, viz: specimens Nos. 295, 501, 669, 742, 850, 1068, 1099, 1129 and 1316. Moreover, eight specimens of hepatic abscess were received at the Museum during and since the war which were not preserved, either on account of the condition of the specimens when received, or the imperfect character of the record transmitted with them. In two of these cases, one a soldier, the other a colored woman, dysentery is said to have preceded the abscess-formation, but there is no record of the post mortem condition of the alimentary canal. The other six cases were unconnected with dysentery. An account of all these cases will be presented hereafter.

A summary of the chief facts with regard to this experience may be advantageously presented in this place. Nowhere has the complication of dysentery by liver abscess attracted greater attention or been made the subject of more numerous studies than by the British physicians in India. Ballingall* found liver abscess in 4 out of 35 autopsies of fatal dysenteries, made from 1808 to 1814. The splendid work of Annesley† contains an account of 51 such autopsies, in 26 of which liver abscess was found. To this enormous proportion it may be objected that these were chiefly cases selected to illustrate the subject of hepatitis, and hence give an undue prominence to this complication; but this objection cannot be urged against the statistics of Waring,‡ who has collected, from the reports of various regiments in the Madras Presidency, 259 autopsies on dysenteries made from 1826 to 1843, in 69 of which liver abscess was observed; and similar results have been more recently obtained by Eyre,§ who found liver abscess in 27 out of 118 autopsies among the 1st Madras fusiliers, and Ranking,‖ who found it in 41 out of 140 autopsies in the 2d Madras European light infantry. Neglecting the figures of Annesley for the reason stated, the sum of the others will represent the occurrence of hepatic abscess in about one of every four fatal cases of dysentery. Moore¶ has tabulated 494 fatal cases of dysentery observed in the European general hospital at Bombay, in 90 of which liver abscess was found, or

The figures in the text embrace those reported by SHANKS, Madras Med. Jour., Vol. I, 1839, p. 258; INNES, same Jour., Vol. VI, p. 172; MOUAT, same Jour., Vol. II, p. 9; HAMILTON, same Jour., Vol. IV, p. 318; DIX, same Jour., Vol. V, p. 214; THOMPSON, same Jour., Vol. V, p. 16; and MCGREGOR, same Jour., Vol. II, p. 376. [I have only been able to verify a part of these references, the files of this journal in the library of the Surgeon General's Office being incomplete.] WARING'S table also includes MACPHERSON'S Calcutta cases and 81 fatal cases of dysentery, in 34 of which hepatic abscess was found, observed by MOREHEAD and STOVELL in the European general hospital, Bombay. Altogether, these make up 633 fatal cases of dysentery, in 149 of which hepatic abscess was found; and these are the figures usually attributed to WARING. I may add that the work of this author, although rudely printed, is a mine of information for the serious student of this subject, not merely because it contains abstracts of numerous cases, but because references are so generally given to the original authorities.

§ E. W. EYRE—*Medical notes on dysentery*, Indian Annals of Med. Science, October, 1855, p. 56. These figures represent the experience of the 1st Madras fusiliers from 1834 to 1851, with a few additional cases.

‖ J. L. RANKING—*Statistical gleanings from the records of the 2nd Madras European light infantry for the years* 1840–1860, *inclusive*, Madras Quarterly Jour. of Med. Sci., Vol. VII, 1863, p. 47.

¶ W. J. MOORE—*The relation of dysentery to abscess of the liver as shown by the clinical records of the European general hospital, Bombay*, Trans. of the Med. and Phys. Soc. of Bombay, No. VIII, N. S., 1862, p. 292; also Annals of Military and Naval Surgery, Vol. I, London, 1864, p. 226. The table given by this author includes, besides statistics cited from various authors, a number of cases observed by himself in the hospital named, as well as those observed in the same hospital by MOREHEAD, STOVELL and LEITH, as shown in the following abstract:

MOREHEAD	No. of deaths of dysentery			30	Hepatic abscess in			12
STOVELL	"	"	"	129	"	"		25
LEITH, one year	"	"	"	47	"	"		4
LEITH, several years	"	"	"	92	"	"		14
MOORE	"	"	"	196	"	"		35
Total				494				90

The original report of MOREHEAD—*Cases illustrative of the pathology of the diseases of Bombay, Part III*, Trans. of the Med. and Phys. Society of Bombay, No. 7, 1844, p. 56 *et seq.*—contains 32 autopsies of subjects dead of dysentery, cases 145 to 176 inclusive, in 13 of which hepatic abscess was found. WARING (*op. cit.*) quotes the figures correctly. Why MOORE has modified them I do not know. STOVELL'S figures are given in his "*Statistics of more important diseases admitted into the European general hospital during* 10 *years*," same Trans., 1855–56, which I have not been able to see. Of these figures those for 1847, 1850–51 and 1851–52, in all 49 cases, with 21 hepatic abscesses, are included in WARING'S figures. Supposing MOORE has cited STOVELL correctly, I have a difficulty in understanding the figures he assigns to LEITH. This gentleman, A. H. LEITH—*Annual report of the European general hospital for the year* 1858–59, same Trans., No. 5, N. S., 1859, p. 89—states that if all the cases of dysentery, with and without hepatic abscess, "that have occurred in this hospital during the last three years be added to those given in Dr. STOVELL'S Decennium of the Hospital Statistics, recorded in the Transactions of the Medical and Physical Society, 1855–56, there will be the aggregate of: Dysentery without hepatic abscess 188, dysentery with hepatic abscess 50." That is 50 hepatic abscesses in 238 cases of dysentery. Subtracting STOVELL'S figures, as cited by MOORE, from these, we shall have 109 cases with 25 hepatic abscesses for the three years' observations of LEITH, instead of those given by MOORE. LEITH'S *Annual report of the European hospital for* 1859–60, same Trans., No. VI, N. S., 1860, p. 217, shows that year 47 cases of dysentery with but 4 hepatic abscesses: this is correctly cited by MOORE. The files of the Transactions cited, in the library of the Surgeon General's Office, are very incomplete, and although, through the great kindness of Sir Joseph Fayrer, I was favored with the loan of seven volumes belonging to the library of the Secretary of State for India, this set was deficient in several volumes. I regret this circumstance the more because MOORE (whose statistics have been praised by AITKEN—*Science and Practice of Medicine*, 3d Amer. Ed., Philadelphia, 1872, Vol. II, p. 649) has duplicated figures in some parts of his table in a manner that throws doubts on the remainder. Thus he ascribed to MACPHERSON 160 cases, to MOREHEAD 39, to STOVELL 129 and to WARING 633, without appearing to know that WARING'S figures include all the cases ascribed to MACPHERSON and MOREHEAD and 49 of those of STOVELL. I may add that MOORE, in the same table, ascribes to MACNAMARA 51 fatal cases of dysentery with 26 examples of hepatic abscess, which figures suspiciously resemble those of ANNESLEY, [see note, *supra*.] I can hardly believe, however, that MOORE has duplicated or seriously misstated the figures of his own hospital, and therefore, in the absence of some of the original documents, accept his summary of the results of that institution.

about once in every five and a half deaths. Macpherson,* in his essay on Bengal dysentery, tabulated 293 autopsies made in the Calcutta hospitals, in 46 of which liver abscess was found, or about one in six and a half deaths. Chuckerbutty† has since reported 39 autopsies, also made at Calcutta, in only 3 of which liver abscess existed, or once out of thirteen deaths. Parkes,‡ at Moulmein, in Burmah, found a larger proportion. In 25 autopsies on cases of acute dysentery he found 7 instances of liver abscess, while Taylor,§ during the Burmese war of 1852–3, in 53 such autopsies found 8 instances of liver abscess. The results of the two observers combined represent the occurrence of hepatic abscess in Burmah once in every four and a half deaths from dysentery. In Ceylon, Marshall || had a similar experience; in 177 autopsies on dysenterics he found liver abscess 43 times, or about once in four deaths.

In Cochin China, two of the French physicians, Bourgarel and Gayme,¶ obtained similar results; they found liver abscess in 13 out of 52 autopsies of dysenterics, or once in four deaths. On the other hand, Julien,** in 108 such autopsies only found liver abscess in 8 instances, or once in thirteen and a half deaths. In Algeria the reports of the French physicians show the frequency of this complication to be nearly as great as in India. Catteloup,†† at Tlemcen, found liver abscess in 47 of 240 autopsies of dysenterics, while Vital, at Constantine, as reported by Mouret,‡‡ found it in 133 of 761 autopsies.

---

* JOHN MACPHERSON—*On Bengal dysentery*, Calcutta, 1850. The figures in the text are made up as follows:

General hospital, Calcutta,	Acute dysentery	No. of deaths of dysentery				160	Hepatic abscess in			21
" " "	Chronic "	"	"	"		55	"	"		6
Seamen's hospital, "	Dysentery	"	"	"		24	"	"		5
Medical College hospital, Calcutta,	Dysentery	"	"	"		54	"	"		14
		Total				293				46

† S. G. CHUCKERBUTTY—*Cases illustrative of the pathology of dysentery*, Indian Annals of Med. Sci., No. XIX, 1865, p. 90.

‡ E. A. PARKES—*Dysentery and Hepatitis of India*, London, 1846, p. 39. It must be remembered that these figures were derived from picked cases of acute dysentery only.

§ J. R. TAYLOR—*Annual medical report of H. M. 80th regiment for the year ending March* 31, 1853, Indian Annals of Med. Sci. for April, 1854, pp. 395 and 404. Mr. STEWART, who accompanied the 18th Royal Irish in the same war, remarks (*ib.*, p. 434) that in fully three-fourths of the fatal cases of dysentery the liver was found "more or less implicated, from simple engorgement to abscess." On the other hand, in the first Burmese war, 1824-25, WADDELL—*Diseases, &c., among the British troops at Rangoon*, Trans. of Med. and Phys. Society of Calcutta, Vol. III, p. 254—did not find organic disease of the liver in any of the cases of dysentery which he dissected.

|| HENRY MARSHALL—*Notes on the Med. Topography of the interior of Ceylon*, London, 1821. The statement in the text is deduced from the tables on pp. 94, 106, 115 and 123, which refer to the years 1817-20 inclusive. During the same time among the native troops, in 70 autopsies on dysenterics, liver abscess was found 6 times. I may remark that CAMERON—*Extracts from the annual report on the health of the troops serving in Ceylon from April* 1, 1850, *to March* 31, 1851, Med. Times and Gaz., Vol. VII 1853, p. 366—asserts that Ceylon dysentery is "very rarely attended with that hepatic complication so much talked of elsewhere." On how many autopsies this opinion is based, if any, does not appear. It would be easy to multiply observations from various parts of India, but those cited are sufficient to show the frequency of the complication in question. Among the older observations I may refer to the case of BONTIUS, cited in note ‡ to p. 394, *supra*, and to two cases of dysentery, in which multiple abscesses were found in the liver, reported by STEPHEN MATHEWS—*Obs. on Hepatic Diseases incidental to Europeans in the East-Indies*, London, 1783, p. 202 *et seq.*, (cases 2 and 3.)

¶ A. CH. AUG. BOURGAREL—*De la dysenterie endémique dans la Cochinchine Française*, Montpellier Thesis, 1866, No. 100, p. 32—observed abscess of the liver 7 times in 22 autopsies of dysenteries, while J. B. L. GAYME—*De la dysenterie endémique dans la Basse-Cochinchine*, Montpellier Thesis, 1866, No. 10, p. 50—found liver abscess 6 times in 30 autopsies on dysenteries.

** CH. M. JULIEN—*Aperçu sur les lésions anatomiques de la dyssenterie en Cochinchine*, Montpellier Thesis, 1864, No. 62, p. 54.

†† CATTELOUP—*Recherches sur la dyssenterie du nord de l'Afrique*, Recueil de Mém. de Méd., etc., Militaires, T. VII, 2me Série, 1851, p. 89:

"Dyssenteries	1,545	non terminées par la mort.
Hépatites	54	
Décès	240	après vérification nécroscopique."
Abcès du foie	47 cas.	

These figures are seldom quoted; those usually given in the text-books are contained in a former article, viz: *Mémoire sur la coïncidence de l'hépatite et des abcès du foie avec la diarrhée et la dysenterie, endémiques dans la province d'Oran*, same Journal, T. LVIII, 1845, p. 30, in which hepatic abscess is said to have been found in 20 of 157 autopsies of subjects "about two-thirds of whom had died of diarrhœa or dysentery." These are the figures cited by MOORE and AITKEN (see note ¶, p. 549, *supra*) as the experience of the "French surgeons in Algeria."

‡‡ A. MOURET—*De la coïncidence de l'hépatite ou des abcès du foie avec la dysenterie, dans les pays chauds*, Paris Thesis, No. 52, 1853, p. 7. These autopsies were made by VITAL between 1841 and 1851. In 589 instances the lesions of dysentery existed without hepatic complication; in 133, liver abscess coexisted with dysentery; in 20, cirrhosis; in 4, atrophy; in 10, induration; and in 5, tubercles. The frequency of liver abscess in the dysentery of Algeria is affirmed in a general way by HASPEL—*Maladies de l'Algérie*, Paris, T. II, 1852, p. 87, and ARMAND—*L'Algérie Médicale*, Paris, 1854, p. 347. It is also indicated by the fact that HASPEL—*Mémoire sur les abcès du foie*, Rec. de Mém. Méd., etc., Militaires, T. LV, 1843, p. 1—reports eleven autopsies on cases of hepatic abscess, in eight of which there had been diarrhœa or dysentery, and ulceration of the large intestine was observed; and that according to ROUIS—*Recherches sur les Suppurations Endémiques du Foie*, Paris, 1860—of 203 cases of hepatic abscess observed in Algeria, 179 were preceded or accompanied by dysentery; the mortality of the complicated cases being about twice as great as that of the uncomplicated ones—p. 147, *et seq.* On the other hand, CAMBAY—*Traité des Maladies des Pays Chauds et spécialement de l'Algérie*, Paris, 1847, p. 211—affirms that hepatic disease only occurs in one case of dysentery out of twenty in Algeria: "Cette complication d'hépatite survient à peu près, d'après les observations que nous avons faites dans ce pays, dans le vingtième des cas de dysenterie."

The two series combined represent the occurrence of liver abscess once in every five and a half deaths from dysentery. The observations of De Castro* show that it is also a very common complication among Europeans in Egypt.

Our information with regard to its frequency in the tropical regions of America is less complete. Sigaud has testified to its common occurrence in the dysentery of Brazil; Y Romay to its frequency in Cuba; Murillo states that it was observed in 21 of 70 autopsies on dysenterics in Chili; Van Archen has testified to the frequency of hepatic abscess in Venezuela, and Mears and Ramirez to its frequency in Mexico, without, however, emphasizing its connection with dysentery.†

These statistics indicate the frequency with which liver abscess complicates dysentery among Europeans in tropical climates.‡ That it is much less common among the natives of these countries appears from the testimony of Marshall in Ceylon; Annesley, Twining and Parkes in India; Griesinger in Egypt,§ and many other observers.‖ That it is possible

* S. V. DE CASTRO—*Des Abcès du Foie*, etc., Paris. 1870. According to this writer, in the European hospital of Alexandria, Egypt, where the patients are chiefly Italian and French, abscess of the liver occurred in the proportion of 1. 04 per cent. of the cases, p. 5, and dysentery in the proportion of 7. 52 per cent., while in the Greek hospital at the same place, abscess of the liver occurred in 1. 98 per cent., and dysentery in 15 per cent. He does not give the numerical proportion of the liver abscess coexisting with dysentery, but remarks that dysentery often precedes the formation of hepatic abscess, and that the greater frequency of dysentery is probably one reason of the greater frequency of hepatic abscess in the Greek hospital, p. 9. On the other hand, he states that among the Arabs abscess of the liver is exceptional, p. 6. The remark of L. FRANK—*De Peste, Dysenteria et Ophthalmia Ægyptiaca*, Vienna, 1820, p. 187—with regard to the post mortem appearances which he observed in the bodies of French soldiers dead of dysentery in Egypt, may also be cited as interesting in this connection: "Dum cadavera hoc morbo defunctorum aperirentur, inveniebantur in abdomine variæ mutationes, frequenter deprehendebantur signa inflammationis intestinorum, exulcerationes, et quandoque maculæ gangrænosæ; interdum reperiebantur etiam in hepate majores minoresve abscessus."

† J. F. X. SIGAUD—*Du Climat et des Maladies du Brésil*, Paris, 1844, p. 337. He regarded both the hepatitis and the dysentery as due to the same cause as intermittent fevers, and believed that hepatitis was the primary disorder and dysentery its consequence. MANOEL-JOSE VILLELA wrote to BROUSSAIS that diseases of the liver were more common in Brazil than diseases of the lungs in France: BROUSSAIS—*Hist. des Phlegmasies*, 3me Édit., Paris, 1822, T. III, p. 276. E. N. Y ROMAY—*Étude des abcès du foie dans la dysentéric chronique*, Paris Thesis, 1872, No. 216. The material for this thesis is collected from European sources, but the author remarks at the outset, p. 5: "J'ai choisi pour sujet de ma thèse inaugurale l'étude des abcès du foie dans la dysentérie chronique, maladie très-fréquente dans mon pays, l'île de Cuba." A. MURILLO—*Contribuzione allo studio della epatite suppurativa del Chile*. Rivista Clinica di Bologna, 1875, p. 331; Dr. E. RODRIGUEZ is credited with 23 of these autopsies, in 11 of which liver abscess was found, and Dr. LETELIER with 47, in 10 of which liver abscess occurred. I learn from a paper by OLOF PAGE, of Valparaiso, Chili—*Case of hepatic abscess*, Amer. Jour. of the Med. Sci., October, 1876, p. 423—that MURILLO'S contribution was originally published in Chili in the Revuta Medica, which I have not access to. PAGE himself affirms that this complication of dysentery only occurs in Chili among individuals addicted to drink; a statement in proof of which he brings forward no statistics. G. VAN ARCHEN—*Hepatitis in the tropics*, American Medical Monthly, Vol. VII, 1857, p. 25. The author affirms that "the disease which annually carries off at least half the number of those that die [in Venezuela] is chronic hepatitis, which either proceeds to induration or suppuration, forming enormous abscesses." J. H. MEARS—*Case of hepatic abscess*, &c., Med. und Surg. Reporter, Vol. XXXI, 1874, p. 84—speaks of the frequency of hepatic abscess at Monterey. L. RAMIREZ—*Du Traitement des Abcès du Foie*, Paris, 1867—also speaks of it as a frequent disease in Mexico, and lauds the operative procedures of Prof. JIMENEZ. Neither of these writers gives statistics.

‡ The statistics of the detachments of the armies of Great Britain and France in the various colonies of those Powers give interesting facts with regard to the prevalence of dysentery and "hepatitis" among European troops in numerous localities. Those relative to the British army will be found in the *Statistical Reports* of Major A. M. TULLOCH, London, 1838-41, and of late years in the *Army Medical Department Reports;* a summary of those relating to the French colonies will be found in the work of A. F. DUTROULAU—*Traité des Maladies des Européens dans les Pays Chauds*, Paris, 1868. The statistics collected by DUTROULAU give the number of cases of dysentery and of hepatitis reported, but do not show the number of cases of hepatic abscess, or even how often the condition, reported as hepatitis, occurred as a complication of dysentery. The same statement is true of the earlier English *Army Medical Department Reports;* their statistical tables reported the number of cases of hepatitis acuta and h. chronica occurring in each command, but had no heading for hepatic abscess. Of late years this has been changed, and a separate heading for hepatic abscess has been introduced; from which, however, the frequency of its occurrence as a complication of dysentery cannot be ascertained. The statistics of our own army also, until very recently, had no heading for hepatic abscess. Acute and chronic hepatitis are reported separately in the statistics of COOLIDGE, and in the First Medical Volume of this work. Cases of hepatic abscess which occurred independently of dysentery were generally embraced under the latter head, in which also various other chronic hepatic disorders were no doubt included. Those cases which occurred during the progress of dysentery were usually reported simply as dysentery. So that it is only from the special reports of cases, and especially the reports of post mortem examinations, that the frequency of this complication in the dysentery of our army can be ascertained.

§ It has already been mentioned (see note to p. 550, *supra*) that MARSHALL found 6 examples of liver abscess in 70 autopsies on dysentery among the native troops in Ceylon, or once in 11½ deaths, while among the Europeans, in the same district and during the same time, he observed it once in every four deaths. ANNESLEY states that he seldom found the liver diseased among natives who died of fluxes in Madras—*Diseases of India*, London, 1828, Vol. II, p. 350. WM. TWINING—*Diseases of Bengal*, 2d Edit., Calcutta, 1835, Vol. I, p. 59: "Moreover, dysentery is observed to be very frequent and very fatal among the natives of Bengal, while affections of the liver are exceedingly rare among these people." PARKES—*Dysentery and Hepatitis of India*, London, 1846, p. 118: "And, lastly, in Asiatics, in whom for weeks together there are often purulent stools to a great amount, and of the most decided character, abscess of the liver is so uncommon, that in a great number of dissections of dysentery I have never found it." W. GRIESINGER—*Krankheiten von Egypten*, Archiv für Phys. Heilkunde, 1854, S. 530 and 541—in 186 autopsies, chiefly of native Egyptians dead of dysentery in hospital near Cairo, found but two examples of liver abscess.

‖ Compare, for example, the relative frequency of hepatitis among English and native troops in the British statistical reports [see note *supra*] and the remarks of DUTROULAU [*op. cit.*] on the diseases of the natives in the French colonies. HIRSCH—*Hist.-Geog. Path.*, Erlangen, 1862-4, Bd. II, S. 312—somewhat sweepingly asserts that "all observers agree that hepatitis is prevalent among the Europeans, much rarer among the negroes, and rarest among the Asiatics." The most important fact cited in favor of this view is from TULLOCH—*Statistical Reports on the Sickness, &c., among Her Majesty's Troops serving in Ceylon*, &c., London, 1841—who reports 4.9 deaths of hepatitis per 1,000 of strength annually among the European; 3.2 among the negro; and a "mere fraction" among the Asiatic troops serving in Ceylon; [the statistics cover 20 years for the European troops, from 1817-36 inclusive, and shorter times for the others.]

for Europeans to become so acclimated as to attain a degree of immunity similar to that enjoyed by the natives would appear to be exceedingly problematical.* In more temperate regions this complication of dysentery is comparatively rare. On the Chinese coast Wilson observed but two examples of hepatic abscess in 61 autopsies on dysenterics, and Traquair states that in a number of such autopsies made at Hong-Kong he did not encounter it in a single instance.†

In Europe the infrequency of liver abscess in dysentery has been abundantly demonstrated by numerous observations. It does, however, occasionally occur in both acute and chronic cases. Broussais has related the particulars of 17 cases of diarrhœa and dysentery, in none of which liver abscess was observed; Rokitansky, in his essay on the dysenteric process, declared that he had never encountered this complication; Baly asserted that it did not exist in one of the many hundreds of cases of dysentery which he observed in the Millbank prison; nor did Finger find a single example of it in the 231 autopsies on dysenterics he made in the hospital at Prague. During the Crimean war Lyons found but one instance of hepatic abscess in 51 autopsies on dysenterics, and Savignac declared that although he had seen a great number of cases of chronic dysentery in the French hospitals, none of them suffered from suppuration of the liver.‡ On the other hand, Cheyne found four examples of hepatic abscess in 30 autopsies on subjects dead of dysentery, in Dublin, during the epidemic of 1818. Louis and Andral have each related a case in which hepatic abscess supervened upon a chronic flux dependent upon intestinal ulceration. Marston, in 48 autopsies on subjects dead, at Malta, of dysentery contracted in the Crimea, found two examples of hepatic abscess. Bristowe found at St. Thomas's hospital, London, four examples in 32 autopsies in which dysenteric ulcers existed in the intestine; and Bergès§ has collected eight examples of hepatic abscess consecutive to dysentery, observed in Paris by

---

* Exact statistics on this subject are much to be desired. See the discussion of the question by HIRSCH—*op. cit.*, Bd. II, S. 314—who concludes that, so far as the facts are known to him, they show that no immunity results from prolonged residence in the tropics. DUTROULAU—*op. cit.*, p. 176—holds the same opinion: "En résumé, pas plus d'acclimatement contre la dysenterie et l'hépatite que contre la fièvre," and W. J. MOORE—*Health in the Tropics*, London, 1862, p. 277—emphatically exclaims: "The fact is, for the white man or his offspring there is no such thing as acclimatization in India."

† JOHN WILSON—*Medical Notes on China*, London, 1846. I have not seen this work, and quote from WARING—p. 121, *op. cit.*, note ‡, p. 549, *supra*; see also a rather full notice of it in the Med.-Chir. Review, Vol. IV, 1846, p. 73. TRAQUAIR—*Dysentery as met with in Hong-Kong*, Med. Times and Gaz., Vol. I, 1854, p. 335.

‡ BROUSSAIS—*Hist. des Phlegmasies*, 3me Édit., Paris, 1822, T. II, p. 517 *et seq.*, Obs. X to XXVII, inclusive. Nevertheless BROUSSAIS believed that hepatitis was always due to a pre-existing gastro-entérite, and held to this view so exclusively that he explained the hepatic abscesses which sometimes follow cranial wounds by the aphorism, "les encéphalites produisent toujours la gastro-entérite, et quelquefois l'hépatite."—T. III, p. 268. See also Proposition de Pathologie, No. 149, "L'hépatite est consécutive à la gastro-entérite, quand elle ne dépend pas d'une violence extérieure"—*Commentaires des Prop. de Path.*, T. I, Paris, 1829, p. 287; CARL ROKITANSKY—*Der dysenterische Prozess*, Oest. Med. Jahrb., Bd. XX, 1839, S. 93: "Eine augenfällige Erkrankung der Leber, wie solche bey den Ruhren in den Tropenländern vorkommen soll, haben wir nicht gefunden;" WM. BALY—*Gulstonian lectures*, London Med. Gazette, Vol. IV, 1847, p. 488; FINGER—*Die epidemische Ruhr*, Prager Vierteljahrschrift, Bd. IV, 1849, S. 145; R. D. LYONS—*Report on the Pathology of the Diseases of the Army in the East*, London, 1856, p. 30 *et seq.*; J. D. DE SAVIGNAC—*Traité de la Dysentérie*, Paris, 1863, p. 173.

§ J. CHEYNE—*Dysentery as it appeared in* 1818, Dublin Hospital Reports, Vol. III, 1822, p. 1. The cases in which liver abscess was observed are Nos. 6, 18, 27 and 28. CHEYNE himself remarks, p. 36, of the liver, "in two cases there were abscesses formed in its substance," a misstatement or misprint which is often quoted, *e. g.*, by J. W. BEGBIE, in Reynolds' System of Medicine, Vol. III, London, 1871, p. 144. P. CH. A. LOUIS—*Mémoire sur les abcès du foie*, Rech. Anat.-Path. sur Diverses Maladies, Paris, 1826, p. 351. This memoir contains five cases of hepatic abscess: the one referred to is Obs. 3, a medical student who had long suffered with diarrhœa; multiple abscesses of the liver and follicular ulcers of the large intestine were found on the autopsy. G. ANDRAL—*Clinique Médicale*, 3me Édit., Paris, 1834, T. II, p. 464; I refer to Obs. 25, a case of "gastro-entérite chronique," in which on the autopsy the liver was found to contain a single abscess about the size of an orange, and numerous ulcers were found in the lower part of the ileum and in the cæcum. The work cited contains the particulars of eleven other cases of hepatic abscess, making twelve in all, viz: one on pp. 319–321, and eleven between p. 449 and p. 497. I note that FRERICHS—*Diseases of the Liver*, New Sydenham Society's Transl., Vol. II, London, 1861, p. 109—remarks: "Of 16 observations collected by Louis and Andral, ulcers were present in only 3, and in 2 of these cases the ulcers were tubercular." ANDRAL himself, however, counts 17 cases, as I do: "Les onze cas qui vont être rapportés, réunis aux cinq relatés par M. Louis, et à un autre que nous avons déjà rapporté plus haut dans ce volume," &c., (*op. cit.*, 449.) Now I am quite clear that the case just cited from LOUIS is not one of tubercular ulceration; about the case cited from ANDRAL, I am not so sure. There were a few "crude" tubercles in the upper part of the lungs in this case, but the description of the ulcers is not very definite. If they were tubercular ulcers, this case might be cited as adverse to the observation of BRISTOWE [*vide infra*] that abscess of the liver did not coexist with tubercular ulcers of the intestine. FRERICHS (*loc. cit.*) remarks further, of his own experience, that of 8 cases of hepatic abscess observed by him, intestinal ulcers did not exist in any. J. A. MARSTON—*On dysentery, a paper compiled from fatal Crimean cases, observed at Malta military hospital*, Med. Times and Gazette, Sept. 20, 1856, p. 284. J. S. BRISTOWE—*On the connection between abscess of the liver and gastro-intestinal ulceration*, Trans. of the Path. Soc. of London, Vol. IX. 1857–8, p. 241. This paper contains an analysis of the records of 324 autopsies in which ulcers or cicatrices were observed in the gastro-intestinal mucous membrane; of these, 45 were specimens of typhoid, and 25 of malignant ulcera-

various physicians. According to Heubner,* it is chiefly multiple or embolic abscess of the liver which is observed in European dysentery, and it occurs chiefly in connection with periproctitic inflammation.

Even in cases of chronic dysentery contracted in tropical climates, and proving fatal after their return to England or France for treatment, abscess of the liver is comparatively rare. Knox found but two examples in 64 such cases observed in Edinburgh, and Roullet but two in 50 autopsies of colonial dysentery recorded at the marine hospital of Rochefort, from 1821 to 1869. According to Ward, hepatic abscess does not occur in five per cent. of the cases of well marked and severe dysentery treated at the seaman's hospital, London.†

When, now, the attempt is made to compare the experiences thus summarized with what occurs in the United States in time of peace, the absence of adequate statistics for the purpose must certainly be regretted. Brokaw had the extraordinary experience of finding hepatic abscess in 22 out of 27 autopsies of dysenteric subjects at the marine hospital, St. Louis, Missouri; and Fox, at the quarantine hospital of the same city,‡ observed it in 5 of 30 autopsies of subjects dead of chronic diarrhœa and dysentery; but these results are not supported by the observations of others. I find in the American medical journals and transactions more or less detailed reports of only about 150 cases of hepatic abscess reported prior to 1876, including alleged cures and traumatic cases. In less than one-fourth of these does the record indicate any connection with dysentery, and in but 21 is this connection supported by post mortem examination.§

---

tion; in none of them did hepatic abscess coexist. In 55 ulcers of miscellaneous nature (including simple ulcers of the stomach, cicatrices, &c.) there were three hepatic abscesses, and in 167 cases of tubercular ulcers there were 12 in which "small tubercular cavities" existed in the liver, but no abscesses of that organ. PAUL BERGÈS—*Étude sur les abcès du foie consécutifs a la dysentérie des régions tempérées*, Paris Thesis, 1876, No. 139. This essay contains three cases observed by BEHIER—Gaz. des Hôpitaux, Oct., 1869, pp. 457 and 461; one by GUBLER—Bull. de la Soc. Anat. for 1871, p. 370; one by GALLARD—L'Union Méd., T. XIII, 1872, p. 232; and one by LANCEREAUX—Mém. d'Anat. Path., Paris, 1863, p. 55. It contains, besides, two previously unpublished cases, and three of the cases of CHEYNE—*vide supra*—making eleven cases in all. I note that one of BEHIER'S cases, however, had been two years a resident in Africa.

* HEUBNER—*Dysentery*, in Ziemssen's Cyclopædia, Amer. Transl., Vol. I, New York, 1874, p. 546.

† ABERCROMBIE—*Diseases of the Stomach, Intestinal Canal, Liver, &c.*, Edinburgh, 1828, p. 250: "I am also informed by Dr. KNOX of this city, that he had opportunities of examining the bodies in 64 cases of chronic dysentery from India, Ceylon, and the coast of Africa, and that he found the liver diseased in two only of all this number." ABERCROMBIE remarks, of his own experience: "I have never seen the liver affected in the dysentery of this country, except in one or two chronic cases." G. ROULLET—*La dysenterie chronique des pays chauds*, &c., Paris Thesis, No. 28, 1870, p. 27 *et seq.* GEORGE BUDD—*Diseases of the Liver*, 3d Edit., London, 1857, p. 73—observed 15 cases of liver abscess, at the seaman's hospital, "in sailors most of whom had been in the East." Eight of these cases coexisted with ulcers of the large intestine; also two cases of dysentery with liver abscess, at King's college hospital, one of them a man who had contracted his dysentery in India, p. 82. But BUDD does not state how many cases of dysentery without abscess occurred in these hospitals in the same class of patients during his time of observation, so that his figures throw no light on the question in the text. STEPHEN H. WARD—*On some Affections of the Liver and Intestinal Canal*, &c., London, 1872, p. 18. He also states that while physician to the seaman's hospital he saw there 22 cases of liver abscess, p. 2.

‡ F. V. L. BROKAW—*Dysenteric ulceration and sloughing of the mucous membrane of the intestines as a cause of abscess of the liver*, St. Louis Med. and Surg. Jour., Vol. XV, 1857, p. 484: "During the past two years, while a resident physician in the marine hospital in this city, in twenty-seven fatal cases of dysentery, in which I made post mortem examinations, there were abscesses in the liver in twenty-two." He further states that 10 of the 22 cases "had been the subjects of intermittent fever at a longer or shorter time previous to their admission into the hospital with dysentery;" and that in 15 of his cases the dysentery was chronic, the abscesses fewer in number, large, and had a wall of lymph around them, while in the acute cases there was sloughing of the intestinal mucous membrane, and the abscesses in the liver were numerous, small, and "uncircumscribed by lymph." I am assured, in a note from my friend Dr. WM. M. MCPHEETERS, one of the most eminent practitioners in St. Louis, that Dr. BROKAW'S narrative is perfectly trustworthy; he adds: "All the patients in the hospital were river men, and the larger proportion of them running on the lower Mississippi, where they were exposed to malarial influences in a concentrated form." THOMAS FOX—*On the relation of hepatic abscess to chronic dysentery and diarrhœa*, St. Louis Med. Archives, Vol. III, 1869, p. 731. According to this writer 122 cases of chronic diarrhœa and 32 of chronic dysentery were treated in the quarantine hospital, St. Louis, during 1868-9: "Among the 122 cases of chronic diarrhœa there occurred 24 deaths, and among the 32 cases of chronic dysentery, 6 deaths. Among the 24 cases of death from chronic diarrhœa there was found ulceration of the ileum in 8 cases, and of the colon in 2 cases. Among the 6 cases of death from chronic dysentery there was found ulceration of the colon and rectum in 3 cases, of the ileum in 2 cases, and of the rectum in 1 case. Among the 24 cases of death from chronic diarrhœa, abscess of the liver was found in 2 cases; among the 6 cases from chronic dysentery, abscess of the liver was found in 3 cases."

§ The following list of references to fatal cases of hepatic abscess consecutive to dysentery or associated with it, in which on autopsy ulceration or other characteristic lesions were found in the large intestine, includes all the cases of the kind I have found by a pretty thorough search of the American medical journals and transactions up to 1876: W. E. HORNER—Amer. Jour. of the Med. Sci., Vol. XIV, 1834, p. 87; WM. PEPPER—same Journal, Vol. XXI, 1837, p. 529; J. T. METCALFE—New York Jour. of Med., Vol. IV, 1850, p. 319; J. M. CLEAVELAND—New York Med. Times, Vol. I, 1852, p. 103; J. B. S. JACKSON—Boston Med. and Surg. Jour., Vol. LV, 1857, p. 527; ALONZO CLARK—New York Jour. of Med., Vol. II, 1857, p. 378—two cases; A. W. PERRY—Southern Jour. of Med. Sci., (New Orleans,) Vol. I, 1866-7, p. 665—three cases; R. B. MAURY—Med. Record, Vol. II, 1867-8, p. 241; MOREHOUSE—Proc. of Path. Soc. of Philadelphia, Vol. I, 1860, p. 56; C. C. LEE—same Proc., Vol. II, 1867, p. 98; MARTIN—same Proc., Vol. III, 1871, p. 46; HERBERT—same Volume, p. 15; DE F. WILLARD—same Volume, p. 104; WEBSTER—Boston Med. and Surg. Jour., Vol. LXXXVIII, 1873, p. 650; L. S. MCMURTRY—The American Practitioner, Vol. X, 1874, p. 280. To these I may add three cases reported in the Trans. of the New York Path. Soc., Vol. II, 1877, viz: MCCREADY, p. 238; ALONZO CLARK, p. 239; and FINNELL, p. 242.

Certainly the comparatively small number of such cases reported in our medical journals would seem to indicate not merely that hepatic abscess is not a frequent complication of dysentery in the United States, but that it is not a very prevalent disease in this country under any circumstances. It might be expected to be more common in the southern than in the northern states, and that it is so in the Mississippi Valley would appear from the testimony of Drake,* who, however, expressed his belief that suppuration of the liver occurred in that region even less frequently than suppuration of the spleen. Drake's opinion of the rarity of liver abscess agrees with that of Nott,† who testified that liver disease generally was exceedingly rare in Charleston, Mobile and New Orleans; and the opinions of these intelligent observers are supported by the several Census Reports and by the Army Statistics of Coolidge,‡ which, indeed, do not give separate figures for liver abscess, but report so small a proportion of deaths from hepatitis (under which head the fatal cases of liver abscess are included) as plainly to indicate its infrequency. Perry§ has suggested that hepatic abscess is really much more prevalent in New Orleans and the southern portions of the United States generally, than the mortuary reports would indicate, believing that, "owing to the obscurity of the disease," it is passed by unappreciated and some other affection diagnosticated. That this occasionally occurs cannot be doubted; but dissections are so frequently made in the hospitals of all our large cities that the lesion in question would assuredly be more frequently reported, in the journals or transactions of societies, if it were not quite rare.‖

The nature of the connection between hepatic abscess and dysentery has given rise to much difference of opinion. The old belief that vitiated bile resulting from the hepatic disease irritated the intestinal mucous membrane and gave rise to dysentery has already been referred to. Annesley,¶ while still holding to this explanation for some of the cases in which the two conditions are combined, admitted that in many others the hepatic complication appeared to be developed subsequently to the intestinal disorder, of which it must be regarded as the consequence rather than the cause. Broussais** went so far as to affirm that all cases of hepatitis which do not result from external violence are consecutive to inflammations of the mucous membrane of the alimentary canal, especially of the duodenum.

---

* D. DRAKE—*Principal Diseases of the Interior Valley of North America*, Second Series, Philadelphia, 1854, p. 171. He appears to have obtained notes of seven cases only, to which he adds: "Dr. Fearn, of Mobile, has had several cases, the termination of which I did not record."

† J. C. NOTT—*Examination into the health and longevity of the southern seaports of the United States*, &c., Southern Jour. of Med. and Pharm., Vol. II, 1847, p. 135: "In Charleston (and so with Mobile and New Orleans) diseases of the liver are almost unknown." * "I can declare with confidence, and my professional brethren here will sustain me, that I see fewer diseases of the liver in Mobile, than of any other important organ in the body. I do not think I exaggerate, when I say, that the cases in my practice, belonging to Mobile, do not exceed one a year."

‡ The number of deaths in the United States in 1870 from hepatitis was 1,534, or 4 to every 100,000 living persons; in 1860, 200, or .6 to every 100,000 living persons: See Vol. II, *Ninth Census Report*, Washington, 1872, p. xviii. In the census of 1850 hepatitis is not even separately reported, but is included under the head of "disease of liver," of which 1,851 deaths are reported, or 8 per 100,000 living persons. In the last report of COOLIDGE—*Statistical Report of the Sickness and Mortality in the Army of the United States*, Washington, 1860, p. 322—the consolidated abstract of the diseases and deaths of the army for 18 years gives only 26 deaths of hepatitis, acute and chronic, out of an average mean strength of a little over 10,000 men.

§ A. W. PERRY—*Abscess of the liver; its connection with dysentery, loc. cit.*, note §, p. 553: "I am satisfied that it is a very common disease in New Orleans, and the southern portions of the country." This opinion is supported by the fact that the author had observed "within a short space of time," at the Charity hospital, New Orleans, five cases of liver abscess, four of which were complicated with dysentery. One of these cases (No. 4) is so doubtful that the author says: "the abscess in this case, if one existed, and I think it did, probably was small and became encysted;" the patient recovered. The three others died, and are referred to in the note cited above. The author also states that of 3,936 deaths entered on the mortuary records of New Orleans between May 20 and October 8, 1866, but two were attributable to abscess of the liver.

‖ As a further illustration of the rarity of liver abscess, especially in the northern portion of the United States, I may mention that the Museum of the Boston Society for Medical Improvement, when catalogued by J. B. S. JACKSON, Boston, 1847, contained 954 pathological specimens, but one of which was an abscess of the liver, and in this the disease, which followed dysentery, had been contracted on the western coast of Africa. The Proc. of the Path. Soc. of Philadelphia from Oct. 14, 1857, to Dec., 1873, (Vols. I to IV inclusive,) only contain reports of five cases of hepatic abscess besides those cited on p. 553. So also the Trans. of the Med. Soc. of the District of Columbia from July, 1865, to Jan. 1, 1878, only contain reports of four cases. The Trans. of the New York Path. Soc., Vol. II, 1877, (from 1844 to 1876,) contain the largest number of cases, viz: 22, besides those cited on p. 553.

¶ ANNESLEY—*Diseases of India*, London, 1828, Vol. II, p. 199. He admitted also that the two diseases may in some cases be "nearly coeval as respects their origin, or at least so very nearly simultaneous in their attack, that the priority of lesion can scarcely be detected."

** See note to p. 552, *supra*. See also the thesis of his son, CASIMIR A. M. BROUSSAIS—*Sur la duodénite chronique*, Paris Thesis, No. 59, 1825—in which this doctrine is developed at length. These views were adopted by ANDRAL—*Clinique Médicale*, 3me Édit., Paris, 1834, T. II, p. 305.

He pointed out that in the normal state physiological irritations of that membrane provoke the hepatic secretion, in accordance with the law of Bichat,* that glands respond to the stimulation of the surfaces on which their excretory ducts open, and regarded the acute and chronic phlegmasiae of the liver as resulting from the pathological exaggeration of this physiological process.

Ribes† first suggested the idea that the inflammation is propagated from the gastro-intestinal mucous membrane to the liver by means of the portal vein and its branches. This view was especially developed by Budd,‡ who taught that in dysentery "the portal blood may be contaminated either by pus, formed by suppurative inflammation of one of the small intestinal veins; or by matter of other kind resulting from softening of the tissues; or by the fetid gaseous and liquid contents of the large intestine in dysentery, which must be absorbed and conveyed immediately to the liver;" and he thought it probable that contamination of the first two kinds gave rise to small scattered abscesses; of the last "to diffuse inflammation, and a larger, perhaps single, collection of pus." It must be admitted, as Frerichs§ has pointed out, that the doctrine of Budd rested chiefly upon speculative grounds; nevertheless in a somewhat modified form it appeared to be countenanced by the generally accepted doctrine of the production of metastatic abscesses by embolism, which the observations of Virchow‖ placed upon a scientific footing, and, hence, what has been known as the embolic or pyæmic theory, as to the origin of the hepatic abscesses which complicate dysentery, has been very generally received with favor.

Morehead,¶ while admitting that abscess of the liver may occasionally arise in this way, adverts to the frequency with which dysenteric ulceration exists without hepatic abscess, and hepatic abscess without intestinal ulceration, or, indeed, any source whence emboli could be derived, as a proof that this explanation cannot be regarded as generally available. Similar objections have been urged by Bristowe and Frerichs.** The suggestion of Morehead that the cachexia induced by residence in the tropics is the predisposing cause of hepatic abscess in those regions, and that the immediate exciting cause is a chill resulting from exposure to external cold, has been adopted by Frerichs as most in harmony with the facts in the case of those abscesses of the liver which accompany tropical dysentery.

The distinction between small multiple, and large, for the most part single, abscesses of the liver has been emphasized by Murchison, who, as has been already mentioned, speaks of the former as pyæmic, the latter as tropical abscesses.†† The pyæmic abscesses, he believes, may result from any of the sources of pyæmic infection; among others, from

‖ R. VIRCHOW—*Gesammelte Abhandlungen*, 2te Aufl., Hamm, 1862, p. 219 *et seq.* The first of the papers on the subject referred to was published as early as 1846.

¶ CHARLES MOREHEAD—*Clinical Researches on Diseases in India*, (1856,) 2d Ed., London, 1860, p. 365. Both these facts have long been known. I need only refer to the statistics of WARING—*Abscess in the Liver*, &c., Trebandrum, 1854, p. 134—as an illustration of the frequency with which hepatic abscess, unconnected with intestinal ulceration, occurs even in India. Of 204 autopsies the intestines were found ulcerated in 147, abraded in 3, cicatrices were found in 3, and no trace of ulceration in 51, or one-fourth of the cases. Compare the statistics of BRISTOWE, *op. cit.*, *supra*; also the figures reported by MOREHEAD himself in a *Note on the pathology of hepatic abscess*, British Med. Jour., March 20, 1869, p. 258, where, consolidating the cases collected by LEITH and STOVELL, as well as his own, he obtains 238 cases of dysenteric ulceration without hepatic abscess and 62 of hepatic abscess without intestinal ulceration: "Sufficient, I apprehend, to disprove the pyæmic theory," he remarks; but certainly it did not need these figures to show that the two conditions named may occur separately. This mode of presenting the subject, however, does not even attempt to deal with the fact of their frequent coexistence. I may add that MOREHEAD's opinions have been reviewed by Assistant Surgeon J. F. FOSTER—*Remarks on the pathology of hepatic abscess*, The Indian Medical Gazette, Vol. II, 1867, p. 219—who ingeniously makes use of MOREHEAD'S own cases to attack his conclusions.

** BRISTOWE—*op. cit.*, p. 552, *supra*. FRERICHS—*loc. cit.*

†† CHARLES MURCHISON—*Diseases of the Liver*, &c., Amer. reprint, New York, 1868, p. 147 *et seq.* Compare p. 396, *supra*.

ulceration of the stomach or intestine; for the tropical, he inclines to the theory of causation proposed by Morehead.* The relation between pyæmic abscesses of the liver occurring in the latter stages of dysentery and the intestinal ulceration is that of effect and cause; the relation between tropical abscesses and dysentery, when the two coexist, is purely accidental and due to the simultaneous action of the causes of the two affections. Murchison† affirms that large single abscesses of the liver are almost unknown in England and in temperate climates generally, except in persons who have sustained some local injury of the liver, or at some time resided in the tropics.

This statement appears to be too emphatic; such abscesses, though infrequent, do occur both in Europe and the United States, and the designation "tropical abscess" appears therefore less appropriate than the old term "idiopathic abscess." Nor is it always possible, even with the amplest opportunities for dissection, to assign individual cases to the one or the other of these two classes. Certainly in many instances the multiple foci found in the livers of subjects dead of dysentery, resemble in all their characters the pyæmic foci in the liver which occur after gunshot wounds. That similar foci may be found in the lungs, the spleen and the kidneys of subjects dead of dysentery, is shown by the autopsies analyzed in this section. In the cases of multiple foci in the liver to which I refer, the foci usually correspond in their distribution to the branches of the portal vein, and in their form and dimensions to a territory supplied by one of these branches. In some of these cases, on microscopic examination, the foci prove to consist merely of liver tissue and extravasated blood in a state of necrotic metamorphosis; in others suppuration has already commenced at the periphery of the foci. In the few cases that I have myself been able to examine I have not been so fortunate as to find recognizable emboli plugging the branches of the portal vein or hepatic artery leading into the necrotic masses; and I incline, therefore, to the belief that in some cases putrid semifluid debris from the thrombi connected with the dysenteric ulcers‡ may lodge in the capillaries of the liver and serve as the starting point of these local necrotic processes, which, I admit, may also result from solid emboli.

It is readily conceivable that in the more advanced stages of the process just sketched the accumulating pus might quite conceal the original infarction, the debris of which would

* MOREHEAD—*op. cit.*, p. 361. According to this writer the months of February and March are those in which the greatest number of cases of hepatitis occur. The following table, combined from the tables on pp. 274 and 362, contrasts the relative proportion of admissions from hepatitis and dysentery in two of the Bombay hospitals, the figures representing the per cent. of total admissions:

Season.	Dysentery.		Hepatitis.	
	European General Hospital.	Jamsetjee Jejeebhoy Hospital.	European General Hospital.	Jamsetjee Jejeebhoy Hospital.
Cold months—November, December, January	10.8	10.2	3.8	1.7
Wet months—June, July, August	7.0	10.7	2.9	1.4
Transition from cold months—February, March	6.3	6.4	4.8	2.0
Transition from rains—September, October	5.4	8.9	3.2	1.0
Hot months—April and May	5.1	7.2	3.4	1.6

These figures, so far as they go, would seem to show that the annual fluctuations of hepatitis in India neither coincide with those of dysentery nor immediately follow them. The author remarks: "It is very probable that future research will show that the exhausted and enfeebled by continued heat, and its associated debilitating conditions, are very prone to hepatitis, and that in such individuals the inflammation is very frequently excited by exposure to external cold—I mean to such depression of temperature as suffices to influence bodies whose power of generating heat is low." But he also thinks that tropical heat of itself "is occasionally an exciting cause of hepatitis," and thinks this explains the occurrence, during the hot months, of hepatitis in "plethoric Europeans, lately arrived in India, with excreting functions deranged by free living," p. 363.

† *Op. cit.*, p. 165.

‡ This view I have elsewhere discussed in connection with the general subject of pyæmia: J. J. WOODWARD—*Causes and pathology of pyæmia, (septicæmia,)* Trans. of the American Medical Association, Vol. XVII, Philadelphia, 1866, p. 173. According to the recent bacteria theories it should be the micrococci in these semifluid debris which do the mischief.

be distributed through the contents of the resulting abscesses. It would then be difficult to be sure, especially when the purulent collections are not numerous, that they arose in this way rather than as a result of acute parenchymatous hepatitis, which is probably, as was formerly believed and as Rindfleisch* still maintains, the precursor of idiopathic hepatic abscess. In a word, while I feel constrained to admit the distinction between pyæmic and idiopathic abscess of the liver, there are certain cases which I find difficult to assign to one category rather than to the other. Nor am I able to admit that no connection exists between large hepatic abscesses and the dysenteric process. The proportion of these cases which coexist with dysentery appears too large to be accidental. I incline, however, to believe that the relationship in these cases between the liver abscess and the dysenteric process is similar to that which exists between pneumonia and dysentery, namely, that the conditions which might produce pneumonia or hepatitis in healthy subjects are still more prone to do so in those who are debilitated by a pre-existing flux.

It has already been shown in the case of pneumonia complicating dysentery that, like uncomplicated pneumonia, it generally proved fatal in the colder months, and as pneumonia is a disease of brief duration, and as the number of cases included in the statistics is large, this fact must be of great significance in connection with the question of causation. Idiopathic hepatic abscess is, however, so often a protracted disease that the date of the fatal issue is less significant. I note that the ten cases of large hepatic abscess summarized on page 548 as having occurred in connection with dysentery during the war all proved fatal between the first of August and the last of January, which is quite consistent with the theory that they all originated from chill after previous exposure to the heat of summer. Unfortunately, however, for any such explanation, the fifteen cases of multiple liver abscess which occurred in connection with dysentery during the war, with a single exception, proved fatal between the first of August and the last of December, so that if it may be drawn from the first group of facts, the opinion would be fairly applicable to the second.†

Besides the *adhesions* which connected the liver to adjacent parts in several of the cases of hepatic abscess just mentioned, it was adherent to the diaphragm in cases 90, 167 and 778, and to the diaphragm and abdominal parietes in case 794. In cases 140, 533, 819 and 868 circumscribed thickenings of the capsule, generally supposed to have been *cicatrices*,‡ were observed on the convex surface of the liver. In case 96 a "cyst," the size and character of which are not recorded, was found in the lower portion of the right lobe of the liver. In case 550 the liver contained *tubercles*, (lung phthisis and tubercles of the spleen coexisted.) In case 833 masses of some undetermined *neoplasm* of "cartilaginous hardness" were found in the liver, and a similar mass existed on the surface of the left lung. In case 859 the left lobe of the liver was larger than the right.

---

* E. RINDFLEISCH—*Lehrb. der Path. Gewebelehre*, 3te Aufl., Leipsic, 1873, p. 419.

† Of 10 cases of large abscess of the liver complicating dysentery, (see p. 548, *supra*,) 1 died in August, 1 in September, 1 in October, 3 in November, 1 in December, and 3 in January. Of 15 cases of multiple abscess of the liver (*loc. cit.*) complicating dysentery, 1 died in February, 3 in August, 5 in September, 1 in October, 2 in November, and 3 in December. It will further be noticed that of the three additional cases mentioned in note ‡, p. 548, those of large abscess died, one in October, the other in November, and the case of multiple abscess in October. I may add that of the nine cases of abscess of the liver unconnected with dysentery, of which specimens are preserved in the Museum, (*loc. cit.*,) one is a case of multiple abscess, which proved fatal in April; the others were large, for the most part single abscesses, of which 1 died in September, 1 in November, 2 in December, 3 in January and 1 in February. Of the 8 rejected specimens (*loc. cit.*) the date of death was not given in 2 cases; in 1 the abscess was multiple—the patient died in January; in the others the abscesses were large, generally single—2 patients died in July, 1 in November, 1 in January and 1 in February. More extensive statistics of the date at which hepatic abscess proves fatal would be useful; still more so would be statistics as to the date at which it originates.

‡ That these were really cicatrices is highly improbable. P. CH. A. LOUIS—*Mémoires ou Recherches Anatomico-Pathologiques*, Paris, 1826, p. 408—would not even admit the cicatricial nature of the fibroid, cicatrix-like structures sometimes seen in the interior of the liver, remarking that, before admitting this interpretation, it would be necessary to have seen them in all their stages "from the moment when they commence to form, still containing between their extremities a certain amount of pus, until they are complete and more or less dense, which has not been done."

The quantity and characters of the *bile* found in the gall-bladder are not mentioned in the majority of these cases. In eight of the cases of follicular ulceration and thirty-eight of the undetermined cases the gall-bladder is said to have been distended with bile, or full of bile, or quantities above half an ounce are recorded as having been observed, although nothing is said of the quality or appearance of the fluid. The latter point is briefly referred to in the following cases of follicular ulceration: In case 543 the gall-bladder was moderately full of healthy-looking bile; in case 195 it was filled with yellow, and in case 198 with amber-colored bile; in case 370 it contained an ounce and a half of clear straw-yellow bile with a yellowish flocculent sediment; in case 351 nineteen drachms of yellowish, very viscid bile; in case 339 a small quantity of light-yellow viscid bile; in case 374 six drachms of orange-yellow bile; in case 293 it was distended with greenish bile; in case 314 full of very green bile; in case 389 it contained two ounces and a half of dark-green bile with considerable intensely green sediment; in case 371 it contained five drachms, and in case 387 three, of dark-green viscid bile; in case 379 it contained one ounce and a half of dark-brown very viscid bile; in case 336 it was filled with dark viscid bile; in case 333 it contained some dark viscid bile; in case 381 six drachms of dark reddish-brown bile; in case 454 an ounce of dark-colored bile; in case 819 it was full of dark-colored bile; in case 350 it contained two drachms of reddish viscid bile; in cases 426 and 428 it was filled with viscid bile. In case 350 the gall-bladder also contained a calculus a quarter of an inch in diameter.

The appearance of the bile is also mentioned in the following undetermined cases: In case 240 the gall-bladder was distended with thin light-colored bile; in case 618 with a colorless albuminous liquid; in case 721 with a light-yellow liquid which had "little appearance of bile;" in case 319 it contained about an ounce of thin orange-yellow bile; in case 356 six drachms of light-yellow watery bile; in cases 193 and 396 a small quantity of light-colored bile; in case 448 an ounce and a half of yellow bile; in case 520 half an ounce of yellow inspissated bile; in case 87 it was distended with dark gelatinous bile; in case 565 it contained six ounces of dark, grumous, viscid bile; in case 621 it was distended with viscid bile; in case 408 it contained seventeen drachms of viscid bile; in case 636 it contained two ounces of black tar-like bile; in case 384 ten drachms of molasses-colored viscid bile; in case 365 seven drachms, and in case 383 ten, of dark-green bile; in cases 777 and 778 each, an ounce of "unhealthy" bile. In case 638 the gall-bladder contained a small calculus; in case 609 five black calculi; in case 743 six small dark-colored calculi; and in case 80 nine calculi. In one of the cases of follicular ulceration and six of the undetermined cases the gall-bladder is said to have been empty.

If the foregoing observations are compared with the condition of the gall-bladder and its contents as recorded in the non-ulcerative and diphtheritic cases,* it will be seen that the quantity and character of the bile found after death from diarrhœa and dysentery are quite as variable as in the case of those dead from other diseases. This agrees with the experience of most other observers.† I am not acquainted with any satisfactory attempts to find morbid peculiarities in the bile of such cases by chemical analysis.

---

* See pp. 316 and 459, *supra*.

† Some few writers state that the bile found after death from dysentery is generally dark-colored and viscid. Thus, according to HAUFF—S. 328, *op. cit.*, *supra*, p. 534—this was the experience of the Wurtemberg physicians, who, however, in some rare instances found a light-colored slimy fluid or a transparent serum. PARKES—p. 46, *op. cit.*, *supra*, p. 551—declares that the condition of the bile is so far abnormal that the liver must be "more or less diseased in every case of dysentery." Usually he found two conditions present: 1, If the gall-bladder was "moderately full or half-empty, the bile is thin, transparent, of a brownish red colour; not stringy, sometimes with particles suspended in it apparently crystalline, and sometimes like particles

The *spleen* is said to have been softened or friable in rather more than a dozen of the cases of follicular ulceration and about twice as many of the undetermined cases. In a somewhat larger number of cases it is spoken of as firm, hard, indurated or tough. In nine of the cases of follicular ulceration and eighteen of the undetermined cases it is said to have been *small*, but its weight is not specified. In fifteen cases of the first class the small size of the organ is shown by its weight, viz: it weighed six ounces in case 746; five ounces in case 368; four and a half in cases 371 and 379; four and a quarter in case 333; four in cases 196, 201 and 381; three and three-quarters in case 336; three and a half in cases 198, 355, 370 and 398; three and a quarter in case 350; and two in case 458. The same occurred in thirty of the undetermined cases, the organ weighing six ounces in cases 727, 759 and 806; five and a half in cases 375, 753 and 772; five in cases 418, 578, 734, 735, 739 and 768; four and a half in cases 384, 406 and 767; four and a quarter in case 356; four in cases 411, 580, 721, 765 and 773; three and a half in case 745; three and a quarter in case 396; three in cases 260, 407, 459 and 755; two and a half in cases 417 and 747; and two in case 296.

On the other hand, in seven of the cases of follicular ulceration and twenty-seven of the undetermined cases the spleen is said to have been *large*, or enlarged, without indicating its weight. In six cases of the first class the abnormal size of the organ is shown by its weight, which was nine ounces and a half in case 195; eleven and a quarter in case 339; twelve and a half in case 389; twelve and three-quarters in case 363; thirteen and a half in case 374; and twenty-five in case 401. Among the undetermined cases the spleen is said to have been twice the normal size in cases 84 and 453; four times the normal size in case 658; and five times in case 636. The abnormal size of the organ is shown by its weight in twenty-six cases, viz: it weighed nine ounces in cases 743, 756, 808 and 812; ten in cases 719 and 813; ten and a half in cases 380, 762, 775 and 807; twelve in cases 726 and 744; thirteen in cases 228 and 736; thirteen and a half in case 365; fourteen in cases 289, 410 and 757; sixteen in cases 728, 737 and 741; seventeen in case 383; thirty-two in case 851; thirty-nine and a half in case 420; forty-three in case 614; and fifty-six in case 791.

In eight of the cases of follicular ulceration and fifteen of the undetermined cases the spleen is said to have been *congested*, and in a few instances its trabeculæ or Malphigian

---

of Cayenne pepper;" 2, "In other cases the gall-bladder is full, perhaps distended with a thick dark green, very stringy viscid bile." SAVIGNAC—p. 278, *op. cit.*, *supra*, p. 534—found the gall-bladder distended with tarry (poisseuse) bile, of a blackish or very dark-green color in acute cases; in chronic cases it was lighter colored and more fluid. BARRALLIER—Art. *Dysenterie*, in Nouv. Dict. de Méd. et de Chir. Pratiques, T. XI. Paris, 1869, p. 764—says the gall-bladder in dysentery is distended by a thick bile which has the consistence of tar, and its color, if examined *en masse*, but is yellow if spread in thin layers. I must confess I agree with HEUBNER—S. 528, *op. cit.*, *supra*, p. 529—that the bile in dysenteric subjects presents no characteristic alterations. In the present state of our knowledge of the chemistry of the bile it is not surprising that nothing definite has been determined by analysis. OESTERLEN—*Zur Chemie der Ruhr*, Zeitschr. für Rat. Med., Bd. VII, 1849, S. 253—in 46 autopsies, found the gall-bladder and its contents "in the same variable conditions as in other dead bodies," S. 276. He made a chemical analysis in but one case, with the following results: water 844.2; bile acids, fat and mucus 142.4; inorganic salts 13.4, in 1000 parts, whence he concludes merely that the bile was concentrated as is usual after long retention in the gall-bladder. Surgeon THOMAS ANTISELL, U. S. Vols.—*On the constitution and source of the bile*, The Amer. Jour. of the Med. Sciences, Vol. XLVII, 1864, p. 91—while in charge of Harewood hospital during the civil war, analyzed the bile found in twenty subjects dead of chronic dysentery, (chronic diarrhœa.) The method used was an application of the principle of dialysis. The gall-bladder containing the bile was suspended for 30 to 48 hours in a vessel containing alcohol or some other selected fluid, then transferred to another vessel for about 30 hours, and subsequently to a third and fourth in the same way; the liquids used besides alcohol were ether, chloroform and coal oil; creasote was added to prevent decomposition. No weighings of any kind appear to have been attempted except in one case, in which the total solids were 10.4 per cent. of the fluid. The chief object appears to have been to arrive at a list of the ingredients, which are given as follows: "1, Epithelium. 2, Mucous corpuscles. 3, Pigment cells, yellow or greenish. 4. Brown coloring matter, resinoid and amorphous. 5, Cholesterin. 6, Fatty globules. 7, Common salt. 8, Carbonate and phosphate soda (neutral) and potassa. 9, Glycocholate soda. 10, Margarate soda. 11, Hæmatoidin. 12, Hippuric acid. 13, Albumen." He "never observed any form like the crystals of taurine or of taurocholic acid, nor any substance having the reactions proper to that acid," and concludes that "it is not present in human bile." Of hippuric acid and hæmatoidin he says: "I have met with one example of each in the twenty specimens examined." The number of cases in which albumen was found is not specified, but as the author concludes that "the bile is an albumino-serous liquid," &c., it may be presumed to have been pretty constant. These analyses, however, cannot be regarded as showing any peculiarities in the bile of chronic dysentery, control-researches conducted in the same way on the bile of subjects dead of other diseases being wanting.

bodies are said to have been unusually distinct. In case 201, in which *metastatic foci* existed in the liver, the spleen is said to have contained "a single deposit of tubercle of some size," which, however, I presume was of the same character as the foci in the liver, and the same remark applies to the "tubercles" said to have been observed in the kidneys in this case. Of the same nature probably were the numerous "small hard nodules" found in the spleen in case 872, in which an abscess of the liver also existed; the "light-yellow masses" found in the lungs and liver, as well as the spleen, in case 727; and the abscesses in the spleen in case 304. In cases 500* and 550 the spleen contained tubercles; in case 745 a few small calcareous deposits. In cases 140, 167 and 601 the spleen was adherent to the abdominal parietes; in case 264 to the liver; in case 593 to the kidney; and in cases 227 and 858 to the diaphragm. In cases 820 and 858 a localized thickening of the splenic capsule existed, forming a white thickened patch on the surface of the organ. In case 371 the upper extremity of the spleen was lobulated, and in case 697 there was a supernumerary spleen as large as a filbert.

A comparison of the foregoing observations with those relating to the spleen in the non-ulcerative and diphtheritic cases† shows that there was no such constant diminution in the size of the organ as some have asserted to exist in dysentery.‡ It is very probable that this condition is of frequent occurrence in uncomplicated cases, but when dysentery attacks those whose spleens are already enlarged in consequence of the malarial influence, or when it is complicated by the typhoid process, the most various degrees of enlargement of the organ may be found after death. Nor should the possibility of embolic processes and consequent inflammatory conditions be overlooked, although these may be expected to occur less frequently than similar conditions in the liver.

The *pancreas* is only mentioned in a few instances, and in these no marked abnormity appears to have been observed.§

The *kidneys* are not mentioned in the majority of the cases, the omission being even more frequent among the undetermined cases than the others. In a large proportion of those cases in which their condition is recorded they were *large and pale*, the result of parenchymatous swelling bordering on fatty degeneration; sometimes they were actually fatty. More or less imperfect descriptions point to this condition in seventeen of the cases of follicular ulceration and twenty-nine of the undetermined cases. Thus, among those of the first class, the kidneys or their cortical substance are said to have been pale, without, however, specifying any abnormal increase in their size, in cases 368, 370, 387 and 426; in case 336 the right kidney was pale, the left congested; in case 310 the right kidney

* The spleen from this case is preserved in the Museum, Med. Sect., No. 298. † *Supra*, pp. 316 and 460.

‡ Although spleens of small size had previously been several times observed in individual cases of dysentery, the opinion that the organ is usually diminished in size seems to have been first suggested by the Wurtemberg physicians during the epidemic of 1834—HAUFF, S. 328, *op. cit.*, p. 534, *supra*—even they, however, in occasional cases, sometimes saw the spleen enlarged. This opinion has been repeated in various quarters, its latest expression being given by HEUBNER—S. 528, *op. cit.*, p. 529, *supra*—"Die Milz ist regelmässig klein." That, on the contrary, the organ is enlarged, especially in cases of malarial complications, has been pointed out by a number of writers, among whom I may specify VOGT—*Monographie der Ruhr*, Giessen, 1856, S. 65; JULIEN—p. 70, *op. cit.*, *supra*, p. 550; and BARRALLIER—p. 764, *op. cit.*, *supra*, p. 559. SAVIGNAC—p. 279, *op. cit.*, *supra*, p. 552—declares "the spleen is healthy except in case of paludal intoxication." On the other hand, according to ROKITANSKY—*Der dys. Prozess*, Oesterreich. Juhrb., Bd. 20, 1839, S. 93—swelling of the spleen, such as occurs in all dyscrasic processes, especially in typhus, is common enough in dysentery, but also very frequently absent. GRIESINGER—S. 541, *op. cit.*, *supra*, p. 551—declares in like manner that he saw in Egypt a series of cases in which there was more or less acute swelling of the spleen, sometimes even wedge-shaped inflammatory foci, (keilförmige Entzündungsherde.) LYONS—p. 96, *op. cit.*, *supra*, p. 552—in the Crimea, appears to have observed similar conditions, chiefly in cases in which dysentery was complicated with typhoid fever: "Extensive deposit, with excessive enlargement of this organ, was a very common occurrence, resulting from the combined influence of coexistent morbid states, such, for instance, as the development of dysentery after typhoid fevers or vice versa." He adds that in such instances the size of the organ was very much increased, and the weight reached 10, 14 or even 20 ounces.

§ In case 198 the pancreas is said to have weighed seven ounces, which is probably a mistake, seven drachms having been intended. The case is cited from the "Observation" book of Assistant Surgeon MCGILL, p. 100, [see note to p. 125, *supra*,] where it is stated of the same pancreas that it was "small and flaccid."

was large and pale, the left healthy; in case 225 both kidneys were enlarged and pale; in case 295, enlarged and friable; in several cases the substance of the kidneys is said to have been pale, and the weights of the organs recorded range from six ounces upwards, viz: in case 195 they weighed six ounces each; in case 355 the right eight and a half, the left seven; in case 339 the right weighed nine ounces, the left nine and a half. In two other cases, viz: 333 and 401, the kidneys weighed above six ounces each, but their appearance is not recorded. In cases 320, 389, 732 and 870 the kidneys are said to have been fatty.

Among the undetermined cases, the kidneys or their cortical substance are said to have been pale in cases 80, 193, 365, 388, 457 and 578; the same appearance was combined with increased weight in case 738, in which the kidneys weighed six ounces and a half each; case 383, the right six, the left seven; and case 807, in which the kidneys weighed together eighteen ounces. In ten cases, viz: 396, 720, 727, 731, 733, 737, 744, 753, 806 and 812, the kidneys weighed from six ounces to nine and a half each, but their appearance is not recorded. In cases 272, 298, 308, 319, 441, 459, 519, 526, 541 and 757 the kidneys are spoken of as fatty. To the foregoing it may be added that in one of the cases of follicular ulceration, 697, and four of the undetermined cases, 688, 700, 704 and 705, the kidneys are said to have been "granular," and that in one of these, case 704, the urine is said to have been albuminous.

The microscopic appearances of the kidneys in many of the cases just enumerated is well described by Assistant Surgeon Harrison Allen, U. S. A., in his record of case 378:* "The kidneys were large; the right measured five inches by two and a half, and weighed seven ounces and a half; the left measured five inches by three, and weighed eight ounces; the cortical substance of both was pale but injected, the section appearing as if sprinkled with red pepper; the bases of the pyramids were of a very dark-purple color, the capsules readily elevated, the pelves highly injected."

A comparison of the preceding paragraphs with the remarks on the condition of the kidneys in the non-ulcerative and diphtheritic cases† would seem to indicate that the kidney complications under consideration were much more frequent in the chronic ulcerative cases than in the acute cases, or even in those chronic cases which were unattended with intestinal ulceration. It is to be regretted, however, that in so large a number of cases of each group the condition of the kidneys was either not examined or not recorded, and that in so many other cases the record is unsatisfactory, for this makes it impossible to express numerically the frequency of the accidents in question. I do not doubt, however, that, especially in those chronic cases in which the intestines are ulcerated, the lesions observed by Alonzo Clark and myself‡ would have been more frequently found had the kidneys been more critically investigated.

---

* See p. 522, *supra*. † *Supra*, pp. 317 and 460.

‡ ALONZO CLARK, see note to p. 500, *supra;* see also HENRY W. COOKE—*The diarrhœa of soldiers*, The Amer. Med. Times, VI, 1863, p. 102—who examined the same cases as Prof. CLARK at Bellevue hospital: "The kidneys in this disease have, without a single exception, been found diseased; a few very markedly so. Their color somewhat lighter than natural, the weight as a rule increased, the extremes being 3½ in the smallest and 6½ ounces in the largest, the vascularity not greatly changed. The longitudinal section revealing more or less disproportion between the secreting and tubular structures, the cut surface usually lighter in color than natural, and having a granular appearance. The microscope revealed uniformly a granular condition of the epithelium lining the tubuli uriniferi; which was readily detached, and occluding the tubules to a greater or less extent. In only one instance was there any excess of fibrous material demonstrable, the kidney weighing only three and a half ounces; in this, however, the excess was very slight. This condition of the kidney, as a rule, is indicated by the presence of casts in the urine previous to death. Albumen is not present." I myself had frequent opportunities to observe this condition of the kidneys in the course of autopsies in the Washington hospitals, or in specimens brought while fresh to the Army Medical Museum. In 1863 I wrote—WOODWARD, *Outlines of the Chief Camp Diseases*, &c., Philadelphia, 1863, p. 251: "The kidneys are very often more or less enlarged, flabby, the cortical portion encroaching on the pyramids, the epithelium of the tubuli uriniferi granular or even fatty." Compare the observations of TREITZ and ZIMMERMANN as to the condition of the kidneys in acute dysentery—see notes to p. 386, *supra*. I may add that the condition of the kidneys in dysentery has not generally received the attention it deserves. Many authors appear to think with PARKES—p. 48, *op. cit.*, *supra*, p. 551—that "what changes are seen are probably antecedent to the intestinal disease." FINGER—S. 134. *op. cit.*, *supra*, p. 552—saw the

Not including any of the foregoing cases, the kidneys are said to have been *congested* in six of the follicular and seven of the undetermined cases. In some of these they were doubtless in an early stage of the condition just described; in others the congestion was merely hypostatic. *Metastatic foci* probably existed in the kidneys more frequently than was observed. Among the cases of follicular ulceration, the deposits described as "tubercles" in the kidneys of case 201, and the depressed softened spot in the right kidney of case 368, "in which the parenchyma was undergoing some degenerative change," were, I suppose, probably of this nature. Among the undetermined cases, in case 290 there was an abscess near the middle of the right kidney; in case 356 both kidneys contained a number of "small, white, purulent deposits," and there was a larger abscess in the left kidney; in case 447 small abscesses were observed in both kidneys. I suppose the deposits interpreted as tubercles in the kidneys in case 469 to have been probably of the same nature. In case 703 *tubercles* are said to have been observed in the left kidney, and in case 722 in both kidneys; (in these cases tubercles existed in the lungs.) In case 370 there were two small cysts in the right kidney; in case 261 the kidneys were greatly enlarged and contained innumerable cysts. [These kidneys are preserved in the Museum, Nos. 27 to 29, Med. Sect.] In case 588 the kidneys were fused together at their inferior extremities—horse-shoe kidney. [The specimen is preserved in the Museum, No. 23, Med. Sect.]

The condition of the *urinary bladder* is very seldom mentioned. In case 447 its mucous membrane seemed thickened, which is the only abnormity recorded. In about two dozen cases the bladder is said to have been full of urine, but this was not generally tested for albumen. Only in cases 194 and 704 was albumen found in the urine. In the first of these cases the kidneys are said to have been "congested," in the second "granular." It is greatly to be regretted that the condition of the vesical mucous membrane was not more critically examined in these autopsies.* It is probable that the catarrhal inflammation of this mucous membrane, which often occurs in dysentery, is generally so slight that no recognizable lesions are found after death, but doubtless in many cases inflammatory changes would be found if they were sought by an instructed observer.†

---

lesions of Bright's disease in 8 of 231 subjects dead of dysentery; he appears to have regarded it as a mere coincidence of the two diseases. He also noticed in several instances a form of partial nephritis, manifested by the appearance in the cortical substance of the kidneys of little gray, yellowish, or purulent infiltrations about the size of millet seeds, S. 145. VOGT—S. 65, *op. cit., supra*, p. 560—states that he found that albuminous urine without dropsy not unfrequently occurred during the course of dysentery, and that in such cases mere hyperæmia of the organs was observed after death, without further degenerative changes; genuine Bright's disease occurs either as a sequel to dysentery, or as the primary disorder during the progress of which the dysentery is developed. LYONS—p. 53, *op. cit., supra*, p. 552—found tubercle "pretty often" in the kidneys; in one instance the organs appeared to be the seat of "granular, fatty degeneration;" in another, of suppurative perinephritis, p. 50. CORNUEL—*Mém. sur la dysent. observée a la Basse-Terre; (Guadeloupe,)* Mém. de l'Acad. Royale de Méd., T. VIII, 1840, p. 117—reports, in the varieties of dysentery which he calls "gangréneuse" and "muco-sanguinolente," that the kidneys were "red, dry, and contained in their pelves a very small quantity of a whitish, fatty liquid resembling pus much more than urine." This description is repeated by SAVIGNAC—p. 279, *op. cit., supra*, p. 552—as his account of the condition of the kidneys in dysentery, to which he adds that similar observations have been made by SIMONNOT. According to BARRALLIER—p. 765, *op. cit., supra*, p. 559—the kidneys may be congested, and of a marked red color, but most frequently present nothing abnormal. HEUBNER—S. 528, *op. cit., supra*, p. 559—more correctly says that venous hyperæmia of the kidneys is found, and that in chronic dysentery they are often the seat of parenchymatous inflammation; also that a suppurative catarrh is very commonly found in the pelves of the kidneys.

* See p. 461, *supra*.

† FINGER—S. 145, *op. cit., supra*, p. 552—in one case found the urinary bladder contracted, its mucous membrane in places of a dirty slate-gray, its muscular coat somewhat hypertrophied. JULIEN—p. 72, *op. cit., supra*, p. 559—examined the bladder in 54 instances: In 2 it was distended with urine; in 22 it contained a good deal of urine, but was not distended; in 12 there was but little urine in it; and in 6 it was completely empty. He observed, however, no noteworthy lesions of the mucous surface; in one instance it presented little injected elevations, (mamelons,) apparently due to irregular infiltrations of the submucosa; in another it presented little hard superficial cords, (de petits cordons,) and the superficial veins were varicose; in the other cases nothing anomalous was found. HEUBNER—S. 528, *op. cit., supra*, p. 529—does not even mention the condition of the bladder in his account of the lesions of dysentery. The plan of this work does not embrace a discussion of the lesions of the female genital organs occasionally observed in dysentery. A few words with regard to them may, however, be added to this note. MURSINNA—*Beob. über die Ruhr*, Berlin, 1787, S. 65—has related a case observed by him during the Herford epidemic, in which a severe dysentery occurring to a pregnant woman, miscarriage at the 7th month followed; subsequently a discharge from the vagina occurred, consisting of blood and mucus and resembling the dysenteric stools in odor and appearance; thereupon the discharge from the bowels ceased and the patient recovered. This was a fortunate termination of a class of cases described by ROKITANSKY—*Oest. Med. Jahrb.*, Bd. XX, 1839, S. 91, *op. cit.*, note †, p. 438, *supra*—who has strongly insisted upon the anatomical analogy between the dysenteric process in the intestine and the puerperal process in the uterus, and has pointed out that the two sometimes coexist in the same individual. VOGT—*Monographie der Ruhr*, Giessen, 1856, S. 65—declares that this observation has been confirmed in his own practice.

PATHOLOGICAL HISTOLOGY OF CHRONIC DYSENTERY.—The processes to be studied in this connection are chronic ulceration consecutive to acute diphtheritic dysentery; chronic non-ulcerative inflammation, including that variety which is accompanied by cyst-formation; follicular ulceration; and ulceration unconnected with the solitary follicles. With regard to the first of these processes nothing need be added to what has already been said when the histology of diphtheritic dysentery was under discussion;* each of the others will require some consideration in this place.

1. *Chronic non-ulcerative inflammation and cyst-formation.*—As to the usual forms of chronic inflammation little need be added to what has been said under the head of "histological changes in the inflamed intestine."† The lesions found in the subacute and chronic cases are very similar to each other. In a general way the pigment deposits become more abundant and the submucosa grows thicker the longer the case lasts, but these characteristics vary also with the intensity of the process as well as with its duration, so that it would be impossible to determine from the anatomical appearances what might have been the duration of the disease. It is also worthy of note that even in the most protracted cases the tissue infiltrated by the lymphoid swarm retains very nearly all the characteristics which it presented during the subacute stages. There seems to be little or no tendency toward the development of a fibrillated matrix between the new elements, a fact which explains why it is that the possibility of resolution and ultimate recovery always remains, even in those cases of chronic dysentery in which there has been ulceration or sloughing, except when too large an area of the mucous membrane has been destroyed. This fact is in marked contrast to what happens when the ulcers heal; in that case an abundant fibrillated matrix is speedily developed between the lymphoid elements of the granulation tissue and a characteristic cicatrix is the result.

It may also be repeated here that amyloid degeneration of the intestine is especially to be looked for in the chronic cases, but nothing need be added to the description of that condition already given.‡ So, too, the peculiar outgrowth of the glands of Lieberkühn into the solitary follicles of the colon, figured by Kelsch,§ has already been described in connection with the histology of the diphtheritic intestine, and it was then stated that in chronic catarrhal inflammation of the large intestine some degree of this process is very frequently present. It will be seen further on that conditions which indicate the previous occurrence of this lesion are frequently encountered in all those follicular ulcers in which the enlarged follicle has not been destroyed by ulceration before the examination is made. Nothing

* *Supra*, p. 461 *et seq.* † *Supra*, p. 325. ‡ *Supra*, p. 333 *et seq.*

§ KELSCH—*Critique et recherches histologiques sur l'anat. path. de la dysenterie*, (read March 15, 1873,) Mémoires de la Soc. de Biologie, 1873, p. 3, with a colored lithograph; also by the same—*Contributions à l'anat. path. de la dysenterie chronique*, Archives de Physiologie, T. V, 1873, pp. 406 and 573—three lithographic plates. According to him, the characteristic lesions in chronic dysenteric diarrhœa, that is, the chronic ulcerative catarrh described further on, are as follows: 1. The development between the glands of Lieberkühn of an embryonic tissue resembling granulations, which gradually takes the place of these glands. 2. The glands of Lieberkühn meanwhile become deformed, are pushed apart, often undergo cyst-like dilatation. 3. The development of a swarm of new elements in the submucosa, especially in that vascular part of it which is nearest the mucous layer and around the closed follicles. 4. The invasion of the tissue of the closed follicles by glandular culs-de-sac, the glands of Lieberkühn transformed by disease, which ultimately replace the proper tissue of the follicles. The plates which accompany the original memoir and the first paper in the Archives cited above illustrate these lesions. The plate accompanying the second paper in the Archives represents chronic dysentery. It shows the same processes, with the addition of losses of substance in the mucosa, and marked alterations in the lymphatics and bloodvessels. The lymphatics are enormously dilated, and contain a fibrinous reticulum, in which lymph cells and large swollen endothelial cells are entangled. Sometimes they are stuffed full of large nucleated cells 12 to 15 thousandths of a millimetre in diameter, (altered endothelium?) The bloodvessels show a tendency to return to the embryonic condition. Their walls are full of new elements resembling those in the submucosa. Their endothelial cells are swollen, and often detached in masses from the elastic tissue beneath. KELSCH suggested that perhaps these changes of the endothelium have some pathogenic relation to the hepatic abscess which so often accompanies chronic dysentery, p. 384, *op. cit.* I may add that the observations of KELSCH were to some extent anticipated by CORNIL—*Note sur l'anat. path. des ulcérations intestinales dans la dysenterie*, same Volume, p. 311; see also Comptes rendus de la Soc. de Biologie, T. V, 1873, p. 97—who has given four wood-cuts which very fairly represent the conditions in question as seen in a case of chronic dysentery. He recognized that the branching cystic forms in question occupied the sites of the closed follicles, and that they were lined by a columnar epithelium, but did not describe the mode in which they originate. Compare CORNIL et RANVIER—*Manuel d'Hist. Path.*, Part. III, Paris, 1876, p. 820.

need be added to the account already given of the nature of this curious affection, and of the usual appearances presented by the diseased follicles. It remains, however, to be explained that the remarkable form of cystic disease of the colon, described and figured in a previous part of this Section,* is in fact due to an extreme degree of this very process.

Figure 22 represents one of a series of cuts through one of the colon-cysts of case 900. The cyst was cut from a portion of No. 603, Medical Section, the specimen represented in the plate facing page 514. It was about one-twelfth of an inch in diameter, and lay in the thickened submucosa, pushing the mucous membrane upwards so as to form a convex elevation. In the mucous membrane covering this convex surface the glands of Lieberkühn lay obliquely, compressed against each other, and in some places quite flattened.

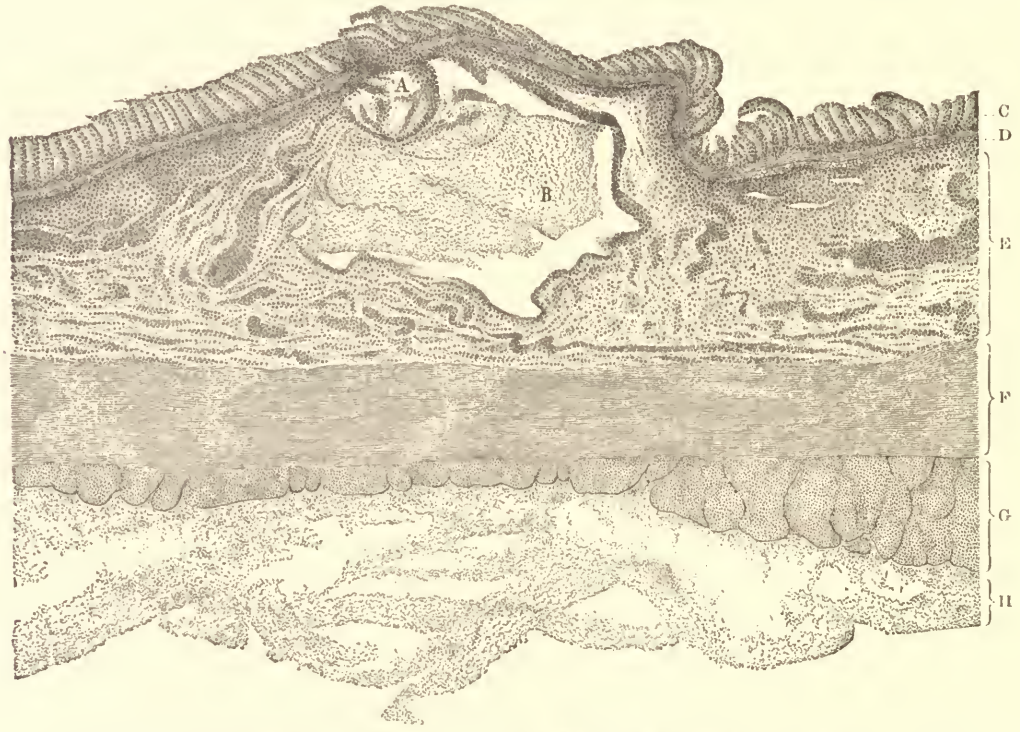

FIG. 22.—Perpendicular section through a cyst of the colon. Magnified 25 diameters by Beck's 3-inch. Copied from a photo-micrograph (Neg. 965, N. S.) of No. 7272, Microscopical Section. A, is the point at which the contents of the cyst become continuous with the lower portion of the glands of Lieberkühn. B. Glue-like mass filling the greater part of the cyst; the action of alcohol has caused it in many places to shrink away from the cyst-walls. C. Mucosa. D. Muscle of Brücke. E. Submucous connective tissue infiltrated, especially in the neighborhood of the muscle of Brücke and in the course of the venous radicles, with swarms of lymphoid cells. F. Circular muscular coat of the colon. G. Longitudinal muscular coat; on the right the edge of one of the ligamenta coli. H. Subperitoneal connective tissue.

At one point in this area the muscle of Brücke was absent, and the contents of the cyst became continuous with the lower portion of the tubular glands of Lieberkühn, (A.) The greater portion of the cyst was filled with a substance which, with a power of 200 diameters or upwards, appeared faintly granular, and had here and there imbedded in it lymphoid elements like those infiltrating the submucosa or the parenchyma cells of the closed follicles; but in the region surrounding the point at which the cyst-contents became continuous with the lower portion of the glands of Lieberkühn a very characteristic structure was presented. Here, instead of the substance just described, dilated and distorted gland tubules imbedded in a soft granular tissue, infiltrated with innumerable lymphoid cells, could readily be distinguished as the chief structural elements.

* Page 512 *et seq.*, *supra*.

Figure 23 represents the appearances of a small area, $\frac{1}{5}\frac{1}{0}$th of an inch in diameter, selected in this region. The columnar epithelium which lines these gland tubules is precisely like that of the follicles of Lieberkühn in form, but the individual cylindrical cells are about one-third larger than the elements of the glands of Lieberkühn in the mucous layer of the same piece; whence it appears that an increased size of the individual elements is a factor in the process of outgrowth which occurs in these cases. Sections cut from the colon in cases 173, 433 and 899 exhibit conditions very similar to those just described.*

Considerable variation exists with regard to the extent to which the distended gland tubules can be detected in the contents of the cysts. In some of the smaller cysts they are found in all parts of the mass; in the medium sized and larger ones they can be recognized only in the peripheral portion of the cyst-contents, and not always in all parts of this. An examination of the series of sections prepared from the four cases leaves no doubt in my mind that these cysts are formed precisely like the smaller ones described in connection with acute dysentery; in fact, in some of the sections various transition forms between the conditions already figured and such as are represented in Figs. 22 and 23† can be seen. I agree, therefore, with Virchow‡ when he declares the cysts of colitis cystica polyposa to result from cyst-like dilatation of the glands of Lieberkühn and the subsequent irregular coalescence of the smaller cysts thus produced, but I also agree with Cruveilhier,§ that the cysts have their seat in the solitary follicles. In catarrhal inflammation of the intestinal mucous membrane the softened parenchyma of the swollen solitary follicles offers a suitable nidus for the peculiar cyst-like development of the glands of Lieberkühn, which elsewhere is prevented from going beyond a very moderate degree by the resistance offered by the muscle of Brücke; and whether the cystic transformation of the hypertrophic gland tubules proceeds to a moderate or an extreme degree, the parenchyma of the solitary follicles is the site in which the cystic development occurs. The contents of the larger cysts, therefore, are partly the altered parenchyma of the solitary

FIG. 23.—View of part of the region marked A in the section represented in the last figure, showing dilated and distorted gland tubules lined by a columnar epithelium similar to that of the glands of Lieberkühn. Magnified 200 diameters by Powell & Lealand's ⅓ immersion. Copied from a photomicrograph, (Neg. 940, N. S.) The space between the gland tubules is filled with a granular tissue densely infiltrated with lymphoid cells. The delicate granular substance in the interior of the dilated tubules, in which lymphoid elements are less numerously scattered, closely resembles the substance described in the text as filling the greater part of the cyst.

* Some of these sections have been preserved in the Microscopical Section of the Museum, viz: From case 900, No. 603, Med. Sect., Nos. 7272–3, Mic. Sect; from case 899, No. 660, Med. Sect., Nos. 7274–5, Mic. Sect.; from case 433, No. 527, Med. Sect., Nos. 7270–1, Mic. Sect.; from case 173, No. 56, Med. Sect., Nos. 7216–18, Mic. Sect. † Compare Figs. 9 and 10, *supra*. ‡ See note ¶ to p. 514, *supra*. § See note ‖ to p. 514, *supra*.

follicles involved, partly the branches of the hypertrophic glands of Lieberkühn which have undergone the cystic change, but chiefly the modified mucous secretion which has accumulated in these cystic dilatations.

When such cysts rupture and discharge their contents, the cavities left closely resemble ordinary follicular ulcers. Such cavities are seen in several of the sections under consideration. When the section passes on either side of the centre of an unruptured cyst, it appears as if situated in the submucosa and entirely detached from the mucous membrane, while in a central cut the connection of the cyst-contents with the glandular layer can be plainly seen. Fig. 24 is an outline, traced from a photograph of one of the sections from

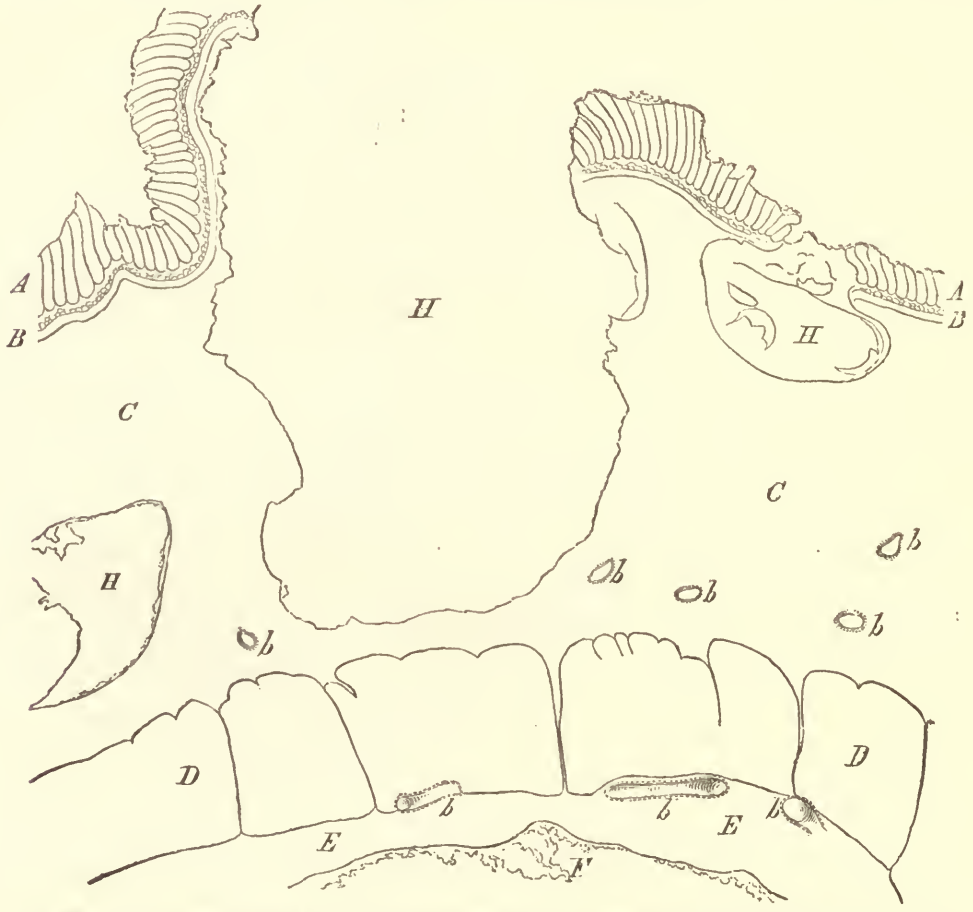

FIG. 24.—Outline of a perpendicular section through three cysts of the colon, traced from a photo-micrograph (Neg. 936, N. S.) of No. 7216, Microscopical Section, (colon of case 173.) Magnified 20 diameters. A. Mucosa. B. Muscle of Brücke. C. Submucosa; *b*, *b*, *b*, *b*, bloodvessels cut across. D. Circular muscle of the intestine. E. Longitudinal muscle. F. Subperitoneal connective tissue. H, H, H. The three cysts described in the text.

case 173, which shows all three of these conditions. The contents of the central cyst had escaped, while those on each side were filled; of these, that on the left hand appears as if deeply imbedded in the submucosa simply because the section passed on one side of the point at which it was connected with the glandular layer of the mucosa; the smaller one on the right hand shows this connection, because the section passes nearly through its centre.

2. *Follicular ulceration.*—The first step in the process of follicular ulceration is the enlargement of the solitary follicles by the accumulation of lymphoid elements in their parenchyma, which has already been described.* The extent to which this process goes on

* Page 326 *et seq.*, *supra*.

before ulceration begins varies in different cases. It has already been remarked* that in the small intestine the enlarged follicle often protrudes beyond the mucous surface as a pedunculated tumor or tiny polypus before ulceration occurs, while in the colon the follicle usually begins to ulcerate before any considerable enlargement has taken place. The latter rule, however, is not invariable, and occasionally the solitary follicles of the colon attain the size of bird-shot before they begin to ulcerate. The following description will be limited to follicular ulceration in the colon, for the process in the small intestine is so similar to the ulceration of the solitary follicles in certain cases of typhoid fever, that the reader may be referred to the account of that process to be presented in the chapter on fever.

The ulcerative process in the enlarged colon follicles begins in one of two ways: In the first case the central portion of the little tumor softens, the reticulum of its parenchyma becomes granular, loses its cohesion, liquefies, the lymphoid elements are set free as pus corpuscles, and a small abscess results, which ruptures at its apex, the drop of pus escaping upon the mucous surface, leaving a tiny cavity, which is the follicular ulcer. In the second, ulceration begins at the apex of the enlarged follicle by the formation and separation of a minute slough, or by the liquefaction of the reticulum and the floating away of the lymphoid elements as pus corpuscles; in this way it invades the follicle from the surface, with the same ultimate result as before. In either case the process continues until the whole follicle is ultimately destroyed. Meanwhile, however, a dense swarm of lymphoid elements has accumulated in the lymph sinuses which bound the follicle, and in the adjacent connective tissue. This infiltrated tissue is progressively invaded by the ulcerative process, the intervening tissue elements continually liquefying and the lymphoid elements floating off as pus corpuscles. In this manner the ulcer extends in the submucous connective tissue; its advance always preceded by a progressive infiltration of the lymph-spaces with lymphoid elements, which gives to its walls many of the characteristics of granulation tissue. At its margins an overhanging edge is formed by the undermined mucous membrane, which continually undergoes necrotic changes because its nutritive supply from beneath is cut off. By this double process the ulcer gradually becomes larger and larger, until, after a time, adjoining ulcers begin to coalesce, forming irregular excavations, which may ultimately attain considerable dimensions, but which, as a rule, preserve, throughout all stages of their progress, the overhanging edges that characterized them at first.

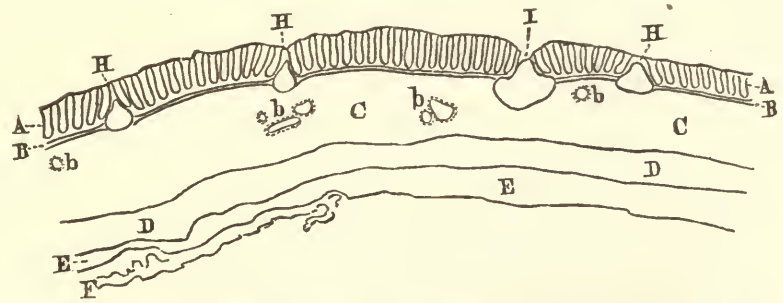

FIG. 25.—Diagram explanatory of the plate facing page 568. A. Mucous membrane. B. Muscle of Brücke. C. Submucous connective tissue; *b, b, b*, distended bloodvessels cut across. D. Circular, E. longitudinal, muscular coat; the latter, on the right, passes through one of the ligamenta coli. F. Subperitoneal connective tissue. H, H. Nearly normal solitary glands. I. Solitary gland enlarged and ulcerated at its apex.

The steel engraving facing page 568 is a copy of a photo-micrograph which represents a comparatively early stage of this process as seen with a magnifying power of 12 diameters. The section photographed, which has since spoiled, was cut from a boiled preparation, stained with yellow aniline, and mounted in gum and glycerine. It belonged to the same series of cuts as Nos. 653 to 658, Microscopical Section, and exhibited similar conditions.

* Page 306, *supra*.

The piece was taken from the colon of a soldier who died in Washington during 1864 of a chronic flux. Well marked follicular ulcers were found in some parts of the large intestine; in others the process appeared to be just beginning. No other particulars with regard to the history of the case were preserved. The portion of the section represented in the plate shows three nearly normal solitary follicles, and a fourth considerably enlarged, which is beginning to ulcerate at its apex. The submucous connective tissue is somewhat thickened, and contains an abundant swarm of lymphoid elements, especially in the vicinity of the muscle of Brücke. Its venous radicles are distended with coagulated blood.

A portion of another section from the same intestine, No. 658, Microscopical Section, is represented in the plate facing page 570, which is reproduced from a photo-micrograph, magnified 63 diameters by a Beck's $\frac{2}{3}$ objective. The design of this plate is to exhibit with a higher power the condition of the submucosa shown with a low power in the last plate. In the portion represented there is a considerable accumulation of new elements in the adenoid tissue of the mucosa, by which the glands of Lieberkühn are pushed preternaturally apart. Two nearly normal solitary follicles are also shown. The submucous connective tissue, increased to about .036 of an inch in thickness, is infiltrated by numerous lymphoid elements which become more and more abundant as the muscle of Brücke is approached; they appear in the plate as circular or oval dots. A number of small bloodvessels filled with coagulated blood are also seen, cut across at various degrees of obliquity.

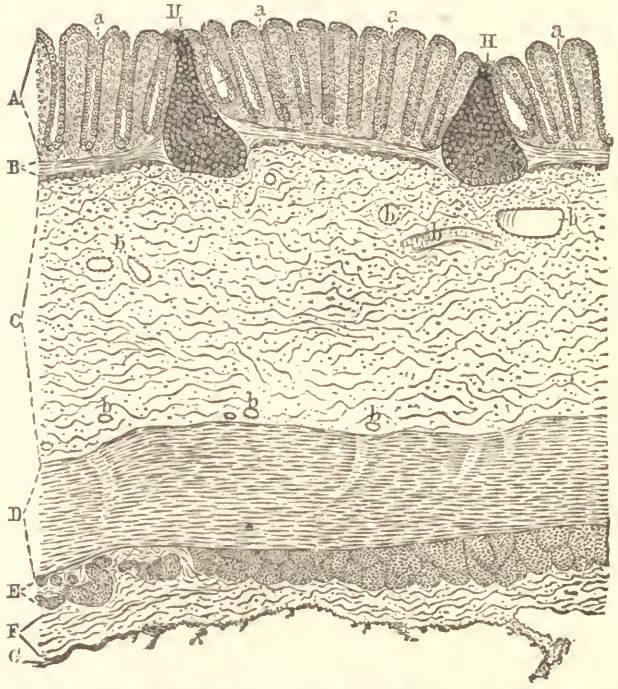

FIG. 26.—Diagram explanatory of the plate facing p. 570. A. Mucous membrane; *a*, *a*, *a*, *a*, glands of Lieberkühn. B. Muscle of Brücke. C. Submucous connective tissue infiltrated, especially near the muscle of Brücke, with lymphoid elements; *b*, *b*, *b*, *b*, bloodvessels cut across filled with coagula. D. Circular, E, longitudinal, coat of the intestine; in the latter, on the right, the cut passes through one of the ligamenta coli. F. Subperitoneal connective tissue. G. Peritoneal epithelium. H. H. Two solitary follicles.

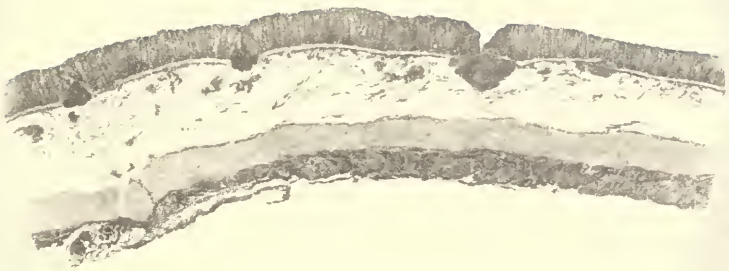
A somewhat similar condition of the submucous connective tissue is exhibited in the plate facing page 572, which also shows an enlarged solitary follicle in which ulceration has fairly commenced. This plate is reproduced from a photo-micrograph of No. 6102, Microscopical Section, magnified 70 diameters by a Beck's $\frac{2}{3}$ objective. The section is one of a series of cuts from the colon of an infant who died of catarrhal inflammation of the intestinal mucous membrane in September, 1873.* The tissue was first hardened by alcohol, and the sections having been stained with carmine were mounted in Canada balsam.

* The child was treated at the Columbia hospital dispensary, Washington, D. C., service of Dr. S. C. BUSEY, who has kindly furnished an account of the case, of which the following is an abstract: E. B———, a male mulatto child, aged 18 months, came to the dispensary Aug. 18, 1873. He was very much emaciated; pulse very feeble; had no teeth, but the lower incisors were advancing; anterior fontanelle enlarged and depressed. Weaning was commenced a week before, but from birth the child had been fed on corn starch, arrow-root, occasionally meat and milk, besides the nourishment derived from its mother, who was at service and could only nurse it twice a day. The child was said to have been plump and fat when first taken sick, which was three weeks previously. The disease began with nausea, vomiting, purging and fever. When first admitted the child had three or four watery, offensive, painful stools daily, and as many during the night; was very thirsty; had but little appetite, some nausea; rolled its head; skin very dry and shrivelled; abdomen retracted and tender. He did not improve under treatment, and died September 11th. One of the lower incisors protruded August 23d. Nos. 6111–16, Microscopical Section, are a series of perpendicular sections from the small intestine, and Nos. 6102–8 from the colon of this case. In the colon the closed follicles were enlarged and some of them ulcerated; those of the ileum were also enlarged but not ulcerated, and some infiltration of the submucosa with lymphoid elements was also observed in this portion of the intestine.



The submucous connective tissue in the portion of the colon represented in the plate had attained .025 of an inch in thickness, and exhibits the lymphoid swarm very much as it is shown in the last plate; it shows also a number of bloodvessels cut across. In the mucous membrane the glands of Lieberkühn are pushed apart by the accumulation of lymphoid elements in the adenoid tissue. But the most conspicuous feature of the plate is the representation of an enlarged and ulcerated solitary follicle near the middle of the upper portion of the piece; its base protrudes downward into the submucous connective tissue, while its apex and central portion have been destroyed by ulceration. The lymph sinuses, which flank its inferior margin, are nearly empty, but in the connective tissue just below, and on each side, there is a dense swarm of lymphoid elements. This follicle had not been invaded by the adjoining glands of Lieberkühn, and a number of the other ulcers seen in sections cut from the same colon were in a similar condition. In some of the other follicles, however, both in those that were not ulcerated and those that were, this remarkable lesion was conspicuously displayed.

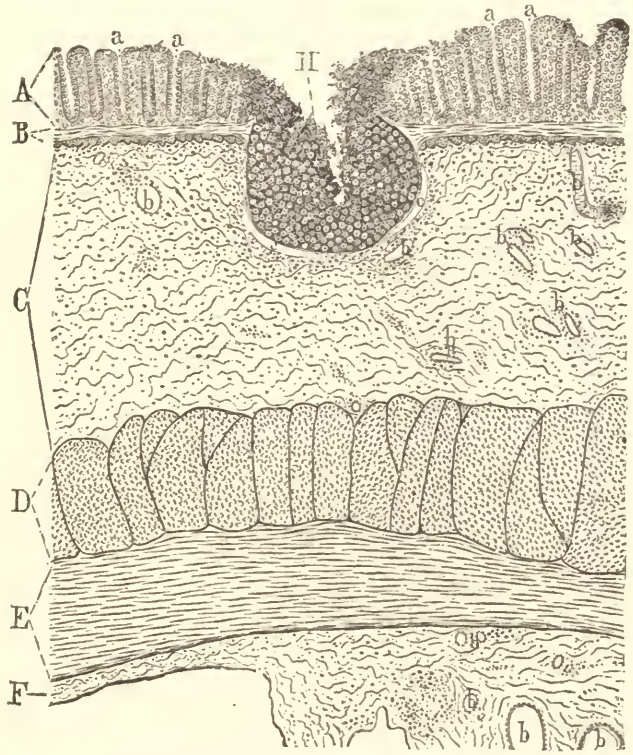


FIG. 27.—Diagram explanatory of the plate facing page 572. A. Mucous membrane; *a*, *a*, *a*, *a*, glands of Lieberkühn pushed apart by the lymphoid swarm in the adenoid tissue of the mucous membrane. B. Muscle of Brücke. C. Submucous connective tissue; *b*, *b*, *b*, *b*, bloodvessels cut across; *c*, *c*, lymph sinuses beneath the enlarged solitary follicle. D. Circular, E, longitudinal, muscular coat of the intestine; their arrangement shows the cut to have been a longitudinal one. F. Subperitoneal connective tissue, which, in the right of the plate, passes into the mesocolon; in the latter some bloodvessels, *b*, *b*, *b*, are seen cut across. H. Enlarged and ulcerated solitary gland.

The general characters of this invasion of the solitary follicles by the adjacent tubular glands and the microscopical appearances to which it gives rise when diphtheritic dysentery supervenes, or when, in certain rare cases, the resulting cystic forms coalesce so as to form compound cysts large enough to be recognized by the unaided eye, have already been described, and it has been shown that the whole process essentially belongs to chronic catarrhal inflammation.* We have now to consider the histological characters that may be observed after ulceration has attacked a solitary follicle which is already the seat of this peculiar morbid condition.

As mentioned, excellent illustrations of these appearances were presented by some of the follicles in the case just described. One of these, in which ulceration had not occurred, was represented in Fig. 9. Another, in which ulceration had already commenced, is shown in Fig. 28, on the next page, which is copied from a photo-micrograph of a part of No. 6105, Microscopical Section. In this instance, while the summit of the enlarged gland has been destroyed by ulceration the cystic forms are distinctly seen in the intact portions of the follicle. The neighboring glands of Lieberkühn are well pushed apart by the swarm of lymphoid elements in the adenoid tissue of the mucosa; in the submucous connective tissue these elements are most abundant in the vicinity of the muscle of Brücke and of the blood-

* See p. 465 *et seq.*, and p. 563 *et seq.*, *supra*.

vessels. In yet other solitary follicles in some of the same sections the ulceration has penetrated more deeply, in some of them destroying a considerable portion of the cystic forms, the remains of which can, however, be distinctly recognized at the bottoms of the ulcers.

These conditions can also be seen in many of the specimens of follicular ulceration of the colon collected during the civil war and preserved in the Museum. In perpendicular sections of such colons it will very often be found that the majority of the ulcers have quite destroyed all the textures belonging to the solitary follicles; but between these fully formed ulcers others will often be found in which more or less of the parenchyma of the follicle has as yet escaped destruction, and in this the distorted gland tubules and cystic forms we have been considering are often encountered.

Fig. 29, on the next page, represents a perpendicular section through such a follicle, seen with a power of 75 diameters by a Beck's ⅔ inch objective. The section was obtained from the colon of case 873.* The coats of this colon varied from one-tenth to one-eighth of an inch in thickness, of which the thickened submucosa constituted nearly one-half; the muscular coat was also greatly thickened, the thickening residing chiefly in its circular layer, and in part, no doubt, due merely to contraction, but in part to an infiltration of its connective-tissue trabeculæ with lymphoid elements. Numerous follicular ulcers were scattered over the mucous surface. Some of these were rounded or oval, punched-out ulcers, penetrating quite to the circular muscular layer, and varying from one-twentieth to one-tenth of an inch in transverse diameter; but the greater number of the ulcers were much smaller, and many of them presented the conditions shown in the figure. In these a portion of the parenchyma of the enlarged follicles was not yet destroyed, and in this portion gland tubules and cystic forms lined by a columnar epithelium, the remains of the branching glands of Lieberkühn, which in the earlier stages of the process had invaded the follicles, could be plainly made out. The thickened submucous connective tissue was infiltrated with innumerable lymphoid elements, which were so abundant in the immediate vicinity of the ulcerated solitary follicles as quite to obscure their peripheral limitation. In this border-territory minute hæmorrhages had occurred at some former period, for numerous yellowish-brown granular masses of hæmatin were observed between the cellular forms. In those parts of the submucous layer in

PERPENDICULAR SECTION OF COLON.

Showing commencing ulceration of the solitary glands, and inflammation of the submucous coat.
Magnified 63 Diameters.

PHOTO-MICROGRAPH BY ASSISTANT SURGEON J. J. WOODWARD, U.S.A.

From No. 658 MICROSCOPICAL SECTION.

which the lymphoid elements were least abundant the characteristic enlargement of the endothelial connective-tissue corpuscles into large granular cells* could be plainly seen, but in other portions of the layer these were quite obscured by the innumerable lymphoid elements. The glandular layer of the mucous membrane where least diseased was a good deal thickened in consequence of the infiltration of its adenoid tissue with lymphoid elements, besides which in many places its superficial portion was destroyed by ulceration, and this was particularly the case in the immediate vicinity of the follicular ulcers.

The invasion of the closed follicles by the adjacent glands of Lieberkühn, although exceedingly frequent, is, however, by no means an invariable concomitant of the process of enlargement which precedes their ulceration; and even when it occurs, the characteristic appearances are speedily quite destroyed by the ulcerative process, so that no traces of them are found in thin sections through the majority of fully formed follicular ulcers. The conditions then presented are illustrated on the next page by Fig. 30, which represents a perpendicular section through a small follicular ulcer as seen with a power of 26 diameters. The figure is copied from a photograph of a portion of No. 684, Microscopical Section, the whole of which, as seen with a power of 12 diameters, was represented in Circular No. 6 by a lithographic plate.† Nothing has been preserved with regard to the history of the case, except that it was one of chronic dysentery in which follicular ulceration of the colon was found after death.

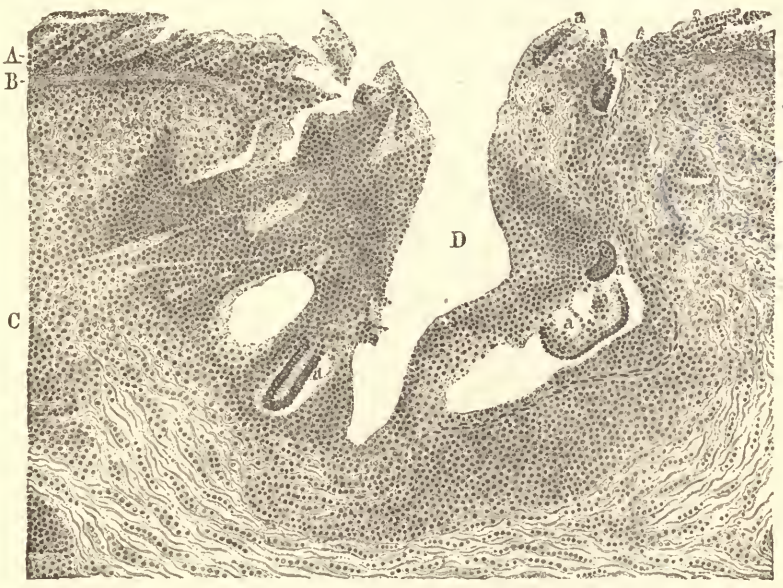

FIG. 29.—Perpendicular section through a follicular ulcer of the colon. Magnified 57 diameters. Copied from a photo-micrograph, (Neg. 964 of No. 7291, Microscopical Section, N. S.) A. Mucous membrane, its surface partly destroyed by ulceration. B. Muscle of Brücke. C. Submucous connective tissue much infiltrated with lymphoid elements. D. Cavity of follicular ulcer; *a, a, a, a*, gland tubules and cystic forms derived from the outgrowth of the glands of Lieberkühn. See p. 570.

It will be observed that the ulcer has penetrated to the circular muscular coat, the surface of which, however, is coated with a thin layer of granulation tissue. On the right, it has burrowed beneath the glandular layer of the mucous membrane which thus forms an overhanging edge; on the left, at the edge of the ulcer, the glandular layer is pulled down towards the muscular coat as though by the contraction of the granulation

* See p. 468, *supra*.

† *Circular No.* 6, Surgeon General's Office, November 1, 1865, p. 150. The preparation is one of a series, Nos. 683–5, Microscopical Section, cut from a boiled piece, stained with yellow aniline and mounted in glycerine in December, 1864. It is one of the few preparations mounted in glycerine about the same time which still show any details. At the date of printing this page, March, 1878, it is still in a tolerable condition. When I wrote the description of the plate in the Circular I still held to the opinion—previously expressed by me in my *Outlines of the Chief Camp Diseases of the United States Armies*, Philadelphia, 1863, p. 247, and in a paper *On the use of aniline in histological researches*, &c., The Amer. Jour. of the Med. Sci., Vol. XLIX, 1865, p. 106 *et seq.*—that the new elements which infiltrate the connective tissue in these cases are derived from the connective-tissue corpuscles by cell-multiplication. This opinion, formed under the influence of the writings of VIRCHOW—*Die Cellularpathologie*, 2te Aufl., Berlin, 1859, Vorlesungen 18 und 19, S. 358 *et seq.*—appeared to be justified by the manner in which the new elements are found in rows and groups, and by the occasional observation of nuclei and individual cells which seemed to be multiplying by division. These latter appearances were, however, by no means constant, and I often spent hours in the vain attempt to find places in which they were shown with sufficient distinctness to serve for photographic representation. I am now satisfied that I was sometimes misled, by the juxtaposition of a connective-tissue cell with one or more lymphoid elements, into the belief that I had actual cell-multiplication before me; but I am by no means convinced that this was always the case, or that no multiplication of the elements of these inflamed tissues ever occurs. But the groups and rows of cells which, in common with so many others, I regarded as abundant proof of cell-multiplication, I am now convinced are produced chiefly by the accumulation of the new elements in lymph spaces of various sizes and forms.

tissue. The submucous connective tissue is infiltrated with great numbers of lymphoid elements, which are most numerous near the edges of the ulcer, where they are so abundant that they appear to replace all the other elements.

The plate facing page 574 represents a section through one margin of a larger follicular ulcer as seen with a higher power. It is reproduced from a photo-micrograph of No. 705, Microscopical Section, (erroneously lettered No. 711 on the plate,) magnified 63 diameters by a Beck's $\frac{2}{3}$ inch objective. The specimen is one of a series of perpendicular sections (Nos. 703 to 710, Microscopical Section) of a portion of the colon of a soldier who died of chronic dysentery in Washington during 1864. They were cut from a boiled piece, stained with yellow aniline and mounted in gum and glycerine. On the left of the upper surface of the piece shown in the plate is a slightly enlarged solitary follicle, at the apex of which ulceration has just commenced. On the right, the section passes into a follicular ulcer with an overhanging margin, the opposite margin of which is not shown. From margin to margin this ulcer measured nearly one-fifth of an inch across. The adenoid tissue of the mucous membrane is infiltrated with great numbers of lymphoid elements by which the glands of Lieberkühn are pushed considerably apart. These glands show slight cystic distention in their inferior portions. The apices of some of them are concealed by the lymphoid swarm. Innumerable lymphoid elements are seen also in the submucous connective tissue; they are most abundant in the vicinity of the ulcer and in the portion of the submucous connective tissue nearest to the muscle of Brücke. In the latter situation they are so numerous that no definite arrangement can be discerned, while elsewhere they appear in groups, whose outline is determined by the form of the lymph spaces in which they are contained. Ulcers of this kind seldom extend beyond the deeper portions of the submucous connective tissue, and their bottoms are usually separated from the circular muscular coat by a thin layer of granulation tissue, consisting of lymphoid elements adhering together by a scanty granular matrix. Occasionally, however, the muscular coat of the bowel is invaded by the ulcer, which may then penetrate to almost any depth. I do not even doubt the possibility of actual perforation, though I have never seen an example except in those cases in which follicular ulceration is complicated by the diphtheritic process.

FIG. 30.—Perpendicular section through a portion of No. 684, Microscopical Section, showing a follicular ulcer of the colon; from a photo-micrograph, (Neg. 912, N. S.) The scale is in $\frac{1}{100}$ and $\frac{1}{1000}$ of an inch. See p. 571.

The minute changes which accompany the invasion of the muscular coat by follicular ulcers are so similar to those which occur during its invasion by spreading diphtheritic

From No. 6102. MICROSCOPICAL SECTION.

ulcers that the description given in connection with the latter* might be repeated here. So also the brief description already given of the process of *cicatrization* in the diphtheritic ulcer† will apply with but little modification to the follicular ulcer. The chief point of difference results from the presence of the overhanging edges in the latter case. During the healing process the granulations first fill up the excavations beneath these edges, and, as they contract, pull the edges down towards the muscular coat. The characteristic appearance of the edges is thus destroyed, and perpendicular sections cut through ulcers in this condition very closely resemble sections of diphtheritic ulcers in the same stage. The appearance and structure of the cicatrices of the large ulcers, which sometimes result from the coalescence and extension of the follicular ulcers, differ, therefore, in nothing from diphtheritic cicatrices. It is only when the cicatrices are numerous and of small size that their origin from follicular ulcers can be inferred, in the manner indicated above,‡ from their macroscopic appearances; in their minute structure they offer nothing characteristic.

Muscle of Brücke. C. Submucous connective tissue; *b*, *b*, *b*, distended bloodvessels cut across; *c*, lymph sinus. D. Circular, E, longitudinal, layers of the muscular coat of the intestine. F. Subperitoneal connective tissue. H. Cavity of a follicular ulcer. I. Solitary follicle at the apex of which ulceration has just commenced. See p. 572.

3. *Ulceration unconnected with the solitary follicles.*—The formation of these ulcers is preceded by an accumulation of lymphoid elements in the adenoid tissue of the mucous membrane, by which the superficial portions of the glands of Lieberkühn are finally entirely obscured. The columnar epithelium of the mucous membrane then separates and leaves an abraded surface composed almost wholly of lymphoid elements, and resembling in its appearance the surface of a granulating wound. By more or less rapid molecular changes, commencing at the surface, the reticulum of the adenoid tissue then liquefies and the lymphoid elements float off free as pus corpuscles. The glands of Lieberkühn appear sometimes to be destroyed, like the reticulum, by molecular changes; sometimes to separate as tiny sloughs, but they are usually so obscured by the dense lymphoid swarm that it is difficult to make out the details of their fate. Ulcers of this kind may frequently be observed which have destroyed only the superficial portions of the mucous membrane, and the bases of the glands of Lieberkühn can still be distinguished beneath the ulcerated surface. In other instances the ulcer invades the submucous connective tissue, and may even penetrate to the muscular coat or deeper. In all cases its margins are surrounded by a dense swarm of lymphoid elements, and the ulcer enlarges either by the liquefaction of the tissue infiltrated by them, which permits them to float off free as pus corpuscles, or this process is accelerated by the separation from time to time of larger fragments of the infiltrated tissue as little sloughs.

* *Supra*, p. 481. † *Supra*, p. 482. ‡ Page 519, *supra*.

When the non-follicular ulcers are small, and no indications of the diphtheritic process can be detected in other parts of the colon, it is comparatively easy to determine their nature; but when they attain considerable size, it is not always possible to discriminate. Nor can large and deep ulcers, which have originated in this manner, always be distinguished from follicular ulcers which have spread into large erosions, so that in certain cases of intestinal ulceration it is not possible to determine by an examination of the specimen in which of the three ways the ulcers have arisen. Simple non-follicular ulcers usually occur in connection with ulceration of the follicles. They appear as superficial or deeper erosions of the mucous membrane between the follicular ulcers, and are of various dimensions from mere points to areas which rival diphtheritic ulcers in extent. Occasionally they occur also in cases in which the follicles themselves are not ulcerated.

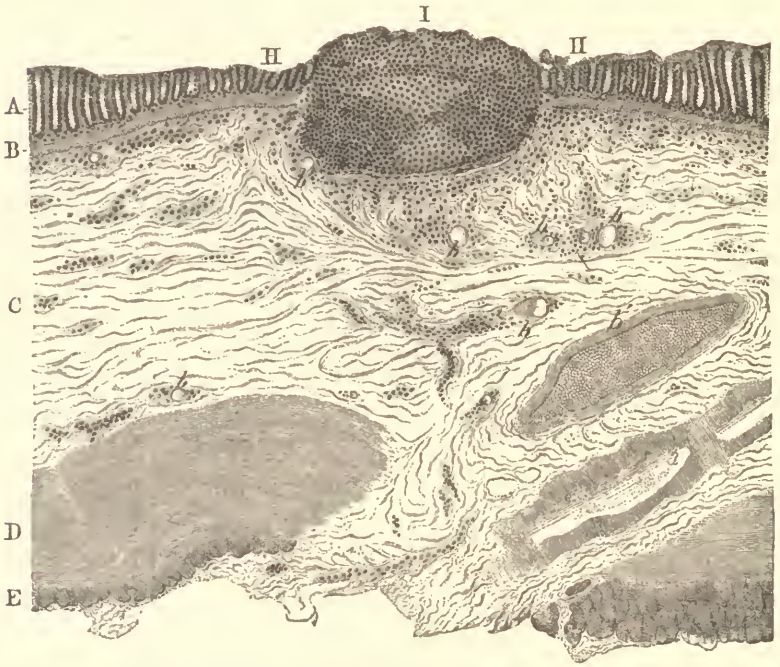

FIG. 32.—Perpendicular section of the colon from case 310, showing a small superficial ulcer H, H, in the centre of which an intact solitary follicle, I, protrudes as a minute nipple-like elevation. Half-diagrammatic drawing from a photograph (Neg. 563, N. S.) of No. 666, Microscopical Section. Magnified 48 diameters. A. Mucous membrane. B. Muscle of Brücke. C. Submucous connective tissue; *b*, *b*, *b*, small veins cut across. D. Circular, E, longitudinal, muscular coats of the intestine; these are divided by the entrance of an artery, *a*, from the mesocolon, which is accompanied by a vein of considerable size and surrounded with connective tissue.

A curious example of this occurrence is afforded by the colon in case 310,* in which the follicles themselves had not been destroyed by the ulcerative process, although each was surrounded by a minute superficial ulcer. Figure 32 is a half-diagrammatic drawing from a photograph of a perpendicular cut through one of these ulcers, No. 666, Microscopical Section. An enlarged solitary follicle, I, is seen intact near the centre of its upper surface; on each side of this there is a limited erosion, H, H, which has destroyed about one-half the thickness of the mucous membrane. A swarm of lymphoid elements is seen in the submucous connective tissue just below the muscle of Brücke, around the enlarged solitary follicle, and around the smaller veins. The colon in this case contained a great number of ulcers resembling that here figured. When seen from above each resembled a tiny circular superficial excavation, in the centre of which the enlarged solitary gland protruded as a tiny nipple-like elevation.

The histological details of the process of cicatrization in the non-follicular ulcers differ in no important particulars from what occurs in the erosions produced by the separation of diphtheritic sloughs, so that nothing need be added here to what has already been said in connection with the histology of diphtheritic dysentery.†

* See pp. 151 and 516, *supra*. No. 405, Medical Section, is a portion of the descending colon in this case, which was one of subacute flux accompanied by subcutaneous abscesses and erysipelas; death occurred 2½ months after the commencement of the disease. Nos. 659–67, Microscopical Section, are a series of cuts of this colon, from a boiled piece, stained with yellow aniline and mounted in gum and glycerine.

4. Diarrhœa connected with tubercular ulceration of the intestines.

This group of cases, as already explained,* was established for anatomical reasons, the clinical phenomena being, in the present state of our knowledge, inadequate to do more than indicate the probable existence of the lesions in question. Tubercular disease of the intestines may occur as one of the lesions of general acute miliary tuberculosis, in which event the patient often perishes before the stage of ulceration is reached. It also occurs in connection with extensive tubercular disease of the abdominal organs manifested as tubercular peritonitis, associated with tubercular disease of the retro-peritoneal and mesenteric glands and of one or more of the great abdominal viscera, occurring in individuals whose lungs are not primarily affected, or even remain quite healthy until the fatal issue; these cases are characterized by the symptoms of chronic peritonitis for the most part complicated with ascites; after a time obstinate diarrhœa sets in, and on dissection, besides the lesions of intestinal catarrh, tubercular ulceration of the intestines is often found. But by far the most frequent form of tubercular disease of the intestines, and the only one that will be discussed in this place, occurs in the advanced stages of tubercular consumption of the lungs and frequently gives rise to extensive intestinal ulceration.

That obstinate diarrhœa often sets in during the later stages of lung phthisis and exercises no slight influence in producing the exhaustion of the patient and the fatal issue, was long known to physicians;† but even after lung tubercles began to be observed in dissections of subjects dead of phthisis‡ the intestinal flux continued to be attributed to a

---

* *Supra*, p. 265.

† Thus Hippocrates—*Aph. V*, 14, [Ed. Littré, T. IV, p. 537,]—declares that diarrhœa supervening in a patient laboring under phthisis is a mortal symptom.

‡ Otto Heurnius—*Hist. et obs. quædam rariores ex praxi et diario*, Hist. 21: appended to Fernelii *Universa Medicina*, Geneva, 1679—appears to have been the first to observe on dissection an unquestionable example of what we now call miliary tubercles. He relates that on the 7th of January, 1639, he dissected the body of a Scotchman, aged 28, dead of tabes, the whole parenchyma of whose lungs was filled with minute tubercles: "Deprehendimus tabificam mortis causam in pulmone resedisse, quippe totum parenchyma minutis tuberculis ex cruda viscosa materia oppletum erat." Sylvius—*Praxeos Med.*, Lib. I, Cap. 24, p. 229, and *Appendix, Tract.* IV, *De Phthisi*, p. 689, in Opera, Amsterdam, 1679, (Lib. I of the Prax. Med. first appeared in 1667, and the appendix, containing Tract IV, posthumously in 1674)—appears to have been the first to frame a theory of lung phthisis that included as one of its forms the development of smaller or larger tubercles in the lungs, which by central softening produce vomicæ. He based this opinion upon his own dissections, and regarded the hereditary disposition to phthisis as due to these tubercles: "Ut proinde, quid mihi observare contigerit, proferam, et quid mihi proinde vomica sit, candide communicem. Vidi non semel glandulosa in pulmonibus tubercula minora vel majora, in quibus aliquando pus varium contineri, sectio manifestavit. Hæc proinde tubercula sensim in pus abeuntia, et membrana sua tenui conclusa pro vomicis habenda existimo, ab illis saltem non infrequenter phthisin ortum habere deprehendi. Quinimo in hisce tuberculis, si in re ulla alia sensibus externis patente, dispositionem illam ad phthisin familiis certis hæreditariam, lethalemque constituere non verebor: solent enim illa tubercula cum ætate augeri, atque sensim ad suppurationem pergere," Tract. IV, Appendix, § 51 and 52, p. 692, Opera, Ed. cited *supra*. It would require too much space to discuss here the older views with regard to lung phthisis. Let it suffice that it has been shown with great probability by Virchow—*Phymatie, Tuberculose und Granulie, Eine historisch-kritische Untersuchung*, Virchow's Archiv, Bd. XXXIV, 1865, S. 18 *et seq.*—that the word φῦμα, applied by Hippocrates to certain morbid conditions of various organs, and translated in the oldest Latin versions by the word tuberculum, was really intended to signify for the most part merely an abscess of no inconsiderable size. Waldenburg—*Die Tuberculose*, &c., Berlin, 1869—in his admirable summary of the historical development of the doctrine of tubercle, has taken a very similar view, S. 6 *et seq.* The Latin word tuberculum, as used by Celsus in various passages, signifies merely a circumscribed outgrowth or swelling of moderate size. (Virchow, *loc. cit.*, p. 19.) It was applied to normal processes of the bones, to exostoses, condylomata, sebaceous cysts, furuncles and tumors of various kinds. In Lib. V, Cap. 28, § 9, Celsus describes the φῦμα of the Greeks as a kind of tubercle, similar to a furuncle but rounder, flatter and often larger; Virchow thinks he intended to indicate abscesses of the lymphatic glands. Even the striking passage in the Hippocratic treatise *De Articulis*, [Ed. Littré, IV, pp. 179–80,] in which it is declared that hard and crude phymata sometimes develop in the lungs of those who have gibbous spines, is interpreted by Virchow (p. 33) in accordance with the views already explained. The words used in the Latin version of this passage, "tuberculis duris et crudis ad pulmonem obortis," [Ed. Kühn, III, p. 189,] are so similar to the modern expression hard and crude tubercles, that they have naturally been supposed to be identical in meaning as well as in sound. If, however, the view of Virchow is correct, the crude phyma of Hippocrates would be simply an abscess in which suppuration had not yet occurred, and the same explanation must be assigned to the "eruda tubercula" spoken of by various writers as late as the beginning of the seventeenth century. Compare, for example, the observation "de tuberculo pulmonis" by Zacutus Lusitanus—*De Praxi Med. Admir.*, (1634.) Lib. I, Obs. 112, in Opera, Lyons, 1649, T. II—who shows himself fully in accord with the Hippocratic view; or the still clearer exposition of Sennertus—*Pract. Med.*, Lib. II, Pars. 2, Cap. 8, Opera, Paris, 1641, T. II, p. 436—"*De tuberculis pulmonis.* Præter inflammationem pulmonis, de qua supra dictum, quæ fit ex materia in pulmonis substantiam imbibita, et in totum viscus dispersa, etiam tubercula in pulmone generantur ex materia collecta in una parte, et inde extuberante. de quibus agit Hippocrates *lib. I. de morb.* et hoc loco agendum videtur. Sunt autem illa tubercula alia cruda, quorum c. 4. etiam mentio facta est, quæ ex materia, quæ nunquam suppuratur, generantur, quorum meminit Hippocrat. *lib.* 3. *de artic. text.* 9. et Galenus, *in comment. et* 4. *de loc. affect. cap. ultim.* in historia Antipatri, et 6. *aphor.* 45. quæ nunquam ad suppurationem deducta et nulla febre comitante sola magnitudine, cum admodum adaucta est, exclusis in totum spiritus viis ægrum interimunt: alia quæ suppurantur, de quibus præcipue, *allegato modo loco* Hippocrates agit." Compare Cap. 12, "*De ulceribus pulmonum, et phthisi*," in which he derives phthisis from ulceration of the lungs, quite after the doctrine of the ancients, and adds, with regard to the diarrhœa of the later stages: "Supervenit denique his omnibus diarrhœa ex retentricis ventriculi et intestinorum imbecillitate, imo et humorum corruptione," p. 442, D.

general colliquation of the tissues, or to a debility of the intestines, rather than to any organic intestinal lesion.* It is true that the intestines were sometimes found diseased in those dead of phthisis, and even tubercles of the intestine were observed in a few rare cases,† but no great attention appears to have been directed to these lesions prior to the commencement of the present century.‡

The first to give a clear description of the intestinal lesion in these cases was Bayle,§ who found ulceration of the intestine in 67 out of 100 dissections of subjects dead of phthisis. In most of these cases the ulceration was the consequence of a prior formation of intestinal tubercles, and in accordance with the views he entertained with regard to lung tubercle, he discriminated in the case of intestinal tubercles between the semitransparent miliary granulations and ordinary miliary tubercles. After this, observations with regard to tubercles and tubercular ulceration of the intestine multiplied. Without attempting to enumerate them I may refer particularly to the accounts of this lesion by Laennec, Andral, Louis, J. Wagner, Rokitansky, Foerster, Lebert, Klebs, Rindfleisch, Ernst Wagner and Hering.‖ I cannot pause to analyze these observations, but pass on at once to an account of the conditions under consideration as observed during the civil war.

---

* See, for example, the treatise of RICHARD MORTON—*Phthisiologia, seu Exercitationes de Phthisi*, London, 1689—who asserts that he had often seen in phthisis hard little tumors (tubercula) seated in the glandulous parts of the lungs, side by side with abscesses and ulcers of other parts of those organs, ("quæ tubercula, sive crudos, et glanduloses tumores, sæpo in phthisicorum cadaveribus deprehendi, cum ceteræ pulmonum partes apostematibus et exulcerationibus essent obsitæ," Lib. II, Cap. 2, p. 73,) and naming this species of the disease scrofulous phthisis. (Lib III, Cap. I, p. 213.) affirmed it to be the most frequent form of the disorder encountered in practice, yet regarded the diarrhœa of the latter stages of consumption simply as the result of colliquation (Lib. II, Cap. 4, p. 119) without appearing to suspect the existence of intestinal tubercles.

† Compare, among the cases of phthisis collected by BONETUS—*Sepulchretum*, Lib. II, Sect. 7—Obs. 63, in which "intestinorum corpus vitiatum erat," and Obs. 103, in which "intestina etiam aliqua ex parte corrupta." The earliest unmistakable case of intestinal tubercles that has been brought to my notice is Obs. 48 of the additamenta which MANGETUS appended to this section of the *Sepulchretum* in the Geneva edition of 1700, T. I, p. 808. This is the case of a young man, aged 17, who died after an illness of about three months, during which loss of strength and appetite, emaciation, cough and obstinate diarrhœa were the prominent symptoms. On the autopsy, July 12, 1690, the lungs were found full of little, whitish, hard bodies about the size of millet seeds: "Tota illorum superficies ante et retro atque intra lobornm majorum interstitia conspersa erat corpusculis albis, duriusculis, magnitudine seminis milii, papaveris albi, quædam magnitudine sem. canabis, densissime junctis, vix remanente spatiolo de pulmonum ab illis immuni." These bodies he calls "grandines," *(i. e.*, hail-stones,) a word long previously applied to certain bodies expectorated in phthisis. Besides other lesions, similar "grandines" were found in the liver, spleen, kidneys, mesenteric glands and intestines, in which latter "conspiciebantur glandulæ hinc indo grandinosæ, imprimis solitariæ in colo prope cœcum; ex quibus compressione prodiit humor turbidus, albicans."

‡ For example, PORTAL—*Obs. sur la Nature et le Traitement de la Phthisie Pulmonaire*, Paris, 1809, T. II—who was well acquainted with the existence of tubercles in many other organs than the lungs. Art. IV, p. 303. Note 1, makes no mention of their occurrence in the intestines in his account of the lesions of those dead of phthisis, and explains the diarrhœa of the later stages of that disease by the old doctrine of colliquation, Art. 1, p. 249, regarding it as due to the same cause as the colliquative sweats and the œdema of the lower extremities so often observed.

§ G. L. BAYLE—*Rech. sur la Phthisie Pulmonaire*, Paris, 1810, p. 59: "Sur les 100 phthisiques morts en l'an XII, 33 avoient le conduit alimentaire tout à fait sain. 67 présentoient des ulcérations dans le canal intestinal. Chez quelques-uns des malades dont les intestins sont ulcérés, l'ulcération intestinale est le résultat des granulations miliaires transparentes; mais pour l'ordinaire, ce sont les tubercules miliaires qui déterminent cette affection." The student of the history of tubercle, in which the observations of BAYLE constitute a noteworthy epoch, should consult also his original articles in Corvisart's Jour. de Méd., etc., viz: *Remarques sur les tubercules*, T. VI, an XI, (1803,) p. 3; *Remarques sur l'induration blanche des organes*, T. IX, an XIII, (1805,) p. 285; *Remarques sur la dégénérescence tuberculeuse non enkystée du tissu des organes*, id., 427. In this article his first account of tubercular intestinal ulcers will be found under the head of "Dégénérescence tuberculeuse du tissu des membranes muqueuses." He states that these degenerations affect chiefly the mucous membrane of the larynx and intestine; in the latter case the ileum, cæcum and colon; so commonly does this lesion of the intestines accompany tubercles of the lungs that if it is found in any cadaver it is safe to affirm the lungs will also be found to be tubercular. These ulcers begin as whitish or reddish circular swellings, 3 to 6 lines in diameter, and half a line to a line in thickness; a central point of ulceration then forms in the swelling, which subsequently spreads; the tubercular nature of these ulcers can be recognized from the characters of their edges. Three-fifths of those who die of phthisis have this affection of the intestine, which appears to be the usual cause of the colliquative diarrhœa observed in the last stages of phthisis. The last article of this series is entitled *Suite des remarques sur la dégénérescence tuberculeuse non enkystée du tissu des organes*, T. X, an XIII, p. 32.

‖ LAENNEC—*Traité de l'Auscultation Médiate*, etc., (1819;) I cite 3me Édit., Paris, 1831, T. II, p. 6 *et seq.*—according to whom the semitransparent miliary granulations of BAYLE are simply the first stage of the tubercles which become converted into the yellowish "crude tubercles" by a process of change that begins in their centres. For his description of tubercular ulceration of the intestine see p. 33 *et seq.* ANDRAL—*Clinique Médicale*, (1824:) I cite 3me Éd., Paris, 1834. T. IV, p. 391 *et seq.* LOUIS—*Rech. Anat., etc., sur la phthisie.* (1825;) I cite 2me Éd., Paris, 1843, p. 84 *et seq.* He describes the tubercular intestinal ulcers as round when small, elliptical when larger. The elliptical ulcers are most frequent; next in frequency comes the annular form, (p. 89.) In the small intestine both the latter and the elliptical ulcers have their long diameter parallel to the direction of the valvulæ conniventes, (p. 94.) JOHANN WAGNER—*Die tuberculösen Darmgeschwüre*, Oesterreich. Med. Jahrb., N. F., Bd. I, 1829, Heft 2, S. 82. A noteworthy essay, in which the appearances of tubercular ulcers that have commenced to heal are described, although the author admits that he has never seen an example of complete cicatrization, p. 93. C. ROKITANSKY—*Ueber Strictnren des Darmkanals*, etc., same Journal, Bd. XVIII. 1839, S. 30 *et seq.*—relates two cases of intestinal stricture resulting from the partial cicatrization of tubercular ulcers. For the classical description of intestinal tubercle by this author, see the several editions of his text-book on Pathological Anatomy, cited p. 438, *supra*. AUG. FOERSTER—*Handb. der spec. path. Anat.*, Leipsic, 1854, S. 61; also 7te Aufl., Jena, 1864, S. 227. H. LEBERT—*Traité d'Anat. Path.*, T. I, Paris, 1857, p. 681. E. KLEBS—*Handb. der path. Anat.*, Bd. I, Abth. 1, Berlin, 1869, S. 256. E. WAGNER—*Das Lymphadenom des Darmcanals;* in *Das tuberkelähnliche Lymphadenom.*, Archiv der Heilk., Jahrg. XII, 1871, S. 6. E. RINDFLEISCH—*Lehrb. der Path. Gewebelehre*, 3te Aufl., Leipsic, 1871, S. 329; also Amer. Transl., Philada., 1872, p. 335. THEODOR HERING—*Stud. über die Tuberkulose*, Berlin, 1873, S. 72, Tuberkulose des Darmkanals.

And first I would point out that, even in ordinary lung phthisis in civil life, every obstinate diarrhœa that occurs during the course of the disease is not to be regarded as due to tubercles of the intestine. On the one hand, it is now very generally acknowledged that all cases of lung phthisis are not tubercular; we have learned to recognize, anatomically at least, forms of phthisis arising from various chronic inflammatory processes in the lungs, which, although often associated with the formation of tubercles, may occur quite independently of them.* In such cases simple intestinal catarrh accompanied by diarrhœa often originates during the advanced stages of the disease.† But intestinal catarrhs of the very same character may also arise during the progress of unmistakable cases of tubercular lung phthisis, and probably in many instances precede the formation of the intestinal tubercles. On the other hand, it is well established that marked tubercular disease of the intestine, and even characteristic tubercular ulceration, may be found after death in cases in which no diarrhœa existed during life.‡ These facts would seem to indicate that the cause of the diarrhœa which occurs during phthisis is to be sought rather in the coexisting intestinal catarrh than in the tubercular disease *per se*.

During the civil war individuals in whom tubercular disease of the lungs, or some one of the various forms of lung phthisis, had actually commenced, were found in great numbers in the military service of the United States. The predisposition to phthisis is so common in this country both among natives and European emigrants, and the exposures of army life in our climate are so favorable to the development of this disease in the predisposed, that in spite of the comparatively severe and careful medical examination of recruits for the regular army, phthisis was always a notable cause of death and discharge for disability among our troops. But after the civil war began the medical examination of recruits was notoriously insufficient and often entirely neglected, so that those predisposed to phthisis or actually suffering with the early stages of this disease found their way into the ranks almost without restraint. Moreover, the unusual exposures and hardships of active campaigning, the exhaustion of fatigue, the nutritive disturbances resulting from insufficient and badly cooked food, and the various inflammatory affections of the respiratory organs produced by exposure to the inclemency of the weather, served as so many exciting causes to determine the development of phthisis among the predisposed, and undoubtedly produced it in many who were apparently healthy when enlisted.

These phthisical patients were exposed simultaneously with their fellow soldiers to all the causes that produce diarrhœa and dysentery; and so far from being protected by any such antagonism between dysentery and tuberculosis as Rokitansky § supposed to exist, these feeble individuals seemed to possess even less resisting power than their comrades with healthy lungs. Accordingly we have already seen || that tubercular disease of the lungs was noted in nearly one-sixth of all the autopsies of fatal cases of the forms of

* On this subject the reader may consult NIEMEYER—*Lehrb. der spec. Path. u. Ther.*, 7te Aufl., Berlin, 1868, Bd. I, Abschnitt 3, Cap. XI u. XIII, S. 220 u. 234, on chronic interstitial pneumonia and pulmonary consumption; BUHL—*Lungenentzündung, Tuberkulose und Schwindsucht*, 2te Aufl., 1873, or Amer. Transl., New York, 1874; JUERGENSEN—Articles on *Croupous and Catarrhal Pneumonia*, in Ziemssen's Cyclopædia, Amer. Ed., Vol. V, New York, 1875, pp. 49 and 199; and RIEGEL—Article on *Croupous Bronchitis*, same work, Vol. IV, New York, 1876, p. 449. Any one who will compare these works, even without going further, will be struck with the great differences of opinion which exist on these subjects; differences which it is impossible to discuss in this place. For agreeable summaries of some of the conflicting views as to the relation of tubercles to these inflammatory processes, see A. W. FOOT—*Tuberculosis*, The Dublin Jour. of Med. Sci., July, 1877, p. 1, and Aug., 1877, p. 101; and D. J. HAMILTON—*On tubercle in the human lung*—Edinburgh Med. Jour., Oct., 1877, p. 289.

† In such cases also, according to COLBERG—S. 481. *op. cit.*, note ‡ to p. 335, *supra*—amyloid ulcers of the intestine are frequently encountered.

‡ See, for example, RUEHLE—*Pulmonary Consumption*, in Ziemssen's Cycl., Vol. V, New York, 1875, p. 555. "On the other hand, post-mortem lesions of considerable extent are sometimes found in the intestine, without there having been any diarrhœa during life. Solid, globular, normally colored fæces may often be found in these cases within the cœcum adherent to the ulcerating surface."

§ See p. 535, *supra*. || *Supra*, p. 535.

flux heretofore described. The fact that this complication was more commonly noted in the chronic cases would seem to render it probable that a protracted intestinal flux favors the development of lung phthisis in the predisposed; but even in many of these chronic cases the lung trouble was undoubtedly the older affection of the two, and this was probably also the relation of the two diseases in the majority of the fatal cases of acute diarrhœa and dysentery in which lung phthisis was found after death. In the larger number of the cases referred to, notwithstanding the lung complication, the intestinal lesions offered no peculiarities. Dissection disclosed simple catarrhal inflammation of the intestinal mucous membrane, with or without thickening of the submucosa and follicular ulceration in the chronic cases; or acute diphtheritic dysentery, which in the chronic cases was recognizable by the great unhealed ulcers resulting from the separation of the diphtheritic sloughs. But besides such conditions, which have already been sufficiently considered, there was another group of cases, differing from the former in no noteworthy particulars during life, while after death tubercular ulcers of the intestine were found, variously combined with the lesions characteristic of the other forms of flux.

Even in the less complicated cases that occur in civil practice there are no positive symptoms by which it can be determined during life whether the diarrhœa of the later stages of phthisis is the result of a simple catarrhal process or is accompanied by tubercular disease of the intestine. It has been shown that in the latter class of cases, consumption of the bowels as they are often called, the diarrhœa is obstinate; is prone to recur if temporarily checked; that the stools are not excessively frequent, varying usually from two to six daily; that they are often painless; that they frequently contain admixtures of mucus, blood and pus, and are often deficient in biliary coloring matter;* but all these phenomena belong to ordinary cases of chronic intestinal catarrh and offer nothing peculiar. The meteorism, abdominal tenderness, ascites and other symptoms that appear after tubercular peritonitis has set in differ in nothing from those which accompany the non-tubercular peritonitis sometimes developed in chronic ulcerative catarrhs. If the practitioner, observing these symptoms during the advanced stages of phthisis, should be led by that circumstance to express the opinion that tubercular disease of the intestines exists, his conjecture will undoubtedly sometimes be verified; but even in civil practice it will also be frequently contradicted by the appearances found on dissection,† and this will still oftener be the case in the military service, because the development of non-tubercular intestinal inflammation is favored by so many circumstances.

The cases of flux, that were observed during the civil war, associated with tubercular ulcers of the intestine presented, then, no characteristic symptoms by which, in the present state of our knowledge, their nature could have been determined during the life of the patient. The symptoms were in part those belonging to the chest affection, in part those of a chronic intestinal catarrh. As in other intestinal catarrhs, acute diphtheritic dysentery sometimes supervened during their progress, and was then apt to prove speedily fatal. This complication appears in one instance, case 200, to have occasioned the diagnosis

* Compare BAMBERGER—*Die Tuberculose des Darmkanals*, in Virchow's Handb. der spec. Path. u. Ther., Bd. VI, Abth. 1, Erlangen, 1855, S. 451; NIEMEYER—*op. cit.*, p. 577, *supra*, Bd. I, S. 658; and RUEHLE—*loc. cit.*, last note.

† Even NIEMEYER—*loc. cit.*—who declares that we should suspect tubercular ulcers whenever diarrhœa occurs during decided tuberculosis of the lungs, admits that in these cases the diagnosis is not certain, and goes so far as to say that the colliquative diarrhœa of consumption may occur without our being able to find any evident structural changes of the intestine on autopsy. I may add that the assertion of G. ABAZA—*Inaug. Diss. über die Darmtuberkulose*, Berlin, 1870, S. 16—that in these cases necrosed shreds of mucous membrane (nekrotisirte Fetzen von der zerstörten Darmschleimhaut) can be recognized, though only scantily, in the stools, is probably the expression rather of a scholastic anticipation than of actual observation; for if such fragments were found in any case, the fact would merely indicate the existence of sloughing ulcers without showing their nature.

typhoid fever to be recorded on the register of the hospital in which the patient died.* Tubercles of the peritonæum and tubercular peritonitis complicated most of the cases; but were not often severe enough to give rise to symptoms. Perforation of the intestine and intestinal stricture resulting from partial cicatrization of the ulcers—rare accidents which have been noted by European pathologists in this form of intestinal disease—were not observed in any of the cases collected during the civil war.

To dwell further on the symptoms observed in this group of cases would merely lead to needless repetition of what has been said in previous parts of this Section, and I pass, therefore, at once to an account of the anatomical conditions actually observed.

POST MORTEM APPEARANCES IN TUBERCULAR ULCERATION OF THE INTESTINES.—According to most authors, intestinal tubercles first make their appearance as enlargements of the solitary and agminated follicles, which offer to the naked eye no peculiarities in size, form or general appearance, by which they can be distinguished from follicles enlarged in consequence of ordinary intestinal catarrh; so that doubtless mere catarrhal enlargement of the follicles has often been mistaken for tubercular disease. Central cheesy metamorphosis speedily attacks the follicles affected by the tubercular process. The result, in the case of the solitary follicles, is the production of a small cup-shaped or crater-formed ulcer varying from the size of a millet-seed to that of a split-pea, the so-called primary tubercular ulcer of Rokitansky.† By a continual formation, cheesy metamorphosis and breaking down of new tubercles in the margins of such ulcers, they may ultimately attain considerable size. Meanwhile the surrounding mucous membrane is generally the seat of a more or less intense catarrhal inflammation, differing in nothing from the ordinary forms of inflammation of the intestinal mucous membrane already described. The most striking results of this complication in the small intestine are a club-shaped or polyp-like hypertrophy of the villi, giving the mucous surface of the affected area a plush-like appearance, and frequently excessive thickening of the edges of the ulcer, which, however, is only partly inflammatory, being partly also due to tubercle-formation. Various forms and stages of these tubercular ulcers of the solitary follicles are shown in preparations Nos. 551, 771 and 798, Medical Section, Army Medical Museum.

A similar central caseous transformation, giving rise to the production of crater-like ulcers, occurs also in the swollen follicles when tubercular disease affects the patches of Peyer. In this case a characteristic feature is generally to be observed from the very first: whereas in ordinary intestinal catarrh, as well as in the peculiar follicular disease of typhoid fever, all the individual follicles of the affected Peyer's patch are pretty uniformly involved; in tubercular disease, on the contrary, a single follicle, or a small number only of the follicles of any given patch, are often found to have undergone considerable enlargement and to have submitted to central caseous transformation or even to ulceration, while the remaining follicles of the patch are but slightly or moderately affected. By the subsequent progress of the ulcerative process the whole of the affected Peyer's patch is indeed often destroyed; but here, again, a remarkable circumstance often happens: The ulcer spreads

* See p. 404, *supra*. In case 200 the patient was admitted to the hospital in which he died but two days before death. He had dry tongue and 30 to 40 stools a day, which were passed involuntarily during sleep. Besides general catarrhal inflammation of the intestinal mucous membrane and transverse or oval tubercular ulcers of the small intestine, incipient diphtheritic deposits were observed in the sigmoid flexure; it was "frosted with minute granules of lymph, which firmly adhered to the congested mucous surface." In case 341 the diagnosis of typhoid fever was also recorded on the hospital register, but in this instance apparently without justification by the symptoms.

† ROKITANSKY—*Lehrb. der Path. Anat.*, 3te Aufl., Bd. III, Vienna, 1861, S. 236.

laterally far beyond the original limits of the affected patch, while at the same time a longitudinal contraction occurs by which its width is greatly diminished and the surrounding mucous membrane thrown into characteristic transverse folds. Like those which arise in the solitary follicles, these ulcers usually have greatly thickened worm-eaten edges, and the surrounding mucous membrane is generally in a state of catarrhal inflammation, a notable feature of which is the polyp-like hypertrophy of the villi already mentioned. Specimens Nos. 674 and 798, Medical Section, Army Medical Museum, illustrate the early stages of tubercular ulcers in Peyer's patches.

The subsequent extension of such tubercular ulcers takes place, as in the case of those seated in the solitary follicles, by the continual formation, cheesy transformation and breaking down of new tubercles in the margins of the ulcers. The enlargement, however, does not take place indifferently in all directions, but usually much more rapidly in a line transverse to the axis of the intestine, and parallel in the small intestines to the valvulæ conniventes. In some few cases this rule is violated, and the form assumed by the ulcer as it spreads is determined by the outline of the affected Peyer's patch, the whole of which is destroyed before the adjacent mucous membrane is invaded. No. 808, Medical Section, is an illustration of this condition. But in the great majority of cases the ulcers spread in the transverse direction, assuming at first an elliptic form, which gradually becomes more and more elongated until ultimately it almost encircles the intestine, a condition which has been described as the annular ulcer or girdle-sore.

This ultimate development into a girdle-sore is quite significant of tubercular ulceration. The only other conditions that give rise to it are embolism of an intestinal vessel* and amyloid ulceration. The first is readily distinguished by the presence of the embolus in the artery leading to the affected part and by the necrotic character of the process in the portion of mucous membrane involved. The second has less prominent edges, and the larger ulcers are prone, especially in the small intestine, to be much wider than is usual in tubercular ulceration.† Moreover, tubercular ulceration can usually be quite positively distinguished from these two forms by the circumstance next to be considered. Successive crops of new tubercles are continually forming in the edges and at the base of the tubercular

* The embolic ulcer results from the plugging of a larger or smaller branch of the mesenteric artery by an embolus. It occurs, therefore, especially to patients in whom the conditions for embolism exist; *e. g.*, those suffering from valvular disease of the heart, atheroma of the aorta, etc. The part of the intestinal mucous membrane whose nutrition is thus cut off falls into a condition of necrosis, which may be preceded by hæmorrhagic infarction or even by diphtheritic exudation. If the territory involved is not too extensive, the ulcer left after the separation of the slough may heal, and in so doing give rise to intestinal stenosis. This process may be recognized by its form, which always corresponds to one or more vascular territories, but especially by the discovery of the embolus in the arterial twig supplying the affected part. The process cannot be diagnosticated during life. See, on this subject, BIESIADECKI—*Ueber die durch Embolie hervorgerufenen Veränderungen im Darme*, in report of a meeting of the Verein der Aerzte Niederösterreichs, Allg. Wien. med. Zeitung, Jahrg. XX, 1875, S. 468, and STANISLAUS PARENSKI—*Ueber embolische Darmgeschwüre*, Stricker's med. Jahrb., 1876, S. 275.

† N. FRIEDREICH—*Ueber Amyloiddegeneration*, Verh. d. naturhist.-med. Ver. zu Heidelberg, 1858, Bd. V, S. 144; I cite the abstract in Schmidt's Jahrb., Bd. 103, 1859, S. 7. E. AUFRECHT—*Amyloid-Geschwüre des Darmkanals*, Berliner Klin. Wochenschrift, Jahrg. VI, 1869, S. 315—speaks in connection with the case which serves as the basis of his description of the ulcers as involving considerable territories of the intestine, ("die sich über so lange Strecken des Darmes hinziehen, und überall die ganze Circumferenz desselben einnehmen," &c.) See also the paper of HAYEM, cited note † to page 334, *supra*, and COLBERG, cited note ‡, page 335, *supra*. A part of the ulcers described by the latter author appear to me to have been really tubercular. Compare, also, on the general subject of annular intestinal ulcers, E. LEUDET—*Clinique Méd. de l'Hôtel-Dieu de Rouen*, Paris, 1874, Art. VII, p. 222: "Des ulcérations annulaires et des rétrécissements cicatriciels de l'intestin grêle." In a general way the annular ulcer of the intestine can result only from processes confined to a number of vascular territories. The form of the vascular territory involved in the process determines the form of the embolic, amyloid and tubercular ulcers. Some similar reason must explain the annular ulcers said by LEUDET and others—*op. cit.*, p. 253 *et seq.*—to occur in constitutional syphilis from the breaking down of syphilitic gummata, if indeed these were really other than amyloid ulcers. DICKINSON—*Cases of perforation of the sigmoid flexure of the colon probably due to the irritation of fæces*, Trans. of the Path. Soc. of London, Vol. XVIII, 1866–7, p. 101—has described a form of transverse or annular ulceration occurring in cases of fæcal obstruction, in which the annular shape appears to be due to the fact that the ulcers form "upon the prominent transverse folds of the bowel, by reason of which they are parallel to each other, and across the axis of the intestine." These appear to result from the direct local irritation of the decomposing fæcal matter, and the parts most prominently exposed are first attacked. There may be yet other rare varieties of annular ulcer, but the sweeping assertion that "all long-standing ulcerations in the bowel" may acquire an annular shape similar to that which occurs in the tubercular variety (WILKS and MOXON, *Lectures on Path. Anat.*, 2d Ed., London, 1875, p. 414) is certainly not in accordance with my own experience. Of the large number of specimens of "long standing ulcerations" collected at the Army Medical Museum, none but the tubercular cases are distinctly annular.

ulcer as well as in the lymphatic sheaths of the arterioles and other lymphatic passages leading from its vicinity. These tubercles arise as the so-called gray granulations, undergo central cheesy metamorphosis, the cheesy portion liquefies and is discharged.* This process is a constant and important factor in the extension of the ulcer, the base and edges of which have in consequence a characteristic worm-eaten appearance.

The as yet unsoftened tubercles can be recognized by the naked eye, or still better by a simple lens, in the vicinity of the tubercular ulcer, whether in the uncut preparations or in sections, and constitute the most characteristic feature in determining the nature of the process. Simultaneously, a crop of miliary tubercles often arises in the subperitoneal connective tissue, which in some cases are irregularly scattered over a limited area, corresponding in size and position to the ulcer on the mucous surface of the piece, while in others they radiate thence towards the mesentery in lines which follow the course of the lymphatic passages. A local peritonitis, corresponding to the area of subperitoneal tubercular deposit, now sometimes glues the adjacent knuckles of intestine together, or a general peritonitis may be set up, but in other cases peritoneal inflammation is very slight or even entirely absent. To illustrate the appearances most frequently presented by characteristic tubercular ulcers of moderate size, I have selected a case observed in Satterlee hospital, West Philadelphia, during the summer of 1862:

CASE 905.—Private Alonzo York, company K, 3d Vermont volunteers, age 23, was enlisted July 16, 1861, and appears on the muster rolls of his company as present for duty from that time to June 30, 1862. According to the regimental hospital records he reported sick July 23, 1862, and was excused from drill; was admitted to regimental hospital for treatment July 26th; diagnosis, remittent fever; and was sent to general hospital August 7th. The register of Satterlee hospital, West Philadelphia, shows him admitted August 10th: Rheumatism. Died September 15th. The following account of the autopsy was furnished by Acting Assistant Surgeon J. Leidy, according to whose report this man was treated in Satterlee hospital for phthisis, rheumatism and chronic diarrhœa *Autopsy*, three hours after death: The body was much emaciated and the skin about the pit of the stomach was in an ecchymosed condition. The right lung was bound to the thoracic parietes by old pleuritic adhesions. A tuberculous deposit occupied its apex, and elsewhere it contained a number of tuberculous masses from the size of a cherry-stone to that of a peach-stone, some of them softened in their centres. The left lung was bound to the thoracic parietes posteriorly by old adhesions and contained about twenty tuberculous masses from the size of a cherry-stone to that of a shellbark. The heart was pale, devoid of fat, otherwise normal, and contained no clots. The liver was of a dull-brown color; the spleen healthy, on section lake-red; the mesenteric glands much enlarged by tuberculous deposits. The stomach was moderately contracted; its mucous membrane presented a few slightly injected patches. The intestines were also contracted. On being opened the mucous membrane of the entire intestinal tract was found to be inflamed from the duodenum to the anus. In the ileum the agminated glands were all destroyed by ulceration; the ulcers had thick, hardened edges, and their long diameters were transverse to the axis of the intestine. Similar ulcers, but of smaller size, existed high up in the jejunum; it was impossible to say whether all of these had originated in agminated glands, for no trace of these latter structures remained. Patches of opaque white tubercles about a line in diameter were situated on the peritonæum beneath the position of every ulcer; quite circumscribed peritonitis accompanied these patches. The inflammation of the mucous membrane of the colon was most acute at its two extremities; it was associated with blackened solitary follicles, desquamated epithelium and patches of pseudomembrane; there were also a number of ulcers where the pseudomembrane had separated. The kidneys were healthy. The cortical substance of the suprarenal bodies was of a dull brownish-yellow color, but did not appear to be altered in structure.

Nos. 244 to 261, Medical Section, Army Medical Museum, are from this case. The first six or seven pieces are successive portions taken from the jejunum; the rest, with the exception of No. 261, which is a piece of the colon, are successive portions selected from the ileum. The pieces of small intestine show altogether twenty-nine tubercular ulcers, and a number of similar ones existed in the intermediate portions which have not been preserved. These ulcers range from less than half an inch to about two inches in long diameter measured transversely to the axis of the bowel. They have irregular thickened edges, and by the naked eye discrete tubercles, some gray, some caseous, can be recognized

* In view of this characteristic process, I find myself quite unable to agree with CHARCOT when he declares that it is not yet demonstrated that it is possible to distinguish between tubercular ulcers and those of typhoid fever.—Bull. de la Soc. Anat. de Paris, an 49, 1874, p. 743. Even with the unaided eye, the process described in the text can generally be recognized.

in their bases and margins. A few of the smallest ulcers have no tubercles on their peritoneal surface, but most of them exhibit peritoneal tubercles as well as shreds of adhesions resulting from the circumscribed peritonitis described by Dr. Leidy in his account of the case. The intestinal walls are quite thin and semitransparent, which would be favorable for observing the agminated glands of Peyer, if any trace of them were left. They appear, however, to have been entirely destroyed by the ulcerative process, and the circumstance that notwithstanding this fact the widest of the ulcers do not greatly exceed half an inch in transverse diameter, as measured with the length of the intestine, is probably to be accounted for by a longitudinal contraction of the ulcerated surface as manifested by the well marked transverse puckering of the mucous surface in the vicinity of the ulcers.

The plate facing this page is reproduced from a photograph representing No. 257, Medical Section, which is one of the pieces of ileum from this case.* In consequence of the coexisting catarrhal inflammation, the existence of which is mentioned by Dr. Leidy, the villi were somewhat hypertrophied, giving the general mucous surface a velvety appearance. A little below the middle of the piece there is an elliptical ulcer about an inch and a half in long diameter and half an inch wide. The edges of this ulcer are quite thick, and in places have the characteristic worm-eaten appearance resulting from the necrotic destruction of individual tubercles. In the base of the ulcer the same process has produced several little cavities big enough to receive a pin's head, which can be well seen in the plate, especially by the aid of a lens. Both gray and caseous tubercles, the size of a pin's head or smaller, can also be distinguished by the naked eye in the edges and bottom of the ulcer in the specimen, but the differences of color being lost, they cannot be positively identified in the plate, though traces of them can be seen. The mucous membrane in the vicinity of the ulcer is thrown into well marked transverse folds, in consequence of the contraction in the direction of the length of the intestine, already described.

The plate facing page 584 is reproduced from a photograph of the peritoneal surface of the same specimen. It exhibits, in a space corresponding to the area of the ulcer and

* I find the following representations of tubercular disease of the intestines in the iconographic works: RICHARD BRIGHT—*Reports of Medical Cases*, London, 1827, Plate XI, "Ulceration of the colon and small intestines in phthisis pulmonalis;" Plate XII, "Ulceration of the cæcum, colon and ileum in phthisis pulmonalis;" five colored figures, (engraved on copper,) which, however, leave much to be desired in regard to the representation of textural details. *Anat. Drawings from Preparations in the Museum of the Army Med. Dept. at Chatham*, London, 1824, Fasc. 1, Plate IX, Figs. 5 and 6: Fig. 5 shows a transversely elliptical tubercular ulcer; Fig. 6, "The external surface of the same, exhibiting the lacteals arising from the ulcer in a varicose state;" Fasc. 2, Plate VII, Fig. 4, "displays several ulcers in the interior of the ileum, produced by the maturation of tubercles." Although coarsely lithographed, these figures give a pretty good notion of some of the appearances of tubercular ulcers. J. HOPE—*Principles and Illustrations of Morbid Anatomy*, London, 1834—Figs. 152 and 161, colored lithographs. Fig. 152 is a coarsely executed but pretty effective representation of a girdle-sore of the small intestine; Fig. 161 represents scattered tubercular ulcers, (seated in the solitary follicles?) ROBERT CARSWELL—*Illustrations of the Elementary Forms of Disease*, London, 1838, Tubercle. Plate III, Fig. 1, a colored lithograph, representing a piece of ileum with a portion of mesentery and some mesenteric glands attached. The mucous surface of the ileum displays two much thickened, oval, Peyer's patches, whose long diameter is parallel to the axis of the intestine. On the surface of these patches a number of tubercles smaller than pins' heads are represented; a number of enlarged solitary follicles and several small ulcers are also seen on the surface of the piece. One end of the portion of ileum is turned over so as to show its peritoneal surface, on which the branches of two lacteals, "dilated and filled with tuberculous matter," ramify. A similar condition of the lacteals is represented in all parts of the mesentery shown. The mesenteric glands are enlarged, and some of them being laid open display tubercular or cheesy deposits in their interiors. This figure is in every way worthy of the reputation the plates of CARSWELL have deservedly acquired. A somewhat similar condition of the lymphatics had previously been represented by J. CRUVEILHIER—*Anat. Path.*, T. I, Paris, 1829-35, Livr. 2, Plate 1, in which a loop of intestine is figured with groups of tubercles on its peritoneal surface; the lacteals dilated, though to a much less degree than in the figure of CARSWELL, are described as filled with tubercular matter—"matière tuberculeuse dans les vaisseaux lactés." GLUGE—*Atlas der Path. Anat.*, Bd. II, Jena, 1850, Die Skrophulose und die Tuberkulose, 15te Lief.—Taf. I, Fig. 3, is a coarse lithograph representing tubercular ulceration of the small intestine; not very satisfactory. Taf. V, Fig. 1, is an uncolored copy of CARSWELL'S figure, described above; and Fig. 16 a magnified view (very unsatisfactory) of a small tubercular ulcer of the small intestine. ALBERS—*Atlas der path. Anat.*, Abth. IV, Bonn, 1832, Taf. XX, Figs. 1-10—devotes a plate containing ten lithographic figures, all but one colored, to tubercular ulcers of the intestine. I cannot speak with praise either of the selection of the pieces or the skill with which they are represented. H. LEBERT—*Traité d'Anat. Path.*, Atlas, T. II, Paris, 1861, Plate CXXII, Figs. 3, 4 and 5—gives three neatly executed figures, (copperplate,) one of them colored, representing tubercular ulcers of the small intestine, in two of which the ulcers have perforated. A. THIERFELDER—*Atlas der Path. Histologie*, Lief. 2, Leipsic, 1873, Taf. XIII, Fig. 1—has given an admirable lithograph of a perpendicular section through a tubercular ulcer of the small intestine as seen with a power of 35 [35?] diameters. I bestow upon this representation the well deserved praise, that it is not merely in all essential features, so far as it goes, nature-true, but that it is the only conscientious attempt to represent a perpendicular section through such an ulcer with which I am acquainted; for of course the little diagrammatic wood-cut given by KLEBS—Fig. 7, S. 258, *op. cit.*, note ‖, p. 576, *supra*—can hardly be regarded as more than a diagram.

No. 257. MEDICAL SECTION.

its immediate vicinity, about fifty tubercles, the largest of which, though not exceeding a pin's head in size, have already undergone central or complete caseous degeneration. Slight peritoneal adhesions, produced by local peritonitis, appear as delicate shreds attached to the peritoneal surface between the tubercles. This case is in several respects a striking one. It appears from the record that the patient, notwithstanding his lung disease, did duty as a soldier until nine weeks before his death. He accompanied the army of the Potomac in its disastrous peninsular campaign, and when first taken on sick report at Harrison's Landing, his symptoms were such as to suggest the diagnosis remittent fever to the regimental surgeon. At some time during the progress of the case diphtheritic dysentery supervened, for the colon did not exhibit the characteristics of tubercular ulceration, but was plastered with pseudomembrane. The ulcers mentioned in Dr. Leidy's account of the autopsy were in part small follicular ulcers, the result of the intestinal catarrah, in part superficial erosions produced by the separation of portions of the diphtheritic slough. These conditions are well displayed in No. 261, Medical Section, which is a portion of the colon from this case. Just when the diphtheritic process set in is not shown by the history of the case; I suspect from the specimen that it was not long before the fatal issue. In any event this series of specimens shows in a striking manner the coexistence in the same individual of exquisitely developed tubercular ulceration of the small intestine, with a diphtheritic dysentery supervening upon a chronic catarrh, resembling in all respects the cases so common during the war in non-tubercular patients.

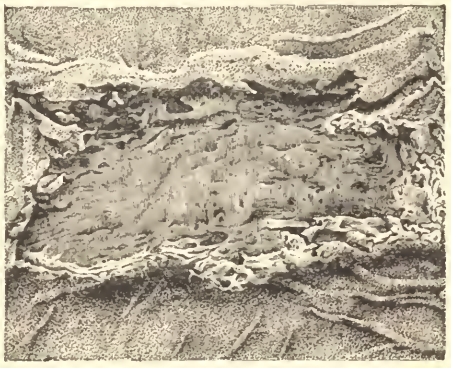

FIG. 33.—Tubercular girdle-sore, natural size. From a photograph of No. 429, Medical Section, Army Medical Museum. (Case 413.) See p. 584.

The series of specimens preserved from case 413* illustrate somewhat different and, if possible, still better marked conditions. In this case there was a history of chronic lung trouble of several years' duration. There is not only no history of diarrhœa, but it is distinctly stated, by the attending medical officer, three days before the death of the patient, that "his bowels are regular." Yet on the autopsy, besides tubercular disease of the lungs and ulceration of the larynx, extensive tubercular ulceration was found in the small intestine, cæcum and vermiform appendix. The ulcers in the small intestine were quite numerous, and for the most part appeared as fully developed girdle-sores enveloping the whole, or almost the whole, circumference of the bowel. In long diameter, they measured transversely to the axis of the bowel an inch and a half or two inches; in breadth, measured parallel to the axis of the bowel, from half an inch to an inch. The characteristic deposit of tubercles and the tiny excavations resulting from their necrosis could be observed in the bases and thickened edges of all these girdle-sores. A conspicuous deposit of tubercle was observed in the peritonæum opposite all of them; it was, however, by no means limited to territories corresponding to the site of the ulcers, but extended in the neighborhood of many of them over irregular areas of several times greater size. These peritoneal tubercles occurred not merely as discrete nodules of pin-head size or smaller, gray, or in various stages of cheesy metamorphosis, but also as irregular yellowish flattened patches, resulting apparently from the caseous metamorphosis and coalescence of a number of closely situated nodules. Besides the girdle-sores, there were

* Page 181, *supra*.

also a number of small ulcers, some situated in the solitary follicles, others in some of the patches of Peyer, other parts of which were but slightly diseased.

Several specimens selected from the intestine of this subject have been preserved in the Medical Section of the Museum.* No. 428 is from the upper portion of the jejunum, and exhibits a very large and very characteristic girdle-sore. No. 429, from the upper portion of the ileum, exhibits two such ulcers. One of these is represented on the previous page by Fig. 33, which gives a just idea of the thickened worm-eaten edges, and the little cavities left by the necrosis of individual tubercles. There was an abundant crop of tubercles on the opposite peritoneal surface, which, however, corresponded rather to the edges of the ulcer, and their vicinity beyond the ulcer, than to the base of the ulcer itself. It is worthy of note that each of the girdle-sores in this case appears to have destroyed the whole of the Peyer's patch in which it was situated, and that the well marked transverse puckering of the adjacent mucous membrane indicates that the process of longitudinal contraction already commented upon had taken place to a marked degree. In striking contradistinction to this is the condition of some of the other Peyer's patches. One of these, in No. 430, Medical Section, is shown in Fig. 34. It is of the usual elliptical shape, and for the most part very slightly thickened, yet displays scattered over its surface no less than twenty-one separate small ulcers, which from their characters I am compelled to regard as tubercular. There are besides, in this specimen, several small ulcers of similar character which I suppose to have originated in the solitary follicles. No. 431 is a portion of the cæcum and the vermiform appendix from the same case. In the cæcum there are four tubercular ulcers, the largest of which is represented in Fig. 35. It is about an inch and a half long and half an inch wide; its long diameter disposed transversely to the axis of the bowel. The figure gives a very good notion of the appearances of a tubercular ulcer of the large intestine. Almost the whole of the mucous surface of the vermiform appendix, as shown in this specimen, was destroyed by a tubercular ulcer, in the base of which tubercles and tiny cavities resulting from their necrosis can be distinctly seen. The rest of the colon in this case presented no marked inflammatory conditions, a circumstance which undoubtedly accounts for the absence of diarrhœa during the progress of the disease.

FIG. 34.—A number of small tubercular ulcers in a very slightly thickened Peyer's patch, natural size. From a photograph of No. 430, Medical Section, Army Med. Museum.

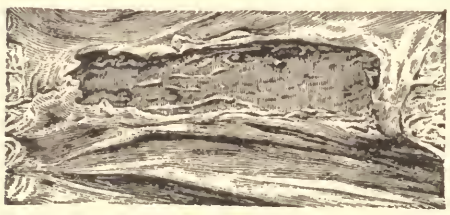

FIG. 35.—Tubercular ulcer of the cæcum, natural size. From a photograph of No. 431, Medical Section, Army Medical Museum.

Case 434† may also be mentioned here as one in which, besides tubercular ulcers of the small intestine, in many respects resembling those found in case 413, marked tubercular ulceration of the large intestine existed. No. 485, Medical Section, is the lower extremity of the ileum, with the ileo-cæcal valve and a part of the cæcum of this subject; there is a transverse ulcer just above the valve; the cæcum is thickened and the whole surface of the part preserved ulcerated. No. 486 is a small part of the cæcum and the vermiform appendix laid open. The mucous surface of this part of the cæcum also is destroyed by ulceration, while that of the vermiform appendix presents altogether

* Besides which, No. 426, Medical Section, is the larynx; 427 a portion of the upper lobe of the left lung; and 432 a mass of the enlarged mesenteric glands. See the brief description on page 181.

TUBERCULAR ULCER OF ILEUM.

PERITONEAL SURFACE.

No. 257. MEDICAL SECTION.

LIBRARY
UNIV.
CALIFORNIA

LIBRARY UNIVERSITY CALIFORNIA

about a dozen ulcers, most of them of moderate size, elliptical, their long diameters transverse to the lumen of the appendix; but one of them, which occupies the whole central third of the appendix, is much larger and apparently formed by the coalescence of several ulcers similar to the others. No. 487 is a portion of the transverse colon of the same subject; it exhibits two oval ulcers, each about three-quarters of an inch in long diameter, which have nearly coalesced, and which, had their union been completed, would have occupied about two-thirds of the circumference of the bowel. There are, besides, a number of smaller ulcers, the least of which offer excellent illustrations of the appearances presented by tubercular ulcerations of the large intestine in their early stages. The tubercular character of all these ulcers is shown by the presence in their bases and edges of numerous tubercles, and of the little cavities left by their necrosis. These characteristic features are especially notable in the large ulcerated surface in the cæcum. In this case the patient, besides the chest symptoms resulting from his lung disease, had suffered from a distressing diarrhœa for some time before death.

To the foregoing illustrations I add Fig. 36, which represents half a dozen crater-like tubercular ulcers of various sizes, as well as an ulcerated Peyer's patch three-fourths of an inch in long diameter, with thickened somewhat worm-eaten edges. The patient was a young mulatto woman who died in the Freedmen's hospital, Washington, D. C., March 3, 1866.* A great number of tubercular ulcers of solitary follicles were found in the ileum, and several of the patches of Peyer were thickened and ulcerated. These patches bore a superficial resemblance to the ulcers of typhoid fever, from which, however, they were distinguishable not only by crops of tubercles in the corresponding portions of the peritonæum, but by numerous tubercles in the bases and edges of the ulcers.

FIG. 36.—Tubercular ulcers of the ileum, natural size. From a photograph of No. 776, Medical Section, Army Medical Museum.

I note in all, including cases 413 and 434, twenty cases in Section II in which tubercular ulceration of the intestines appears clearly to have existed, viz: cases 98, 168, 413, 434, 524, 862, 863, 864, 865, 866 and 876, in all of which the diagnosis is confirmed by specimens preserved at the Army Medical Museum, and cases 236, 323, 341, 403, 455, 529, 530, 553, 592, which, from the record, appear pretty clearly to have been of a similar nature. Five of these cases, viz: 862, 863, 864, 865 and 866, were patients in the Freedmen's hospital, Washington, D. C.; two, 98 and 553, were colored soldiers; the remaining fourteen white soldiers. In all these cases tubercular disease of the lungs is stated to have existed, except case 553, in which the condition of the thoracic viscera is not recorded, and 592, in which they were not examined. There are, besides, nine cases, viz: 105, 199, 200, 349, 463, 608, 723, 740 and 748, which may possibly be examples of tubercular disease of the intestines, although from the imperfect character of the record, or other circumstances, all of them are open to more or less doubt.

It cannot, therefore, be said that the record indicates very great frequency for this form of flux; but on the other hand it may be remarked that the recognition of the lesions

* See *Catalogue of the Medical Section, Army Medical Museum*, Washington, 1867, p. 82, for particulars. The patient, a mulatto girl, age 18, admitted July 5, 1865, was jaundiced and anæmic. In August she had an intercurrent attack of acute pneumonia, followed by alternating constipation and diarrhœa, night sweats, extreme emaciation, and death March 3, 1866. On the autopsy both lungs were found to contain many tubercles, and there were large vomicæ in the left lung. The bronchial glands were enlarged and tubercular. The liver contained many miliary tubercles. There were also tubercles in the spleen, kidneys and mesenteric glands. Besides the ulcers of the small intestine described in the text, there were numerous tubercular ulcers in the colon.

in question requires a degree of training in pathological anatomy which many of the medical officers who made the autopsies reported in Section II did not possess; and I may especially suggest that I have classed as "undetermined"* some cases, in which it is merely recorded that the intestines were ulcerated and the lungs tubercular, that were very probably of this nature Nor shall I attempt in this place any detailed analysis of the other lesions observed in the cases just enumerated, but refer the reader interested on this head to the reports in Section III. I will merely remark that in most of them the mesenteric glands are said to have been enlarged, cheesy or tubercular, and that in a number of them the presence of tubercle was noted in other organs besides the lungs. In case 524 there was a perineal abscess, communicating with the rectum; and in case 876 anal fistulæ, which, being laid open, did not granulate. I may add that there are in the Army Medical Museum several other specimens of tubercular ulceration of the intestine from children, from women treated in the Freedmen's hospital, &c., which for obvious reasons are not described in this work.

HISTOLOGICAL CHARACTERS OF THE TUBERCULAR ULCERS.—The contradictory views with regard to the minute structure of tubercle which have been advanced, especially during the last ten years, make this subject one of peculiar difficulties, and the time has not yet come in which it could be hoped that any attempt to reconcile the conflicting testimony with regard to many matters of detail can be entirely successful. No such attempt will be made here. I shall limit myself to a brief account of the appearances which I have been able to recognize in the specimens preserved in the Museum, with references to such of the modern works on the subject as have guided me in forming an opinion as to the nature of the changes observed.

When, then, perpendicular sections are cut through the edges of a tubercular ulcer of the small intestine, and the tissues adjacent, and examined with a power of ten or twenty diameters, the first circumstance that arrests attention is the occurrence of numerous tiny nodules which are found most abundantly in the immediate vicinity of the ulcer, but also, though in diminishing frequency, at a considerable distance from it, especially in the course of the arterial twigs, that supply the territory occupied by the ulcer, and of the lymphatics that issue from it. These occur either singly as exceedingly minute formations $\frac{1}{200}$ to $\frac{1}{100}$ of an inch in diameter or even smaller, or as compound nodules consisting of three or four to fifty or more of the smaller ones grouped together. The compound nodules are the smallest tubercles which can usually be distinguished by the unaided eye in unstained sections. The isolated ones, which may be designated the ultimate tubercle-granulations, are for the most part quite invisible without a lens unless the preparation is stained, when they are seen as colored points on account of the tinge acquired particularly by their peripheral portion. The central portion of those tubercle-granulations which lie nearest the edges of the ulcer is usually found converted by cheesy metamorphosis into granular debris, and often drops out from the thin sections during the process of preparation, leaving a tiny cavity. Similar cavities are formed when the ulcerative process invades the cheesy tubercle, and the little excavations left after the dropping out of the cheesy mass are often shown in the sections at the edges of the ulcer. Between the tubercles the submucous connective tissue is in a state of chronic inflammation, with dilated bloodvessels, and infiltrated by a swarm of lymphoid elements which are most abundant just beneath the muscle

* Page 535, *supra*.

of Brücke and near the edges of the ulcer, as in the case of ordinary catarrhal ulcers. The mucosa also presents the usual phenomena of chronic inflammation; its adenoid tissue is infiltrated with lymphoid elements, by which the glands of Lieberkühn are pushed apart and its villi are hypertrophied, appearing as cylindrical or clavate forms often several times larger than their normal size.

A good idea of the general relations of these various processes in the neighborhood of a small crater-like tubercular ulcer is given by Fig. 37, which represents a section through such an ulcer from a portion of the ileum of case 413,* as seen with a magnifying power of fifteen diameters. The ulcer appears in the sections as a little cavity about $\frac{1}{8}$ of an inch across, communicating with the lumen of the intestine by an orifice $\frac{1}{20}$ of an inch in diameter. Fig. 38, on the next page, represents a perpendicular section, cut transversely through the edge of a tubercular girdle-sore of the ileum; magnified eighteen diameters.

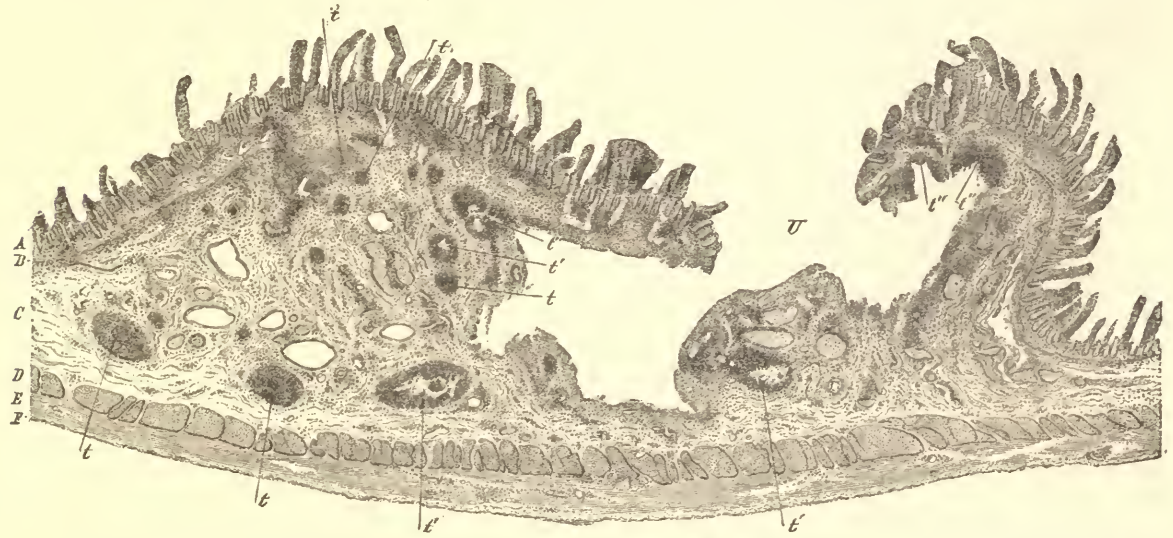

FIG. 37.—Perpendicular section through a small tubercular ulcer of the ileum. Magnified 15 diameters. From a photo-micrograph [Neg. 978, N. S.] of No. 7540, Microscopical Section, from case 413. A. The mucous membrane, with its tubular glands pushed apart by the accumulation of lymphoid elements; its villi greatly hypertrophied. B. The muscle of Brücke. C. Submucous connective tissue infiltrated with lymphoid elements, containing a number of tubercles in various stages; its bloodvessels dilated. D. Circular muscular coat of the intestine. E. Longitudinal muscular coat. F. Peritonæum. U. Cavity of the ulcer. *t, t, t, t, t, t.* Unsoftened tubercles. The two letters below the lower edge point to tubercles, in the centres of which peculiar oval forms are seen, (lymphatic vessels cut across? giant-cells?) the nature of which will be discussed further on. There are besides several unsoftened tubercles which are not lettered. *t', t', t', t'.* Tubercles with central softening in which part of the cheesy mass has fallen out. *t'', t''.* Softened tubercles whose cavities form part of the ulcer.

The patient was a colored man, who died of lung phthisis and tubercular ulceration of the intestine in the Freedmen's hospital, Washington, D. C., 1866. A brief account of the autopsy is appended in the foot note.† It is not recorded to what extent he suffered from diarrhœa, but the small intestine contained numerous tubercular ulcers both large and small. The large ones for the most part were elliptical with their long diameters transverse to the axis of the intestine, or formed actual girdle-sores. On the peritoneal surface, opposite the larger ulcers, a luxuriant crop of tubercle granulations could be seen, some of them isolated, others in groups of two to ten, twenty or more, forming compound tubercle-nodules. These were seated in the subperitoneal connective tissue, which was considerably thickened.

---

* See p. 583, *supra*.

† Joshua Jackson, colored, age 27; admitted September 23, 1866, in the last stages of consumption. Died October 8th. *Autopsy:* Lungs infiltrated with tubercle; a large cavity in the upper lobe of the left lung. The left pleural sac contained 8 ounces of fluid, and the left costal pleura was studded with tubercles. Near the anterior extremity of the left sixth rib, and connected with it, there was a yellow cheesy mass 2 inches in transverse diameter and an inch thick. Liver weighed 58 oz.; spleen, 5½ oz.; right kidney, 5½ oz.; left, 7 oz. The liver was amber-yellow and contained a few tubercles, as did also the spleen. The small intestine presented a number of tubercular ulcers, some apparently seated in Peyer's patches, others in the solitary follicles. The former were for the most part large, their long diameters transverse to the bowel, and had numerous tubercles seated beneath the peritonæum opposite them. The large intestine was not ulcerated and no inflammation was detected in its mucous membrane.

Other tubercles were found between the fasciculi of the muscular coat and in the submucous connective tissue beneath the ulcer and at its edges. [See Fig. 38.] Sections cut in like manner through tubercular ulcers of the large intestine present very similar appearances, except, of course, that there are no villi to be seen.

When, now, tubercles such as those shown in these sections are examined with a magnifying power of two to five hundred diameters it will be found that, besides the nodules whose central portions have dropped out from the sections, many others have undergone the cheesy metamorphosis. All degrees of this process will be found, from a mere dot of central change to the complete transformation of all parts of the nodule. The result is in every case the production of a granular detritus through which shrivelled nuclei are

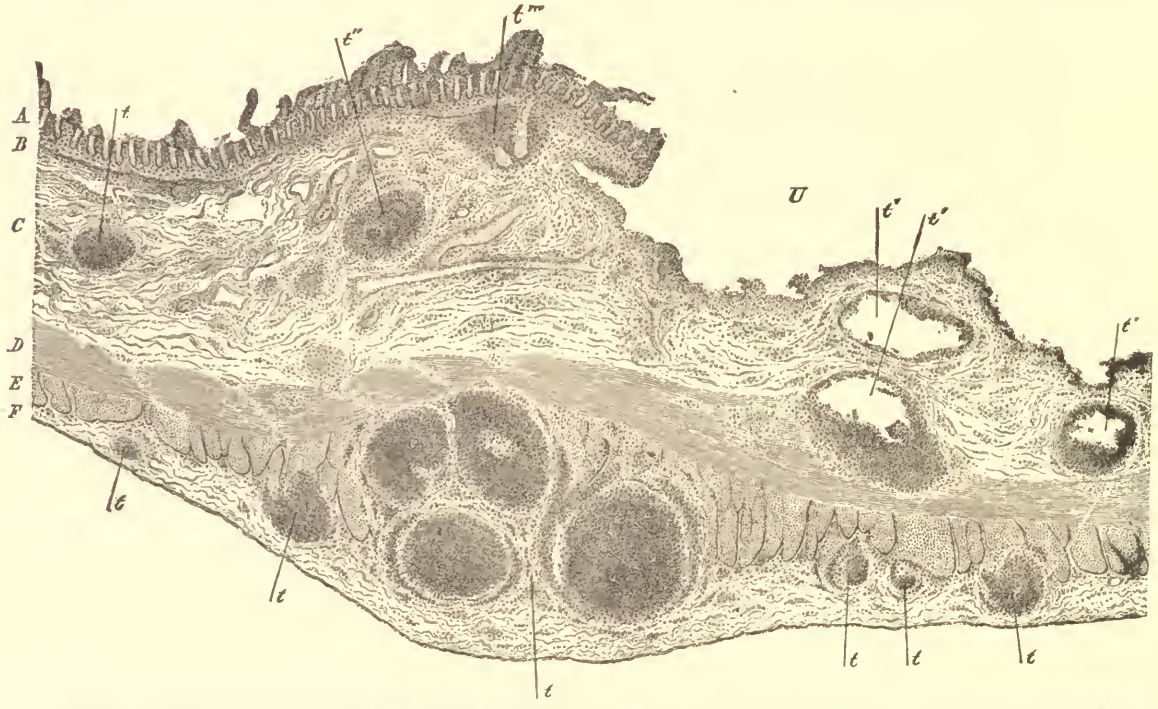

FIG. 38.—Perpendicular section cut transversely through the edge of a tubercular girdle-sore of the ileum. From a photo-micrograph [Neg. 978, N. S.] of No. 7519, Microscopical Section. A. Mucous membrane; its tubular glands pushed apart by an accumulation of lymphoid elements in the adenoid tissue; its villi hypertrophied, but most of them accidentally broken off in making the section. B. The muscle of Brücke. C. Submucous connective tissue, infiltrated with lymphoid elements, especially in the vicinity of the muscle of Brücke and near the edges of the ulcer; its bloodvessels dilated; it contains also a number of tubercles. D. Circular muscular coat of the intestine. E. Longitudinal muscular coat. F. Subperitoneal connective tissue, much thickened, and containing tubercles. *t, t, t, t, t, t.* Tubercles; there are also several not lettered; near the centre of the lower edge of the section five tubercles grouped together form a compound one. *t', t', t'.* Softened tubercles from whose interior the cheesy mass has dropped out in making the section. *t''.* A tubercle containing one of the peculiar bodies alluded to in the description of Fig. 37. *t'''.* A tubercle in the substance of which a vascular loop (arteriole?) can be clearly seen. Such vessels ultimately cease to be permeable. Magnified 20 diameters.

irregularly scattered. Those ultimate tubercle-granulations which have escaped this process, whether lying isolated or seated in the peripheral portion of larger nodules, appear at first sight, for the most part, to consist merely of a delicate reticulum infiltrated with innumerable lymphoid cells, very similar to the reticulum and cells of the normal adenoid tissue of the intestinal closed glands, or of a little group of lymphoid cells between which no reticulum can be distinguished. These lymphoid elements were the only cells believed to be essential to tubercle by Virchow as late as 1865; they are still regarded in the same light by some excellent histologists, as, for example, Max Wolff in 1876,* and are admitted on all sides to be the most numerous and most constantly present cellular forms.

* R. VIRCHOW—*Die Krankhaften Geschwülste*, Bd. II, Berlin, 1864-5, Vorlesung 21, S. 637—expressly said: "Das eigentliche Tuberkelkörperchen ist eine wirkliche Zelle, und weder ein blosser Kern, noch ein solider Körper. Wie die leukämischen, typhösen und scrofulösen Zellen, gleicht sie im Wesentlichen den Lymphdrüsen Elementen." He had previously maintained this view in *Die Cellularpathologie*, 2te Aufl., 1859, S. 427, and

The occasional occurrence of other elements in tubercle had indeed long been known. Rokitansky,* as early as 1855, described and figured large nucleated and polynucleated forms which he regarded as mother-cells engaged in the endogenous formation of the smaller elements of the gray granulations. Virchow, in 1858, saw huge branching multinucleated forms in tubercle of the omentum, and supposed them to have originated by the transformation of the fat cells. In his work on tumors † he mentions that similar forms are of frequent occurrence in tubercles situated in dense fibrous parts, but by no means represents them as essential to the idea of tubercle.

These large multinucleated elements, now generally known as giant-cells, were also observed in the tubercles of certain tissues and organs by several other histologists,‡ but, so far as I know, Langhans § (1868) was the first to take the ground that they are constantly present in all tubercles. His studies were made chiefly on teased preparations, in which, besides the multinucleated giant-cells, he succeeded in isolating cells intermediate in size between these and the lymphoid elements, and containing from one to three or more nuclei. Soon after followed the remarkable investigations of Wagner and Schüppel,‖ (1870–71,) made for the most part on thin sections of the diseased tissues, which have been widely accepted as establishing the view that the larger nucleated and giant-cells are the essential elementary forms of the ultimate tubercle-granulation.

According to the beautifully illustrated description of Schüppel, an ultimate tubercle-granulation in a lymphatic gland consists of a reticulum closely resembling that of the adenoid tissue of the lymphatic glands, in the meshes of which lie three kinds of cells, viz:

illustrated it by a diagram representing a tubercle of the pleura, Fig. 140, consisting of a group of small round nucleated cells, surrounded by small lymph spaces filled with similar elements, which he interpreted as proliferating connective-tissue corpuscles. This figure is reproduced in his work on tumors, *loc. cit.*, Fig. 191. MAX WOLFF—*Ueber entzündliche Veränderungen innerer Organe nach experimentell bei Thieren erzeugten subcutanen käsigen Heerden mit Rücksicht auf die Tuberkulosenfrage*, Virchow's Archiv, Bd. LXVII, 1876, S. 234—with a full knowledge of the recent investigations to be presently alluded to, declares that he has recently frequently (hinreichend oft) found tubercles even in the pleura and omentum in which the reticulum was absent, and not merely the inconstant giant-cells, [den inconstanten Riesenzellen,] but also the epithelioid elements were wanting, so that the tubercles consisted merely of a group of round cells in which frequently the central part of the nodule was already converted into a detritus of fatty granules justifying the old definition of tubercle as a small-celled new formation: "Und die alte Definition des Tuberkels als einer kleinzelligen Neubildung nach wie vor zu Recht bestand," S. 251.

* C. ROKITANSKY—*Lehrb. der Path. Anat.*, 3te Aufl., Bd. I, Vienna, 1855, S. 291, Fig. 121. The figure is evidently drawn from a teased preparation and represents, besides nuclei set free by the destruction of the cellular forms and lymphoid cells, larger cells containing two to five or more nuclei, evidently the epithelioid (or endothelial) forms which will be presently described.

† R. VIRCHOW—*Reizung und Reizbarkeit*, Archiv, Bd. XIV, 1858, S. 49—after describing these large multinucleated branching cells as occurring in the lymphatic glands, under what circumstances he does not explain, adds: "Genau dieselben Formen fand ich später im Netz des Menschen bei tuberkulöser Peritonitis und ich konnte mich bestimmt überzeugen, dass sie hier aus metamorphosirten Fettzellen ihre Entstehung nahmen." See, also, S. 639 *et seq.*, in *Die Krankhaften Geschwülste*, [cited note *, *supra.*]

‡ As, for example, in tubercle of the liver, by E. WAGNER—*Die Tuberculose der Leber.*, Archiv der Heilkunde, Jahrg. II, 1861, S. 35—who, however, described them as only of occasional occurrence: "Bisweilen endlich finden sich sehr grosse, graubräunliche Körper mit sparsamen oder zahlreichen, meist kurzen, schmalen, spitz endenden Ausläufern und von platter Gestalt; sie erscheinen meist fein granulirt, zeigen aber nach Essigsäure sehr zahlreiche, meist mittelgrosse, runde oder längliche Kerne, welche grösser und deutlicher bläschenförmig als die obengenannten sind (sogen. placques à plusieurs noyaux.") So also F. BUSCH—*Zwei Fälle von Geschwulstbildung im Augenhintergrunde*, Virchow's Archiv, Bd. XXXVI, 1866, S. 448—observed these forms in a case of "Tuberculosis chorioideæ;" and they were also seen and figured by K. KÖSTER—*Ueber fungöse Gelenkentzündung*, Virchow's Archiv, Bd. XLVIII, 1869, S. 95, also Taf. III—in tubercles of the synovial membrane.

§ TH. LANGHANS—*Ueber Riesenzellen mit wandständigen Kernen in Tuberkeln und die fibröse Form des Tuberkels*, Virchow's Archiv, Bd. XLII, 1868, S. 382, also Taf. VII–VIII. Figs. 4 and 5 are said to have been drawn from sections, but these were evidently minute fragments, rather than such as served for the studies of WAGNER and SCHÜPPEL. His conclusions are well expressed in the following sentence: "Wie mir genauere Untersuchung einer grösseren Zahl von Fällen ergab, sind diese Riesenzellen in der That ein fast constanter Bestandtheil von Tuberkeln in fast allen Organen des menschlichen Körpers."

‖ E. WAGNER—*Das tuberkelähnliche Lymphadenom*, Archiv der Heilkunde, Jahrg. XI, 1870, S. 497, also Taf. VI u. VII; same Jour., Jahrg. XII, 1871, S. 1. As the title of this admirable paper shows, the writer supposed that he was describing, not tubercle, but a special form of growth resembling tubercle only in external appearance. To any one who may now doubt this fact, I commend the following passage from the first paper, S. 498: "Das knötchenförmige und dann häufig miliare Lymphadenom der Pleura gleicht nach Zahl, Grösse, Anordnung u. s. w. der Knötchen so vollständig dem Tuberkel dieser Haut, dass nur die mikroskopische Untersuchung darüber Aufschluss giebt." When, then, the author in a later publication—*Manual of General Pathology*, Amer. Transl. of 6th German Ed., New York, 1876, p. 445—repeats the description given in his former papers, but now very properly making it generally applicable to typical tubercle, it is somewhat amusing to find him claiming priority as follows: "The histology, just given, of tubercle of the most different organs is by the author. SCHÜPPEL determined it in a special manner, with respect to the lymph-glands," &c., without any mention of his original misconceptions. OSKAR SCHÜPPEL—*Untersuchungen über Lymphdrüsen-Tuberkulose*, Tubingen, 1871, S. 84. I have selected this paper as the basis of the short description given in the text, partly on account of the clearness of the descriptions, partly because of the beauty of the illustrative plates. I may add that SCHÜPPEL was not misled by WAGNER'S original article, the first part of which he mentions, remarking: "Die Knötchen in den Lymphdrüsen, welche Wagner als tuberkelähnliches Lymphadenom bezeichnet, während ich sie schlechthin Tuberkel nennen will," &c., S. 6.

giant-cells, large epithelioid (or endothelioid) cells, containing one or more nuclei, and small round lymphoid cells. The giant-cells are rounded, elliptical or irregularly oblong branching masses of very finely granular protoplasm, of various sizes, somewhere between $\frac{1}{100}$ and $\frac{1}{600}$ of an inch in diameter being the usual limits; they are found on examination to contain from half a dozen to thirty, fifty or even more oval nuclei, for the most part situated, with their long diameters arranged as radii, in the peripheral portion of the protoplasmic mass. Each ultimate tubercle-granulation contains usually a single centrally situated giant-cell, or several may be found, without it being possible to affirm from the arrangement of the other elements that the granulation is made up by the confluence of several smaller ones. The larger epithelioid cells lie in the meshes of the reticulum nearest the giant-cells; they are rounded, oval or somewhat polygonal cells, 6 to 8 ten-thousandths of an inch in long diameter, composed of a finely granular protoplasm, and containing one to four or more rounded or oval nuclei 3 to 6 ten-thousanths of an inch in diameter. Beyond these larger epithelioid cells the meshes of the reticulum are stuffed with a swarm of ordinary lymphoid elements, which forms the peripheral portion of the tubercle.

This description, drawn from tubercle of the lymphatic glands, was found by Wagner to apply to the tubercles of various other organs, among them, to tubercles of the intestine.* Substantially the same views of the minute anatomy of the ultimate tubercle-granulation have since been adopted by many histologists, among whom I may particularly mention Thierfelder and Friedländer.† The latter has gone so far as to affirm the tubercular nature of various quite local processes, such as lupus and certain skin ulcers, on the ground that they contain nodules such as have just been described.

As to the origin of the giant-cells there is considerable diversity of opinion. Virchow‡ suggested that those observed by him in certain tubercles were perhaps merely small lymphatic vessels filled with swollen proliferating endothelium, and seen in section; but confessed that he had been unable to demonstrate to his own satisfaction that such was actually the case. This view, rejected by Langhans, has been adopted as the most probable by Hering.§ Klebs|| has expressed the same opinion in a somewhat modified form; according to him the ultimate tubercle-granulations originate in the interior of small lymphatic vessels, the endothelium of which swells and proliferates, but the central portion at least of the giant-cell is probably formed by the coagulation of an albuminous substance contained in the lymph. Schüppel, on the other hand, seeks the origin of the giant-cells in the interior of the small bloodvessels; in a special essay on the subject,¶ he derives them from little non-nucleated masses of protoplasm, possibly coagulated fibrin, which are arrested in the minute vascular twigs, and in which nuclei subsequently arise. An origin

* E. WAGNER—second paper cited in note ||, p. 589, *supra*. He found the giant-cells, &c., in many of the ultimate tubercle-granulations in the vicinity of the intestinal ulcers.

† A. THIERFELDER—*Atlas der Path. Histologie*, I Lief., Leipsic, 1872, Taf. V, Fig. 2—gives a beautiful figure of the structure in question as seen in a miliary tubercle of the lung. C. § LANGHANS—*op. cit.*, p. 589, *supra*. THEODOR HERING—*Hist. und Exp. Studien über die Tuberkulose*, Berlin, 1873, S. 105: "Riesenzellen des Tuberkels höchst wahrscheinlich Lymphgefässdurchschnitten entsprechen."

|| KLEBS—*Ueber die Entstehung der Tuberculose und ihre Verbreitung im Körper*, Virchow's Archiv, Bd. XLIV, 1868, S. 286–289. KÜSTER—S. 114, *op. cit.*, p. 589, *supra*—also regards this view as highly probable, and intimates that it is supported by observations of his own, the publication of which was rendered unnecessary by the beautiful investigations of KLEBS.

¶ In an earlier essay SCHÜPPEL—*Zur Histogenese der Lebertuberculose*, Archiv der Heilkunde, Jahrg. IX, 1868, S. 524—derived the elements of tubercle from the white corpuscles of the blood, (S. 536,) but not the giant-cells, as has been erroneously asserted by BRODOWSKI, (S. 114, *op. cit.*, *infra*,) for he expressly declares that he found no giant-cells in tubercle of the liver. In his work on tubercle of the lymphatic glands, S. 92–94, *op. cit.*, p. 589, *supra*, he suggested that they might arise from the coalescence (verschmelzung) of endothelial elements or white corpuscles in the interior of the small bloodvessels; possibly a little mass of some coagulated albuminous body formed the central portion of the giant-cell. The views expressed in the text will be found in his essay *Ueber die Entstehung der Riesenzellen im Tuberkel*, Archiv der Heilkunde, Jahrg. XIII, 1872, S. 69; also Plate I.

from the small bloodvessels, though in a modified way, is also maintained by Brodowski,* according to whom a tubercle represents an aborted attempt at the new formation of a bloodvessel, and the giant-cells arise by the transformation of protoplasmic buds in the vascular walls. Meanwhile, according to others, especially Buhl and Rindfleisch,† the giant-cells, and with them the tubercles, may arise from any endothelial elements: from those that cover the surface of serous membranes and those that imperfectly line the lymph spaces of the connective tissue, (connective-tissue corpuscles,) as well as from those of the inner coat of the minute bloodvessels and lymphatics. Lastly must be mentioned the opinion supported by Ziegler,‡ on the basis of his ingenious experiments, that the giant-cells are derivatives of the white blood corpuscles.

The mere enumeration of these conflicting views is sufficient to awaken the suspicion that the observations by which they are supported are not of the most convincing kind, and a perusal of the several papers which have been cited confirms this view. Nor has the opinion that the giant-cells are especially characteristic of tubercle been received without opposition. To the fact, admitted by Friedländer,§ that they occur in morbid conditions not usually admitted to be tubercular, it must be added that they occur also in morbid growths which are certainly not of this nature; accordingly their significance as elements peculiar to tubercle is denied by many histologists, among whom I may particularly mention Klebs, Hering, Buhl, Rindfleisch, Brodowski and Max Wolff.‖ The French histologists have never accepted the doctrine of the giant-cells, but have either regarded their presence as of little importance, or have boldly declared that the name has been bestowed upon appearances which are properly to be interpreted as transverse sections through bloodvessels filled with coagula in which endothelial cells and lymphoid elements are entangled. In

* W. BRODOWSKI—*Ueber den Ursprung sogenannter Riesenzellen und über Tuberkeln im Allgemeinen*, Virchow's Archiv, Bd. LXIII, 1875, S. 113. He proposes for these little protoplasmic masses the term angioblasts or angioplasts, S. 126.

† BUHL—*Lungenentzündung, Tuberkulose und Schwindsucht*, 2te Aufl., Munich, 1873; I cite the Amer. Transl., New York, 1874, p. 97: "My view demands, then, only the existence at the point of irritation, of a pre-existing element from the series of connective-tissue corpuscles and endothelium, chiefly from the endothelium of the lymphatics and serous membranes, from which the new lymphatic growth may develop and become further organized." E. RINDFLEISCH—*Chronische und acute Tuberkulose*, in Ziemssen's Handb., Bd. V, Abth. 2, Leipsic, 1874, S. 163; I cite the Amer. Transl., Vol. V, New York, 1875, p. 644: "It has already been taught by many that the vascular connective-tissue system of the body is in general the tissue in which tubercles are developed. Within this system we must distinguish mobile and stable cellular elements. To the mobile elements belong the blood globules and the wandering cells; to the stable the endothelium of the blood-vessels and of the lymphatics, the epithelium of the serous membranes, and the fixed connective-tissue cells. It is from these latter elements, from the fixed cells of the vascular connective-tissue system, that the miliary tubercles, in my opinion, originate. Many of the more recent authors regard the formation of a giant-cell as always the first step. But I believe that a giant-cell is nothing but an endothelial or a connective-tissue cell enlarged, and with an increased number of nuclei." Compare, by the same, *Die chronische Lungentuberculose*, Deutsches Archiv für Klinische Medicin, Bd. XIII, 1874, S. 43. E. KLEIN—*The Anatomy of the Lymphatic System. II. The Lung*, London, 1875, p. 76—derives the giant-cells in lung tubercle from the alveolar epithelium.

‡ ERNST ZIEGLER—*Experimentelle Erzeugung von Riesenzellen aus farblosen Blutkörperchen;* vorläufige Mittheilungen, Centralblatt für die Med. Wiss., Jahrg. XII, 1874, S. 801 u. 913; also *Exp. Untersuch. über die Herkunft der Tuberkelelemente mit besonderer Berücksichtigung der Histogenese der Riesenzellen*, Wurzburg, 1875—inserted small glass plates 10–20 mm. long by 10 broad, to each of which a covering-glass of the same size was cemented, so as to leave a minute capillary space between the two, beneath the skin or periosteum, or into the cavities of the bodies of rabbits and dogs. The plates were left from 10–25 days, then removed, soaked for two days in a one per cent. osmic-acid solution, and afterwards immersed in glycerine. In all cases white blood corpuscles were found to have wandered between the glass and the cover; in some cases retrogressive changes had commenced in these; in others progressive changes had taken place, manifested in some instances by the development of connective tissue and bloodvessels, in others by the formation of a reticular tissue with epithelioid cells and giant-cells resembling in the most striking manner those of tubercle. He concluded from these observations that the giant-cells are formed out of the colorless blood corpuscles. Compare G. WEISS—*Ueber die Bildung und die Bedeutung der Riesenzellen*, Virchow's Archiv, Bd. LXVIII, 1876, S. 50—who derives the giant-cells formed around foreign bodies from the coalescence of "granulation cells."

§ FRIEDLÄNDER—*op. cit.*, p. 590, *supra*.

‖ Thus, KLEBS—S. 289, *op. cit.*, p. 590, *supra*—mentions having found them in a foot affected by elephantiasis. HERING—S. 106–7, *op. cit.*, p. 590, *supra*—declares that they occur in various new formations and pathological processes, and infers that their occurrence in tubercle is of no specific significance. BUHL—p. 93, *op. cit.*, note †, *supra*—declares that "there are tubercle-lymphoma in which we seek in vain for the giant-cells, at any stage of their existence; and in others, if a giant-cell develops early, it perishes later on, and in this way we may fail to find it. Again, it is difficult to discover genuine histological marks of distinction—that is, belonging to the cell itself, between other well-known giant-cells (for example, those on the inner surface of the periosteum, in growing bone, in myeloid sarcoma, true myoma, epithelial new growths, etc.) and those which we find in tubercle-lymphoma." RINDFLEISCH—pp. 644–5, Amer. Transl., *op. cit.*, note †, *supra*—declares that though he has often used these cells "as a sort of sign-post" in his studies of tubercle, "no special reliance can be placed on them. They occur in many non-tubercular new-growths," &c. BRODOWSKI—S. 127, *op. cit.*, note *, *supra*—found them in lupus, in syphilitic gummata, in the margins of chronic leg ulcers, in glanders (Rotzknötchen) of the human nasal mucous membrane, &c. The views of MAX WOLFF have been already mentioned: see note to p. 588, *supra*. Here, too, I may refer to the debate on the tubercle question in the Versammlung Deutscher Naturforscher und Aerzte in Wiesbaden, (1873,) Berliner Klinische Wochenschrift, Jahrg. X, 1873, S. 518, in which Virchow declared himself in the strongest manner against accepting the structure described by SCHÜPPEL as the criterion of tubercle.

the latest utterances of Cornil and Ranvier on the subject of lung tubercle I find this latter view maintained with considerable warmth.*

In view of the contradictory interpretations of the German histologists, it is not surprising that the opinion of Rindfleisch,† who regards the epithelioid cells rather than the giant-cells as the essential elements of tubercle, should have begun, as we learn from the communication of Max Wolff,‡ to find favor in many quarters in Germany. But Rindfleisch himself admits that the stage in which these large epithelioid cells, which he boldly designates "tubercle-cells," are produced is not always reached. According to him, their development represents the acme of the process, and hence their presence is hardly to be expected in the earlier stages of the growth.

As for the only other remaining cellular forms, the small round cells which are constantly present in tubercle, it is generally conceded that they possess no specific characters. The opinion of Buhl,§ that there are unmistakable differences between them and white corpuscles, or lymph cells, has not been generally accepted, and certainly does not correspond with my own observations. Nor can the specific characters, which have been vainly sought in the cells of the ultimate tubercle-granulation, be found in the reticulum, upon the existence of which so much stress has been laid by both Wagner and Schüppel. I cannot wholly agree with Friedländer,‖ who declares it to be a mere artificial product, only seen in chromic-acid preparations, and resulting from the action of that reagent, for, unlike him, I have quite frequently seen it well marked in preparations hardened by alcohol and mounted in Canada balsam. The reticulum is, however, far from being a constant element in tubercle. According to Buhl,¶ it is less and less marked the younger the growth, and is entirely wanting in the earliest stages, the cells being then in contact with each other. Whether this is a correct statement of the actual circumstances or not, the frequent absence of any reticulum in the ultimate tubercle-granulations has been noted by several observers, among

* The reader desirous of following the progress of recent French investigation of the histology of tubercle may consult especially: E. BOUCHUT—*Traité Pratique des Maladies des Nouveau-nés*, etc., 4me Éd., in which will be found an account of the histology of lung tubercles prepared with the collaboration of CH. ROBIN; see, also, 5me Éd., Paris, 1867, p. 367 *et seq.*; G. S. EMPIS—*De la Granulie*, Paris, 1865, p. 41 *et seq.*; HERARD et CORNIL—*De la Phthisie Pulmonaire*, Paris, 1867; CORNIL—*Du tubercule, spécialement étudié dans ses rapports avec les vaisseaux*, Archives de Phys., T. I, 1868, p. 98, (also Plate 2;) CORNIL et RANVIER—*Manuel d'Histologie Path.*, Partie 1, Paris, 1869, p. 199 *et seq.*; J. GRANCHER—*Étude sur le tubercule et la pneumonie caséeuse*, Archives de Phys., T. IV, 1871-2, p. 624, and Plate 22, Figs. 1-7; also by the same—*De l'unité de la phthisie*, Paris Thesis, No. 50, 1873. According to this author giant-cells are sometimes to be seen in tubercle-granulations; but "Elles n'ont pas une grande signification en ce qui touche l'origine du tubercule," p. 27. Some of them are possibly formed by the fusion (accolement) of several cells, or by the multiplication of the nuclei of a single cell, but others do not merit the name of giant-cells, they are mere intra-vascular coagula of an albumino-fibrinous nature. L. THAON—*Recherches sur l'Anat. Pathologique de la Tuberculose*, Paris, 1873, p. 14 *et seq.*—declares that he has vainly searched for giant-cells in tubercle: "We have seen, it is true, almost constantly in the interior of the granulations, figures quite similar to giant-cells, but these figures are to be referred to the transverse sections of vessels in which fibrin and round cells have accumulated," p. 16. - CORNIL et RANVIER—*Manuel d'Histologie Pathologique*, 2me Partie, Paris, 1873. See especially the account of tubercles of the bones, p. 377, the lymphatic glands, p. 596, and tubercular meningitis, p. 607; also 3me Partie, Paris, 1876, in which see especially the account of lung tuberculosis, p. 717 *et seq.*, intestinal tuberculosis, p. 850, tubercular peritonitis, p. 963, tubercles of the spleen, p. 993, kidneys, p. 1074, etc. These authors speak in no uncertain language: "The bloodvessels are always obliterated in tubercular nodules, and very often in the surrounding embryonic tissue. * * * The vessels seen in transverse sections exhibit their lumen filled with granular fibrin, and between this coagulum and the vascular wall a row of white globules and endothelial cells can be seen. White globules may also be entangled in the centre of the coagulum. In recent tubercles the wall of the vessel is readily distinguished; but if the centre of the tubercle has already undergone cheesy degeneration, this wall itself is altered and indistinct, it becomes indistinguishable from the cheesy tissue that surrounds it. If the preceding alterations were unknown, it would be impossible to say what the little granular nucleated mass, occupying an ill-defined cavity in the centre of the granulation, was due to. SCHÜPPEL has described these elements and the granular substance that surrounds them as giant-cells formed of a granular protoplasma and provided with nuclei. He regards them as characteristic of tubercle. But there are no giant-cells here, simply a coagulation of fibrin and cells previously formed, the nature of which we long ago indicated. After having hesitated as to their mode of formation, SCHÜPPEL, without citing our works, has ended by discovering that these pretended giant-cells are developed in the interior of the vessels," p. 719. On the other hand, CHARCOT, if I may judge from the abstract of his lectures on *Pulmonary tuberculosis and caseous pneumonia*—Med. Times and Gaz., Vol. I, 1878, p. 29—accepts the doctrine of the occurrence of giant-cells in tubercles, and the view of BRODOWSKI as to their origin. The former belief is clearly stated in his *Note sur la pneumonie caséeuse*—Bull. de la Soc. Anat. de Paris, An LII, 1877, p. 477—"On se rappelle que le tubercule, lorsqu'il est isolé, offre à son centre une cellule géante entourée de cellules epithélioïdes en dehors desquelles se voient de nombreux noyaux."

† RINDFLEISCH—p. 642-3, Amer. Transl., *op. cit.*, note †, p. 591, *supra*.

‡ MAX WOLFF—S. 251, *op. cit.*, p. 588, *supra*.

§ BUHL—p. 92, *op. cit.*, p. 591, *supra*. The only difference he mentions is that the tubercle cells and particularly their nuclei are smaller and more glistening: an appearance which I suppose is observed only after degenerative changes have commenced. At any rate, these characters are to be observed only in the central parts of the tubercles: the round cells in the peripheral parts differ in nothing from the lymphoid cells seen in other morbid processes.

‖ FRIEDLÄNDER—S. 516 note, *op. cit.*, p. 590, *supra*. ¶ BUHL—*loc. cit.*, note §.

others especially by Max Wolff. In the absence of specific characters in any of its elements, we can therefore as yet find no anatomical characteristics peculiar to tubercle, except the grouping of the elements in the form of the ultimate granulations and the marked tendency to central cheesy metamorphosis.

Since the publication of the researches of Wagner and Schüppel I have reëxamined the histology of intestinal tubercle, using for the purpose especially the alcoholic preparations in the Museum, from which I have had a considerable number of thin sections cut, stained with carmine and mounted in Canada balsam. Studied with a power of 250 to 500 diameters or upwards these preparations exhibited the following structural details: Those of the smallest, presumably the youngest tubercle-granulations in the submucous connective tissue, through the midst of which the sections had fairly passed, presented central figures $\frac{1}{500}$ to $\frac{1}{250}$ of an inch in diameter, or even larger. These, for the most part, were rounded or oval in form, and bounded by a distinctly recognizable external wall, like that of a small vein or lymphatic vessel cut across. The space within this boundary was generally filled with a granular or indistinctly fibrillated material resembling coagulated fibrin, entangling in its substance a number of cells; some resembling endothelial elements, and these usually lay on the periphery; others, and these the most numerous, ordinary lymphoid cells. Outside of the limiting wall of the central figure the granulation was made up of two kinds of cells: large, oval, nucleated cells, corresponding in size and form to the swollen endothelial elements seen in chronic inflammations of the submucous connective tissue of the intestine;* and a swarm of small round cells resembling ordinary lymphoid elements. The relative numbers of these two kinds of cells varied very greatly. The small round cells occurred sometimes in moderate numbers, chiefly on the periphery of the granulation; sometimes they infiltrated all parts of it, and were so numerous as to obscure the large oval cells, which, however, with a good immersion objective, could generally still be recognized between them. All these elements lay in the meshes of a fibrillated reticulum, continuous with the surrounding connective tissue, as shown in Fig. 37, which represents a very small tubercle-granulation from the submucosa of the ileum of case 413.

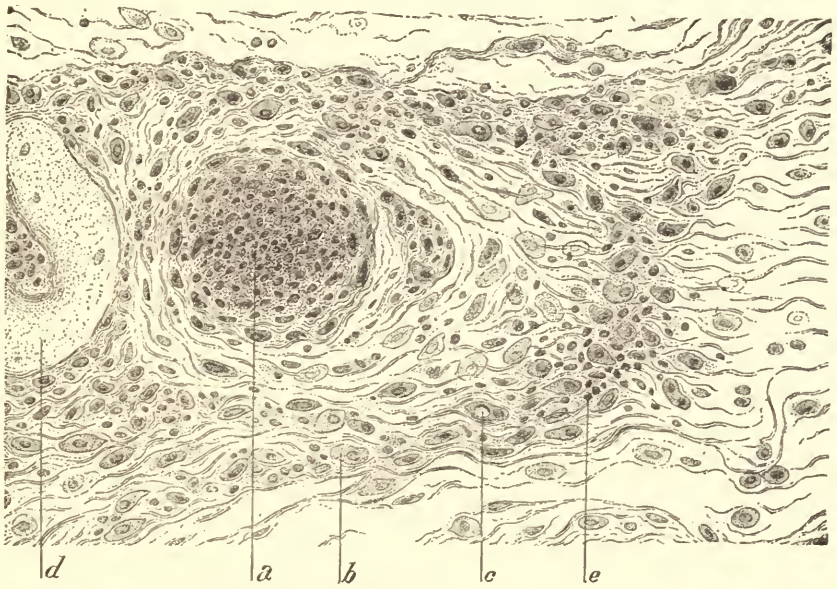

FIG. 39.—Small tubercle in the submucosa of the ileum. From the same case as Fig. 37. Magnified 370 diameters by Powell & Lealand's immersion $\frac{1}{12}$th. Copied from a photo-micrograph (Neg. 988, N. S.) of a part of No. 7541, Microscopical Section. *a*. Central figure (lymphatic) cut across; it is stuffed with granular fibrin, in which lymphoid elements, and on the periphery endothelial cells, are imbedded; indications of the limiting wall and of a small branch are also seen. In the space around the central figure are numerous granular nucleated endothelial cells like that indicated at *b*. In one of these cells, *c*, a vacuole has formed. There are also numerous lymphoid elements; a group of four is indicated at *e*. A small vein, *d*, passes through the margin of the tubercle. Traces of a fibrillated connective-tissue matrix are seen everywhere, outside of the central figure, between the elements.

* See pp. 326, 468–70 and 571, *supra*.

As to the significance of these parts, I incline to interpret, with Virchow, the central figure as a lymphatic vessel cut across,* rather than with Cornil and Ranvier as a bloodvessel. If a bloodvessel, it must be a small vein; for the walls are much too thin for an artery of the same diameter. But the veins in other parts of the sections show no particular indications of disease, while the lymphatics everywhere exhibit more or less tumefaction of their endothelial elements, which in many places are so swollen as almost or quite to fill the lumina of the vessels, giving rise in all parts of the sections not occupied by the tubercles to characteristic figures filled with large cells more or less polyhedral from mutual pressure. These may be seen in the submucosa, between the circular and longitudinal muscular coats, and in the subperitoneal connective tissue. When the section passes through them transversely or obliquely they appear as rounded or oval figures, as in Fig. 40; when it runs parallel to their course, as more or less elongated cylinders; in either case they are lined, or quite stuffed, with large granular oval or more or less polyhedral cells with large oval or round nuclei. Occasionally such a vessel may be encountered in which a part of the lumen is filled by what appears to be a small fibrin-clot adhering to one side of its wall, entangling in its substance endothelial and lymphoid cells, while similar cells lie free in the remainder, as in Fig. 41, on the next page.

FIG. 40.—Transverse section through the lumen of a diseased lymphatic vessel in the submucosa of the ileum. Same case as Fig. 37. Magnified 480 diameters by Powell & Lealand's immersion $\frac{1}{12}$th. Copied from a photo-micrograph (Neg. 986, N. S.) of a part of No. 7541, Microscopical Section. The lumen of the vessel was filled with a mass of large endothelial cells, *(a.)* between which a few lymphoid elements have crept. In preparing the specimen this mass has shrunk away from the wall of the vessel, leaving a space, *b*. In the neighborhood of this stuffed lymphatic the section passes through a venous radicle, *c*. The surrounding connective tissue is infiltrated with lymphoid elements and presents also a few large endothelial cells.

A larger fibrin-clot, completely filling the vessel and entangling similar elements in its interior, forms, I suppose, the round or oval figure seen in the centre of the young tubercle-granulation. It is easy to understand that some of these figures, if shrunken by the more potent influence of chromic-acid hardening instead of being hardened by alcohol alone, would bear a striking resemblance to the descriptions of giant-cells. Indeed I have seen, in sections of tubercular intestines thus treated, a number of figures which had this appearance, and in alcoholic preparations have occasionally encountered similar ones, but on carefully examining these with high powers have found them to be mere modifications of the conditions just described. I incline, therefore, to regard the so-called giant-cells, in intestinal and peritoneal tubercles, as figures resulting from the action of chromic acid on sections of lymphatic vessels stuffed with coagulated fibrin. The large endothelioid elements of the primary tubercle-granulation outside its central figure, I suppose to be formed by mere enlargement of the endothelial elements of the lymph spaces in the connective tissue. These elements are not always limited to the tubercle-granulations.

* The first speculation in this direction was that of SYLVIUS, who plainly taught—*Appendix*, Tract. IV, § 59, *op. cit.*, note ‡, p. 575, *supra*—that lung-tubercles originate by the enlargement of little lymphatic glandulæ, normally quite invisible to the naked eye. Nearer to the truth was the doctrine of BROUSSAIS—*Hist. des Phlegmasies*, 3me Ed., T. II, Paris, 1822, p. 1, *et seq.*—who held that phthisis originates from an "inflammation lymphatique" of the lungs, the tubercles being derived from the lymphatic capillaries of these organs. This latter conjecture finds a solid support in the observations of VIRCHOW, HERING and KLEBS—see p. 590, *supra*—and in the account of lymphangitis nodosa, given by RINDFLEISCH—*Lehrb. der path. Gewebelehre*, 3te Aufl., Leipsic, 1873, § 451, S. 378—as well as in the observations recorded in the text. I by no means suppose this morbid process to be the only one that gives rise to what are commonly called tubercles, or doubt that, under certain conditions, "giant-cells" may be formed in the testicle from the epithelium of the tubuli seminiferi—J. GAULE, *Anat. unters. über Hodentuberculose (Phthisis testis,)* Virchow's Archiv, Bd. LXIX, 1877, S. 221—or in the kidney from the tubuli uriniferi—*op. cit.*, S. 225—or from the epithelium of the lung-alveoli—see KLEIN, note †, p. 591, *supra*. Nor will I enter here into the question whether the term tubercle should be refused to these processes, as GAULE suggests; but may point out that a formation of tubercles having their origin in the lymphatics of the interstitial connective tissue, is also probable in all these cases. Compare, for example, in connection with the testis, MALASSEZ—*Note sur le siége et la structure des granulations tuberculeuses du testicule*, Archives de Phys., T. III, 1876, p. 56.

In several specimens in which the tubercle-formation was accompanied by a protracted intestinal catarrh I have found them in all parts of the submucosa. Figure 42, on the next page, shows the condition of the submucosa in such a specimen. The part selected for representation was situated at some distance from any of the tubercles.

The cheesy metamorphosis of the ultimate tubercle-granulations appears to commence in the contents of the central lymphatic, but it speedily invades the adjacent exterior elements, and then all trace of a wall is lost and the central portion of the tubercle appears simply occupied by a granular mass in which shrivelled nuclei are imbedded. This granular mass passes by gradual transitions into the part of the tubercle in which the elements are as yet unchanged; and in this transition-territory the round cells particularly are more or less shrunken and altered, so that they appear smaller and more highly refractive than the more peripheral ones in which degenerative changes have not yet commenced.

If the foregoing descriptions are substantially correct, the development of the ultimate tubercle-granulation would seem to be determined by the formation of a fibrin-clot obstructing a small lymphatic vessel. Around the vessel, at the point of obstruction, lymphoid cells accumulate in a group. According to this view the lymphoid cells are to be regarded as representing probably a swarm of migrated white corpuscles, while the large endothelioid elements are produced by the gradual enlargement of the fixed corpuscles of the area of connective tissue involved.

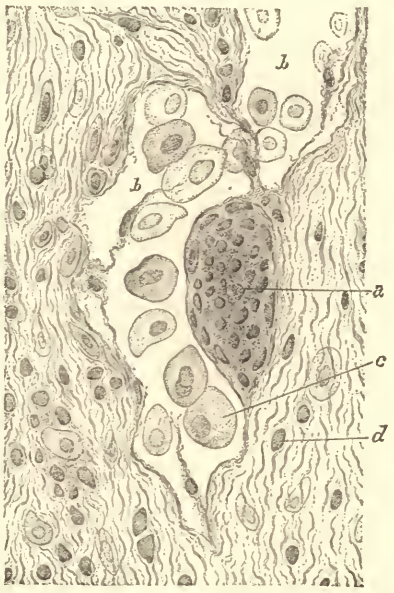

FIG. 41.—Section through the lumen of a lymphatic in the submucosa of the ileum. Same case as Fig. 37. Magnified 480 diameters by Powell & Lealand's immersion $\frac{1}{16}$th. Copied from a photo-micrograph (Neg. 985, N. S.) of a part of No. 7541, Microscopical Section. A granular fibrin-clot, *a*, in which both lymphoid and endothelial elements are imbedded, adheres on one side to the walls of a lymphatic vessel, in whose lumen, *b*, *b*, loosened endothelial elements lie free. Similar elements appear in the connective tissue surrounding the vessel, with a number of lymphoid elements, one of which is indicated at *d*. See p. 594.

If we seek for the momenta by which the process is determined, we are led at once into the realm of conjecture. According to Buhl* the necessary stimulus is supplied by those convenient bacteria which have played so conspicuous a part in modern pathological speculations. These circulate with the blood-stream, bore into the protoplasm of some doomed endothelial cell in the walls of a small vein, increase up to a certain point at its expense, and stimulate it to growth and nucleus-multiplication. This opinion appears to be based upon the erroneous supposition that the contents of the so-called giant-cells are actually spherical bacteria, which Friedländer, and especially Max Wolff,† have disproved by the use of reagents.

It is easier to conceive reasons for the central cheesy degeneration with which sooner or later the tubercle-granulation is inevitably smitten. This is generally accounted for by the fact that the nodules are never penetrated by blood-carrying vessels. No new formed vessels arise in their substance, and in any that may be embraced by their growth the circulation speedily ceases. This circumstance alone hardly suffices to account for the facts, for tubercles are often seen in which the central degeneration is well advanced, although

* BUHL—p. 115, *op. cit.*, p. 591, *supra*.

† FRIEDLÄNDER—S. 516, *op. cit.*, p. 590, *supra*—remarks: "The protoplasm of these giant-cells is characterized by a very homogeneous, tolerably dark granulation, which gives it, on superficial observation, some similarity to certain forms of bacteria colonies. A few investigaters have, therefore, without anything further, interpreted the dark granules of the giant-cells as micrococci; but the simple reaction of potash solution, which immediately dissolves the granules, especially on the application of moderate warmth, shows that this opinion is untenable." MAX WOLFF—S. 261 *et seq.*, *op. cit.*, note * to p. 588—has shown that the same result is produced by other reagents, especially acetic acid. He has also established the absence of actual bacteria or micrococci in any of the elements of recently formed tubercle.

the whole nodule is so small that the distance from its centre to the bloodvessels on the periphery is not greater than is found quite compatible with the nutrition of certain healthy tissues and of non-vascular morbid products in vigorous individuals. But when, in addition to this circumstance, we consider the diminished vitality which the elements of the new formation must share with the organism in which they arise, the result will not appear surprising. Be the cause what it may, central cheesy degeneration sometimes commences at a very early stage. Max Wolff* declares that he has seen tubercles composed merely of a little group of round cells, in the central portion of which the transformation to fatty detritus had already commenced. I have myself seen very small nodules, cheesy in the centre, on the periphery of which numerous small round cells, but none of the enlarged endothelioid elements, could be recognized, the degeneration having antedated their formation. The shrivelled nuclei which abide in the granular detritus produced by the cheesy metamorphosis are the so-called tubercle-corpuscles which were described by Lebert and Gluge† as specific elements, a doctrine which was widely accepted until it was shown by Virchow‡ that they may be produced by the caseous metamorphosis of almost any cellular mass, from the products of ordinary inflammation or even from sarcoma or cancer. In tubercle, as in these other cases, they are mere results of the process of necrobiosis.

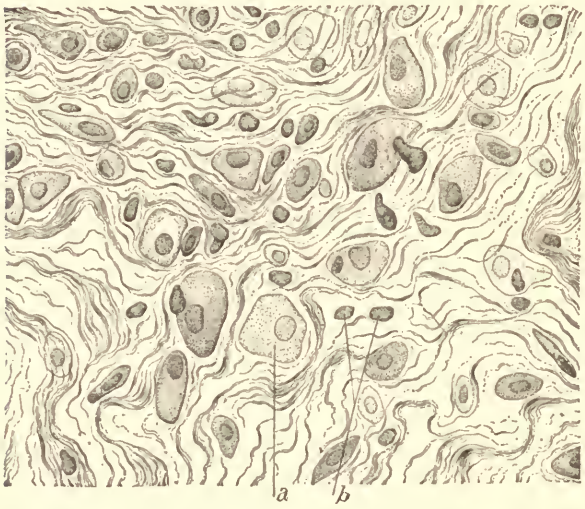

FIG. 42.—Portion of the submucosa of the ileum from the same case as Fig. 37. Magnified 480 diameters by Powell & Lealand's immersion $\frac{1}{25}$th. Copied from a photo-micrograph (Neg. 987, N. S.) of a part of No. 7541, Microscopical Section. In the meshes of the fibrillated matrix there are a number of large granular nucleated cells (transformed connective-tissue corpuscles, endothelial cells,) one of which is indicated by *a*, and numerous smaller lymphoid elements, two of which are indicated by *b*. See p. 595.

We have already seen that, when in the study of thin sections we approach the edges of a tubercular ulcer, the submucous connective tissue between the ulcers is found to become more and more infiltrated with a dense swarm of lymphoid elements, quite like those which occur in the vicinity of ordinary intestinal ulcers. It is easy in such sections to see that the enlargement of the tubercular ulcer is effected by a double process; in part by the dropping out into the cavity of the ulcer of the necrotic masses produced by the caseous metamorphosis of the tubercles; in part by liquefaction of the connective-tissue matrix and the floating off of the individual lymphoid elements as pus corpuscles, as has been described in connection with catarrhal ulcers of the intestine.§ The first of these processes produces the peculiar little cavities that give to the edges and bases of the tubercular ulcers the characteristic worm-eaten appearance which is so readily recognized by the naked eye. The small arteries in the vicinity of such ulcers often exhibit various degrees of the so-called amyloid degeneration, manifested by glassy swelling of the intima and indistinctness of the nuclei of the muscular coat. By the use of iodine the characteristic reaction is distinctly produced. I cannot,

* See note to p. 588, *supra*.

† G. GLUGE—*Anat.-mik. Untersuch. zur allg. u. spec. Path.*, Heft II, Jena, 1841, S. 181; also, by the same, *Atlas der path. Anat.*, Jena, 1850, Tuberkel: Taf. I, Fig. 9; Taf. III, Figs. 5, 6, etc.; Taf. IV, Figs. 7, 8, etc.; Taf. V, Figs. 3 and 17. H. LEBERT—*Phys.-path. Untersuch. über Tuberculosis*, Müller's Archiv, Jahrg. 1844, S. 190. See, especially, Abschnitt I, Mikroskopischer Bau der Tuberkeln; also, by the same author, *Phys. Pathologique*, Paris, 1845, T. I, p. 351 *et seq.*, and *Atlas* to the same, Plates VIII and IX.

‡ VIRCHOW—*loc. cit.*, p. 588, *supra*. § See p. 567 *et seq.*, *supra*.

nevertheless, in view of the evident participation of tubercle-formation in their production, agree with Colberg* in calling these amyloid ulcers. The amyloid degeneration appears here as a mere complication, the presence or absence of which has not been shown to exercise much influence on the progress of the disease.

What, now, is the behavior of the solitary follicles and the patches of Peyer during the progress of intestinal tuberculosis? In the specimens I have examined they have either been already destroyed by ulceration or converted into cheesy masses surrounded by a dense swarm of lymphoid elements. According to Klebs,† the tubercular process begins in the follicles as a simple swelling produced by the accumulation of lymphoid elements in the parenchyma of the follicles and the surrounding submucous connective tissue. Cheesy metamorphosis, commencing in the centres of the follicles, ultimately leads to their destruction and to the production of the primary tubercular ulcer. Rindfleisch,‡ who gives essentially the same account of the process, refuses, on account of these characters, to regard it as tubercular; according to him it is merely a form of scrofulous inflammation, and the undoubted tubercles in the vicinity are secondary formations originating by infection from the neighboring cheesy mass. Hering§ adopts substantially similar views. I must confess that I regard this interpretation with distrust; and, indeed, all the descriptions of the commencement of the process in the closed follicles are highly unsatisfactory, and further investigations are needed.

According to Wagner,|| the earliest tubercle-granulations do not make their appearance in the follicles, but, quite independently, in the lower portion of the glandular layer and in the submucous connective tissue just beneath the muscle of Brücke. These nodules are too numerous to be solitary follicles; moreover, the glands of Lieberkühn above them are not arranged as over these follicles, but quite as in the rest of the mucous membrane, except that they are often more or less shortened. With this description my own observations fully agree; but I have seen these conditions only in cases in which the closed follicles of the affected territory were already destroyed by ulceration,¶ so that the nature of the incipient process in the follicles is not explained by this observation.

Klebs has suggested that intestinal tubercles are produced by direct inoculation, the virus being supplied by the secretion from the diseased lungs, more or less of which is constantly swallowed by phthisical subjects. This is a plausible explanation, especially in view of the results of experiments in which tubercular ulcerations of the intestine seem to have been produced by feeding healthy animals with tubercular matter.** But this result is by no means uniformly attained, and moreover this explanation does not account for many of the other secondary deposits of tubercle which occur in cases of phthisis, as, for example, in the meninges of the brain, and in the peritonæum in cases in which the intestinal mucous membrane is not tubercular. If it be necessary to suppose an infection by way of the blood for these cases, why not explain in the same way those in which the intestinal mucous membrane is involved? A thorough discussion of these etiological questions would be out of place in this work, even did space permit; they must, therefore, be passed over with this brief mention.

5. Causes of Diarrhœa and Dysentery.

The evidence presented in the previous portions of this chapter will, it is believed, satisfy the reader that the phenomena of diarrhœa and dysentery result from various degrees of irritation or inflammation of the mucous membrane of the alimentary canal. Diarrhœa only, ensues from any degree of irritation that does not amount to actual inflammation. Simple inflammation, whether mild or severe, acute or chronic, with or without ulceration, also gives rise only to the symptoms of diarrhœa, so long as it does not involve the mucous membrane of the sigmoid flexure and rectum to such a degree as to produce tenesmus. When this happens the flux takes on the characters of simple inflammatory dysentery, which is most apt to be the case in the severer forms of the inflammatory process. The diphtheritic inflammation is anatomically, as has been shown, merely a more intense variety of inflammation, which, from the very fact of its intensity, gives to the resulting flux the characters of dysentery. The causes of diarrhœa and dysentery are therefore to be found in the conditions capable of producing irritation or inflammation of the mucous membrane of the alimentary canal. Hence, the attempt to group separately the causes of each variety of flux would lead to needless repetition. Even in the case of diphtheritic dysentery the determining momenta are to be sought chiefly in conditions which intensify and modify the inflammatory process. It seems, therefore, most convenient to discuss in order in this place the several causes which may give rise to irritation or inflammation of the intestinal mucous membrane, and to endeavor to point out in connection with each its relations to the several forms of flux.

These causes may be conveniently divided into two groups: those which act directly upon the intestinal mucous membrane, irritating or inflaming it; and those which produce the like result indirectly in consequence of their primary action upon some other part, or upon the general constitutional condition of the individual. This classification cannot be rigidly maintained, for we shall see that certain causes may act simultaneously in both

---

der Tuberculose, etc., Virchow's Archiv, Bd. LI, 1870, S. 290—had shown can be produced by the use of the milk of tuberculous cows, begins commonly with an intestinal catarrh, which lends next to tubercular affections of the mesenteric glands, and subsequently of other organs. This is no place to undertake a history of the voluminous, and in many respects contradictory, investigations into the question of the transmissibility of tubercle from individual to individual by inoculation or by feeding; nevertheless it seems proper to allude briefly to the subject. As is well known, modern interest in the matter was aroused by the now celebrated investigations of Villemin—*Cause et nature de la tuberculose*, Bull. de l'Acad. Imp. de Méd., T. XXXI, 1865–6, p. 211: second memoir, same title, same Jour., T. XXXII, 1866–7, p. 152. See also the report of the committee appointed to consider these two communications, same Volume, p. 897, and the report of the discussion which ensued, same Volume, p. 1160 *et seq.*, and T. XXXIII, 1868, p. 75 *et seq.* See also the larger work of Villemin—*Études sur la Tuberculose*, Paris, 1868. In the investigations that followed, while several observers obtained results which appeared to substantiate the conclusion of Villemin that general tuberculosis occurs in animals inoculated by tubercular matter, others arrived at the conclusion that similar lesions occurred when, instead of tubercular matter, any cheesy mass was used as the inoculating material, or from the introduction of substances neither tubercular nor cheesy, such as simple catarrhal sputa, or even bits of paper, charpie or India rubber. Among those who obtained these results were such trained observers as Burdon Sanderson—*Report on the communicability of tubercle by inoculation*, Tenth Report of the Medical Officer of the Privy Council for 1867, Appendix, p. 111: see, also, abstracts in the Trans. of the Path. Soc. of London, Vol. XIX, 1867–8, p. 456, and the British Medical Journal, Vol. I, for 1868, p. 388; Wilson Fox—*A lecture on the artificial production of tubercle in the lower animals*, same Volume, p. 499 *et seq.*, also The Lancet, Vol. I, for 1868, p. 649 *et seq.*; Cohnheim u. Fränkel—*Exp. Untersuch. über die Uebertragbarkeit der Tuberkulose auf Thiere*, Virchow's Archiv, Bd. XLV, 1869, S. 216; and Waldenburg—S. 403 *et seq.*, *op. cit.*, p. 575, *supra*. At a subsequent stage of the discussion several skilful histologists denied that the lesions obtained in these experiments were really tubercles, regarding them as local inflammatory nodules, and the whole process as allied rather to pyæmia than to tuberculosis. This opinion, boldly formulated by Friedländer—S. 530 *et seq.*, *op. cit.*, p. 590, *supra*—was more or less completely shared by Hering—S. 57, *op. cit.*, p. 591, *supra*—and Max Wolff—S. 254, *op. cit.*, p. 588, *supra*. Nor has the opinion, supported by Gerlach, Bollinger, Klebs and others, that tubercle can be communicated from one individual to another by the food, especially by the milk and flesh of tubercular animals, escaped similar contradictions. I may particularly refer to the negative results of the experiments of Roloff, Möller—Jahresbericht, Virchow u. Hirsch, Jahrg. IX, 1874, Bd. I, S. 709 *et seq.*—and Schreiber—*op. cit.*, Jahrg. X, 1875, S. 289. I shall express no views as to the merits of the controversy on this subject, but may remark that so plausibly has the affirmative view been urged, that in June, 1875, the *Deutsche Gesellschaft für öffentliche Gesundheitspflege* adopted a resolution declaring it to be their opinion "that the results of the inoculating and feeding-experiments with the flesh and milk of animals affected with tubercle justify the assumption of a danger of infection to man, and therefore merit the greatest consideration by the sanitary police." Berliner Klin. Wochenschrift, Jahrg. XII, 1875, S. 550. I refer the reader who desires to pursue the study of the questions referred to in this note to the work of Waldenburg—cited *supra*—for the literature prior to 1869, and, for the titles of subsequent memoirs, to the Jahresberichte of Virchow and Hirsch. A very readable review, presenting the subject as it appeared to many minds in 1874, has been published by George Fleming—*The transmissibility of Tuberculosis*, The British and Foreign Med.-Chir. Review, Vol. LIV, 1874, p. 461.

manners; yet it seems to suggest a convenient method of grouping the individual causes and will serve to keep their modes of action prominently in view.

FAULTY ALIMENTATION.—Among the causes which act directly upon the intestinal mucous membrane I shall first discuss the various unhealthy alimentary conditions, which unquestionably play a considerable part in the production of the intestinal fluxes; and here the various forms of improper *drink* are to be considered, as well as unsuitable, insufficient or badly cooked *food*.

BAD DRINKING WATER.—Impurities in the water used for drinking purposes have been reckoned among the causes of disease from the earliest times. We have already seen that Hippocrates,* who discussed this question at some length, attributed the diarrhœas and dysenteries, as well as the agues, of those who dwell in marshy districts to drinking the stagnant waters of lakes and ponds. This opinion was accepted by Galen,† in whose writings, also, two notable passages occur in which he affirms disease to have been produced in camps and armies by bad drinking water. According to Galen, the best water for drinking purposes is that which is devoid of any noticeable quality either to the sight, the taste or the smell; muddy waters should be clarified by filtration through porous earthenware vessels, the more subtly poisonous waters of marshes and stagnant ponds should be purified by boiling. The Arabian physicians also embraced, without questioning, the Hippocratic opinion that dysentery may be produced by drinking stagnant waters, as may be seen, for instance, in the Canon of Avicenna,‡ in which the observations of Hippocrates

* See note ‖, p. 398, *supra*. In the treatise on *Airs, Waters and Places, loc. cit.*, HIPPOCRATES treats quite fully of the various kinds of unwholesome drinking water and of the diseases supposed to arise from their use.

† GALEN—*Comm. III in Hippoc. de Humoribus Lib.*, § 20, [Ed. Kühn, XVI, p. 435]—cites with approval many passages from the Hippocratic treatise mentioned in the last note, among others that referring to the production of diarrhœas and dysenteries by drinking the stagnant waters of lakes and marshes. The two passages relating to army diseases produced by bad drinking waters, to which I have referred in the text, are the following: "Potest interdum quoque pravæ aquæ potus morbum omnibus communem efficere idque in castris evenisse memoriæ proditum est, quomodo et ob loci naturam, ubi omnes eodem loco castra metati permanserunt." *Comm. I in Hippoc. Epidem. I, Praefatio*, [Ed. Kühn. XVII, A, p. 9;] and again in another passage, after speaking of diseases resulting from eating semiputrid wheat, he adds: "Sed et exercitus quandoque dum pravis uterentur aquis, simili in omnibus militibus noxa vexatus est," *Comm. II in Hippoc. de Nat. Hom. Lib.*, § 3, [Ed. Kühn, XV, p. 119.] In neither of these passages does GALEN specify what the disease "common to all" the soldiers was. I have no doubt, however, that he meant camp dysentery, which had long before acquired the evil reputation of being *the* camp disease, which it has never since lost. Thus in the *Theætetus* of PLATO—*Opera Omnia*, Tauchnitz Ed., Leipsic, 1867, T. I, p. 193; also Cary's translation in Bohn's Classical Library, London, 1870, Vol. I, p. 369—*Euclides* says of his friend *Theætetus*, just brought back to Athens from the army then besieging Corinth: "He is in a bad state from several wounds, though he suffers more from the disease that is prevalent in the army." On which *Terpsion* asks: "Is it dysentery?" *Euclides*. "Yes." With regard to the purity of water GALEN says: "Judicentur autem hæ tribus sensibus, nempe gustu, visu et odoratu. Gustu pura est, si nullam offerat qualitatem, sed ad nnguem qualitatis expers appareat; visu pura est, quum sincera fuerit ac plane pellucida. Sic nec odoratu ullam præ se ferre qualitatem debet," &c., *De Simpl. Med.*, Lib. I, Cap. 5, [Ed. Kühn, XI, 399;] compare *De Sanitate Tuenda*, Lib. I, Cap. II, [Ed. Kühn, VI, 56.] The advice to filter muddy water, *e. g.*, that of the Nile, before drinking it, will be found in the treatise *De Simpl. Med.*, Lib. I, Cap. 4, [Ed. Kühn, XI, 389;] he advises that it should be percolated through porous clay vessels, and that if one filtration does not remove all the impurities the process should be repeated several times. Elsewhere GALEN mentions—*Comm. IV in Hippoc. Epidem.* VI, Sect. IV, § 10, [Ed. Kühn, XVII, B, p. 155]—that he had seen water exposed in porous clay vessels for the purpose of cooling it, both in Alexandria and throughout all Egypt; so that the practice of filtration, also, is probably of Egyptian origin. The advice to boil the water of marshy pools before drinking it will be found in *Comm. III in Hippoc. de Humoribus Lib.*, § 3, [Ed. Kühn, XVI, p. 362;] he explains that after boiling, the impurities promptly settle, and the supernatant clear water can be decanted and drunk with impunity. GALEN mentions further that the quality of water may be modified by herbs growing in it or metals dissolved by it. The former may produce either beneficial or injurious effects, according to the nature of the herbs; the latter are always injurious, *loc. cit.* As a striking example of the bad effect of such waters, he elsewhere particularly specifies water which has been carried in leaden pipes; such waters contain poisonous matters dissolved from the lead, and those who drink them become dysenterics: "Quæ per plumbeos canales derivatur, fugienda erit; limus enim quidam ex plumbo in ea continetur. Unde etiam qui aquæ ejusmodi faecem combibunt dysenterici evadunt," *De Compos. Med. Secundum Locos*, Lib. VII, Cap. 2, [Ed. Kühn, XIII, p. 45.] This passage will serve to illustrate in how broad a sense the word dysentery was sometimes used by the Greek physicians, who, at times, designated by it almost any painful affection of the intestines.

‡ AVICENNA—*Canon*, Venitiis, 1595, apud Juntas, Lib. I, Fen 2, Doctr. 2, p. 114, Cap. 16, De dispositionibus aquarum. See, with regard to the production of dysentery by drinking stagnant waters, p. 116. With regard to the modes of purifying water mentioned in the text, see Lib. I, Fen 4, Doctr. 5, Cap. 7, De conservando iter agentem a nocumentis aquarum diversarum, p. 194. After mentioning filtration and boiling, I find the following passage: "Et majus hoc toto est, ipsam sublimando distillare. Est etiam, quum ex lana retorta fit lychinium, cujus una extremitas in vas plenum ponitur, altera in vas vacuum: et guttatim aqua ad vacuum dilabitur." I am a little at a loss to interpret the first sentence, but suppose the second to show its meaning. The annotators add to this chapter, after stating that it sets forth several modes of purifying water: "Sublimationem addit eam, quæ distillatio per filtrum dicitur inventum Arabum." AVICENNA further recommends that bitter and bad waters be boiled, that while boiling some clay be thrown in, and then to use the twisted wool as above directed. He commends also the admixture of wine to remove the bad qualities of water, and admixtures of vinegar, etc. Alum (alumen jameni) he particularly recommends for turbid waters. The alum method is still in use; see PARKES—*Manual of Practical Hygiene*, 4th Ed., London, 1873, p. 27—as to its modern employment. Compare RHAZES—*Ad Mansor. de Re Med.*, Lib. III, Cap. IV, in Opera, Basil, 1544, p. 58—"Turbida autem aqua, in hepate oppilationem, et in renibus lapidem generat. Salsa etiam aqua, prius ventrem solvit, postea vero stringit, si quis eam consuete biberit, corpusque desiccat, in quo scabiem atque rhagadias generat. Aqua vero stans et putrida, splenem augmentat, ac complexionem corrumpit et generat febres."

and Galen with regard to drinking waters of various kinds, and their real or supposed morbific influences, are repeated at length, with, however, some important additions to the methods of purifying bad water. Besides purification by filtration and boiling, we read here of the use of a wick of twisted wool, one end of which is to be introduced into a vessel full of water, while the other end hangs over into an empty vessel, into which the purified water will fall drop by drop. So also we find mention made of the use of alum to purify water, and of the admixture of wine for the same purpose.

These references will serve to show that the attention of the medical profession has been critically directed from the earliest times to the real or supposed influence of bad drinking water in the production of disease, but it is only within comparatively modern times that the methods available for the chemical examination of waters have reached such a degree of approximate accuracy as to elevate inquiries of this class to the dignity of scientific investigations. I shall not attempt in this place to give an account of the various expressions of opinion on this subject, which can be found in medical literature from the time of the invention of printing to the commencement of the present century. These opinions were usually mere repetitions of the utterances of Hippocrates and Galen, or vague generalizations such as Sennertus* uses when he enumerates too abundant or vicious food and drink among the external causes of diarrhœa. Even the army surgeons, prior to the present century, for the most part laid but little stress on bad water as a cause of intestinal fluxes, or denied its influence in toto; Sir John Pringle and Donald Monro have been erroneously referred to as believing bad water to be a cause of dysentery.† Any detailed examination of the modern literature of this subject is precluded by the great space which it would necessarily occupy, and I must, therefore, limit myself to a very brief presentation of the evidence which at the present time is regarded as connecting certain impurities of potable waters with the production of intestinal fluxes. The impurities to which this effect has been assigned may be of inorganic, vegetable or animal origin, and may be merely suspended or actually dissolved in the fluid. A particular water may be rendered unwholesome by the excess of any one of these impurities, or several of them may coexist.

Inorganic substances in suspension.—The water of certain streams, as, for example, that of various great rivers, is often turbid with mud, clay or other undissolved inorganic impurities; and this is especially the case during the floods which follow heavy rains, or the melting of snow in the highlands and mountains of the water-shed during the spring of the year. The use of such water, which was supposed by the Greek physicians‡ to produce kidney disease and stone in the bladder, has of late been accused of causing intestinal

* SENNERTUS—*Pract. Med.*, Lib. III, Pars 2, Sect. 2, Cap. 6, Opera, Paris, 1641, T. III, p. 115: "Cibus et potus copiosus vel vitiosus."

† Thus, for example, PARKES—*Manual of Practical Hygiene*, 4th Ed., London, 1873, p. 41—remarks: "Dysentery also is decidedly produced by impure water, and this cause ranks high in the etiology of dysentery, though perhaps it is not the first. Several of the older army surgeons refer to this cause. Pringle does so several times, and Donald Monro in the campaigns in Flanders and Germany." I could well wish that this passage had been accompanied with references to the places cited, especially as both the writers named appear to me to have exercised extreme caution in their expressions of opinion on this subject. Sir JOHN PRINGLE—*Obs. on the Diseases of the Army*, 7th Ed., London, 1774, p. 91—remarks that the water commonly used by the English army in Flanders was "plentiful and good. The only exception worth notice was in Zealand, where the water being indeed less pure, it might concur with other causes in making the sickness more general in that province. But in most other places our water was blameless, and particularly in the two seasons during which the bloody-flux was most epidemic. To conclude, whoever will give attention to the account of the several campaigns, will see such an uniformity in the rise and periods of the diseases, and that so much connected with the state of the air, as will be sufficient to convince him, that neither the abuse of spirits, nor of fruit, nor drinking bad water, could have any considerable share in producing them." Indeed, when he treats particularly "of the causes of the dysentery," Part III, Cap. VI, p. 251, he does not so much as mention the drinking water. Nor do I find that any such views as PARKES has attributed to him were expressed by DONALD MONRO—*Account of the diseases which were most frequent in the British Military Hospitals in Germany*, &c., London, 1764, p. 57; also, *Obs. on the Means of preserving the Health of Soldiers*, &c., London, 1780, Vol. I, p. 314—who does not even so much as mention bad water in his account of the causes of dysentery, which he attributed to the effect of moist putrid vapors, or to "an obstructed perspiration joined to a putrescent acrimony of the blood, or of the bile or other gastric liquors arising from heat and motion."

‡ See, for example, HIPPOCRATES, *op. cit.*, in note *, p. 599, *supra*, and GALEN—*Comm. III in Hippoc. de Humor. Lib.*, § 20. [Ed. Kühn, XVI, p. 438.] They also attributed hip-joint disease and even hernia to the same cause.

fluxes. The opinion expressed by Wm. A. Hammond,* that the waters of the Mississippi, the Missouri, the Kansas and the Rio Grande produce diarrhœa in those who drink them, particularly if unaccustomed to their use, has been brought forward by Parkes, and after him by Roth and Lex,† as testimony in favor of this view. We learn from Chapman‡ that it was popularly believed in 1836 that the use of the water of the Mississippi for drinking purposes produced diarrhœa; and I occasionally hear the same opinion expressed verbally at the present time. Those said to have been affected are generally strangers, who, shortly after arriving at Cincinnati, St. Louis, New Orleans or some other western city, are attacked with diarrhœa, which forthwith, without further evidence, they ascribe to the drinking water of the place.

The sagacious Drake§ has recorded his testimony in the most unqualified manner against this view. He declares that even in the case of the turbid waters of the Missouri, and of the Mississippi below the point of its influx, the testimony of the population on its banks, and of the boatmen who ply their craft on the stream, is unequivocally favorable to its use, and that its salubrity cannot be regarded as an open question. This testimony of Drake, based upon the laborious inquiries instituted by that faithful observer among the physicians of the villages and towns that dot our western waters, is not contradicted by any statistical facts with which I am acquainted. The chart illustrating the geographical distribution of the mortality from diarrhœa, dysentery and enteritis, according to the census of 1870, to which I have already referred,‖ shows no relationship between the mortality from these diseases and the water-courses. Nor do I find, according to the census reports for the same year, or those for 1860 and 1850, that the states which border on the Mississippi, the Missouri or the Kansas have, as a rule, any greater mortality from diarrhœa or dysentery than other states.¶ I have vainly examined the reports of the

* W. A. HAMMOND—*A Treatise on Hygiene*, Philadelphia, 1863, p. 218: "The earthy matters which are so abundant in some of our western river waters almost invariably cause diarrhœa in those who are unaccustomed to their use, though this effect gradually ceases to be produced if the drinking of the water is persisted in. I have very frequently known the water of the Mississippi, the Missouri, the Kansas, and the Rio Grande give rise to severe diarrhœa, continuing for several weeks, and occasionally terminating in ulceration and death. Even in persons who can at ordinary times drink the water of these rivers with impunity, frequent intestinal discharges are produced when floods have caused an increased quantity of earthy matters to be held in suspension." This opinion, which is merely expressed *ex cathedra*, without bringing forward any evidence in its support, I suppose to have been based upon the occurrence of diarrhœa among soldiers at military posts, on the streams in question, of which the writer was post-surgeon. But in such cases a variety of other causes may have been more influential in determining the result.

† E. A. PARKES—p. 38, *op. cit.*, note ‡, p. 599, *supra*. W. ROTH und R. LEX—*Handb. der Militär-Gesundheitspflege*, Bd. I, Berlin, 1872, S. 23. According to the preface, this work was originally commenced as a translation of the 3d edition of the *Hygiene* of PARKES, but subsequently much enlarged.

‡ N. CHAPMAN—*Loc. cit.*, note **, p. 401, *supra*.

§ DANIEL DRAKE—*Principal Diseases of the Interior Valley of North America*, Cincinnati, 1850, p. 72: "The salubrity of the Mississippi water, or that of the Missouri, which imparts the character of turbidness, is not an open question. From St. Louis to New Orleans, the testimony of the population on its banks, and of those who spend a great part of their lives upon it as watermen, is unequivocally in its favor. Many persons drink it before its suspended materials have subsided, and seem to prefer it to that which has been rendered transparent by time or art. That it produces some effects on the system, which transparent water, from wells and springs, and our other rivers, does not, is an established popular opinion. It is even regarded by many persons as being, to a certain extent, medicinal, and especially adapted to the cure of chronic functional disorders of the stomach, bowels, and liver—an opinion in which I am disposed to concur. That its daily use averts some forms of disease, may be admitted as probable; but precise observations on all these points are wanting." Elsewhere, in the same work, DRAKE testifies (p. 662) that "in most of the larger towns and cities" of the great interior valley of the United States, as Pittsburgh, Detroit, Cincinnati, St. Louis and New Orleans, the people drink river water. It stands in reservoirs, exposed to the air and sun, "until it has deposited a part of the earthy matters suspended in it; but, in floods, when the quantity is great, it is sometimes distributed and drunk while it is yet turbid. Besides the matters thus suspended, but heavy enough to be deposited, there are traces of muriate of soda, and carbonate and sulphate of lime, in solution; and, from the vast amount of dead vegetables and animals on their banks, it can scarcely be doubted that they contain, in suspension, or solution, or both, a minute quantity of organic matter. Still, while some constitutions may never become reconciled to the use of river water, I am not in possession of facts to show that it produces or averts any serious disease. The water in St. Clair, Detroit, Niagara, and St. Lawrence Rivers, is strictly that of the lakes, and approaches nearer to the character of rain water than that of our rivers. The water of the Missouri and lower Mississippi, again differs, as we have seen, from that of the upper Mississippi, of the Ohio, and of their tributaries, in the great amount of suspended materials. Notwithstanding, but rather in consequence, it is universally regarded as salubrious, and even, by many persons, alterative and medicinal; especially in chronic ailments of the abdominal viscera. To produce any effects of this kind, it should, no doubt, be drunk immediately from the river, and before it has undergone clarification by deposition, or by any artificial process." This testimony is supported by the opinion expressed by BENNET DOWLER—*Psychological and hygienic observations and reflections on rivers*, The New Orleans Med. and Surg. Jour., Vol. XVIII, 1861, p. 56—that "the expensive chemical processes, which, by the way, are of dubious salubrity, now practised for the deodorization of rivers, the Thames, for example, is not required for the sweet, odorless, and potable waters of the lower Mississippi."

‖ See p. 419, *supra*.

¶ See note * to p. 420, *supra*.

boards of health of the cities of St. Louis and New Orleans.* whose water supply is derived from the turbid Mississippi, for opinions unfavorable to the use of this water for drinking purposes, or for facts in any way indicating that it produces intestinal fluxes. I find in the reports from both cities earnest protests against the use of the impure water of wells dug within the city limits, but no voice raised against the river water. Nor is there any apparent connection between the spring floods, with the resulting increase in the turbidity of the river, and the monthly fluctuations in the mortality of the intestinal fluxes or of the number of cases treated at the city expense, so far as can be ascertained by the statistical tables contained in these reports. So, too, I have vainly examined the official publications of the medical department of the United States Army, edited by Forry, Coolidge and Billings,† for expressions of opinion with regard to any injurious effects from drinking the waters of muddy rivers, though several medical officers in their reports contained in those works give instances in which the dissolved impurities in the waters of certain rivers, springs and wells are supposed to have caused diarrhœa.

Parkes makes a statement with regard to the water of the Ganges similar to that just discussed in connection with American rivers, but cites no authority for his opinion, which is contrary to the officially reported testimony of Medical Inspector General James Anderson and the observations recorded by Stewart Clark.‡ The same writer cites two interesting statements in support of the view that drinking water turbid with suspended mineral matters produces intestinal fluxes. One is the old observation of Lempriere,§ that the bowel complaints in Jamaica increased after the spring floods, when the water contained "a

* I have examined for this purpose the reports from each city for nine years, viz: *First Annual Report of the Board of Health of the City of St. Louis* for the year ending Dec. 31, 1867; 2d ditto, for 1868; 3d ditto, for 1869; 4th ditto, for 1870; 5th ditto, for 1871; 6th ditto, for 1872; 7th ditto, for 1873; 8th ditto, for 1874; 9th ditto, for 1875; *Annual Reports of the Board of Health to the legislature of the State of Louisiana* for 1867, 1868, 1869, 1870, 1871, 1872, 1873, 1874 and 1875. I note that J. W. CLEMENS, in the 2d St. Louis Report, p. 30, expresses the opinion that, "strange as it may seem," the mud of the Mississippi river "acts in an efficient manner as a purifying agent, so that the settled water is really purer than if it had previously contained no mud." He thinks the use of the "unsettled or unfiltered" Mississippi water "unadvisable," but makes no suggestion with regard to the nature of the injurious effects, if any, likely to result therefrom. In the Louisiana Report for 1873, p. 17, after a comparison of the impurities of the Mississippi water at New Orleans, as ascertained by analysis, with those of the Hoogly at Calcutta, as officially reported, I find the following passage: "The Mississippi water, unfiltered, is much purer and safer to drink than the filtered water of the Calcutta river, for the average amount of animal matter, [meaning the albuminoid ammonia as determined by Nessler's test,] which is the worst impurity in drinking water, is much less. The suspended matter, clay and mud, is far greater in amount, but is not particularly unwholesome."

† FORRY and COOLIDGE, cited on p. 416, *supra*. The report edited by Surgeon J. S. BILLINGS, U. S. A., to which I refer, is *Circular No.* 8, War Department, Surgeon General's Office, May 1, 1875. *A Report on the Hygiene of the United States Army, with descriptions of military posts*, Washington, 1875. I note that in the first statistical report of COOLIDGE, p. 364, Assistant Surgeon G. E. COOPER expresses the opinion that the diarrhœa occurring at Fort Duncan is "probably attributable to the saline waters of the Rio Grande," attaching the supposed injurious effect to the dissolved rather than to the suspended mineral matters of the stream. In *Circular No.* 8, p. 296, Assistant Surgeon S. S. JESSOP, U. S. A., reports from Fort Selden, New Mexico, which is supplied with drinking water from the Rio Grande: "I may observe that all cases of chronic diarrhœa appear to do badly at this post, and that, with my present convictions, I would not suffer, if it could be avoided, a patient laboring under this disease to remain at Fort Selden, or any point where the Rio Grande constituted the water-supply." Here the water is blamed without specifying which of its ingredients is supposed to be at fault. But I must point out that the consolidated sick report from Fort Selden for four years prior to June 30, 1874, published on the page opposite to this remark, does not indicate any greater proportion of diarrhœa and dysentery at that station than is shown in the same volume to have existed during the same time at many of the posts whose water supply has never been accused. Indeed, I may add that during the four years represented in this volume the average proportion of cases of diarrhœa and dysentery to strength at the posts on the Rio Grande is less than that which existed during the same period at David's Island, Fort Columbus, or Fort Hamilton, New York harbor, or even at Fort Ontario, New York.

‡ See PARKES—p. 38, *op. cit.*, p. 599, *supra*. Now Deputy Inspector-General JAMES ANDERSON—*Royal Commission on the Sanitary State of the Army in India*, Vol. II. Appendix; Answers, Fort William, Calcutta, p. 11—affirms that the water of the Hooghly river from off Fort Point "is soft, and its quality good, and not injurious to health." He admits that the river water is "unsuitable for six weeks annually" from its muddiness, but does not attribute any disease to its use. STEWART CLARK (Inspector-General of Prisons, Northwest Provinces, India)—*Practical Observations on the Hygiene of the Army in India*, London, 1864, p. 78—in speaking of the water of the Hooghly at Calcutta, declares that "we have no positive proof that the water is injurious to health to the extent some authorities would wish us to believe. Were it so, few of the ships which arrive at Calcutta would ever leave it again; for nine-tenths of the crews would be poisoned by the water." He goes on to show the general use of this water, often unfiltered, by the shipping at all times, and points out the imperfect character of the method of filtration usually resorted to; after which he relates that he had four times accompanied detachments of European invalids from Calcutta to England, and found that even in the case of chronic bowel complaints the cause of anxiety diminished the longer the ship was at sea, although the patients were still drinking the Ganges water with which the ship's tanks were filled.

§ WM. LEMPRIERE—*Pract. Obs. on the Dis. of the Army in Jamaica*, London, 1799, Vol. I, p. 25—after mentioning the increase of fluxes in May, after the floods, adds: "Much pains were taken by myself, and other medical gentlemen, to ascertain what share this water might have in the production of bowel complaints: on this account the commanding officer of the regiment to which I was surgeon (at my recommendation) purchased drip stones, for the purpose of affording the men an opportunity of using pure water for their common drink. Upon trial, we did not find any material difference in the number of cases that came under our care, so that we naturally attributed the principal cause of the disease to arise from a damp atmosphere." He also remarks that after the rains the air became hot, oppressive, and induced general relaxation.

quantity of filth and dirt, forced down by the heavy rains," but it must not be forgotten that Lempriere himself submitted the speculation, in support of which his views are now cited, to the test of experiment; he filtered the turbid water supplied to the men, and found that no diminution in the number of cases of bowel complaints resulted, whence he wisely concluded that they must have some other cause. The other is the ingenious report of Whitwell,* who imagined the hill diarrhœa of Dhurmsala to be produced by very fine scales of mica, suspended in the drinking water, which acted as irritants to the intestinal mucous membrane. A perusal of his report, however, leads me to regard the evidence adduced in favor of this conjecture as inconclusive; nor do I find any other testimony in its favor, or indeed any in favor of the opinion that fluxes ever result from the use of muddy drinking water, in the elaborate official reports on water analysis in Bengal,† in one of which Whitwell's essay was published.

The inorganic matters in suspension in the waters of great rivers, when turbid with mud, are for the most part quite insoluble, and can only be supposed to produce fluxes in consequence of mechanically irritating the intestinal mucous membrane. If this were the effect of the ingestion of such substances, the experimental administration of similar quantities of clay and mud ought to produce similar results. This experiment was tried by Grellois,‡ who, for fifteen days, swallowed daily two grammes of earthy matter taken from the banks of a stream, but without any appreciable effect upon his health.

On the whole, then, notwithstanding the opinions to the contrary which have been expressed in certain quarters,§ I have been led by my examination of this subject to the conclusion that the injurious effects of suspended inorganic matters in drinking water have been grossly exaggerated, if, indeed, they are not altogether imaginary. Of course muddy water may also contain other impurities of such a character that it may unmistakably cause fluxes in those who drink it. But in most of the instances in which the turbidity

* Assistant Surgeon H. WHITWELL—*Second Report on the Water-Supply of Dhurmsala*, in the Eighth Report of the Analysis of Potable Waters of Cantonments in the Bengal Presidency, by F. N. Macnamara, Calcutta, 1871, p. 43—arrived at the conclusion that the diarrhœa which prevails at Dhurmsala "is due to the minute scales of silica and mica, which accumulating in the vicinity of the rocks from which the springs emerge, formed by the action of the atmosphere on the rocks leading to a slow disintegration, become washed down in the different water-courses, and being swallowed set up by mechanical irritation, the peculiar symptoms of hill diarrhœa." He shows that when this water is boiled the mica scales are "entangled in the other foreign matters present" and precipitated, and recommends that the drinking water of the station be thus treated as a prophylactic measure. He states, in support of this view, that "in two cases of obstinate diarrhœa, which all previous treatment had failed to benefit, a perfect cure followed the continued use of boiled water, a relapse following immediately the water was not boiled;" that in the case of a particular family, "a perfect immunity from the disease has been obtained by a rigid adherence to boiled water;" and that he himself "obtained perfect and speedy relief by boiling the water" he used, and "when puzzled one day by a relapse, apparently without cause," ascertained that he had been supplied with unboiled water. Now evidence of this character would certainly sustain his position, if there was enough of it, but the experience of three patients and one family will hardly settle a question of this kind. When, in further support of this speculation, he points out that those of the inhabitants of the station whose drinking water contained most organic matter suffered least from the diarrhœa, he proves only that the organic matter of the drinking water cannot be charged with causing the diarrhœa of this station; but the argument which he places foremost, and on which he appears chiefly to rely in support of his view, appears to me a striking example of the *non sequitur*: "Every circumstance connected with the disease would serve to show that it is one due to mechanical irritation; commencing as diarrhœa it speedily proceeds, if not arrested, to dysentery and death; and it is confessed that the usual remedies employed in diarrhœa and dysentery produce no effect whatever on this variety. The post-mortem examination of those who die of the disease also supports it, for almost invariably congestion and ulceration of the mucous membrane of the intestines were to be observed, and these appearances were also noted in those dying from fever with great biliary derangement.' This description, which would be of equal accuracy and force if applied to the diarrhœa of Cochin China, in support of the speculation of NORMAND that it is caused by an anguillula, [see p. 372, *supra*,] might be repeated wherever chronic fluxes prevail, even at stations where mica scales in the water are quite out of the question.

† I have examined for this purpose both the *Reports on the Water Analysis in Bengal*, from 1857 to 1871, and the *Answers* to the questions propounded by the *Royal Commission on the Sanitary State of the Army in India*, Vol. II, Appendix. I may mention, however, in this connection, the statement made by BARRALLIER—Art. *Dysenterie*, Nouv. Dict. de Méd. et de Chir. Pratiques, T. XI, Paris, 1869, p. 720—on the authority of an inedited note by C. SENELLE, that the marines occupying barracks in the quartier d'Orléans (La Basse-Terre, Guadeloupe) were formerly supplied with water from the river Dugommier by means of a canal which commenced some distance up the mountain in order to secure its purity. The water, however, contained a good deal of inorganic matter, ("une grande quantité de résidus salins.") These men suffered frequently from severe dysentery until cisterns were formed and rain water supplied, after which the disease almost entirely disappeared, and the few cases which occurred were no longer as grave as formerly. Unfortunately we have the testimony of Dutrouleau that a similar experiment tried at St. Pierre (also in the French Antilles) was quite unsuccessful; p. 564, *op. cit.*, note *, p. 551, *supra*.

‡ GRELLOIS—*Études hygiéniques sur les eaux potables*. Rec. de Mém. de Méd. de Chir. et de Pharm. Militaires. T. II, 1859, p. 134.

§ See, besides the authorities already cited in favor of the supposed injurious effects of muddy drinking water, the work of C. KIRCHNER—*Lehrb. der Militär-Hygiene*, Erlangen, 1859, S. 101—and various other text-books which repeat the assertion as an established fact without appearing to think it at all necessary to adduce proofs in its support.

of the water has been blamed, I suspect that much more serious morbific influences coexisted and were the real causes of the disease. This appears to me to have happened during the civil war in the case of those fluxes which occurred among the troops on transports on the lower Mississippi. I have not unfrequently heard the opinion expressed in conversation that they were caused, in part at least, by drinking the turbid water of the river, and the same view is maintained in a few of the reports in Section II.* But I must believe that the evidence I have just presented vindicates the harmless character of the water of that stream, and that the fluxes which occurred among the troops on transports during the operations in question were due to the same causes that produced the equally numerous and fatal fluxes among their comrades in camp in various parts of the Central Region.

Inorganic substances in solution.—The evidence connecting certain inorganic impurities in solution with looseness of the bowels is of a much stronger character. The purgative effects of the waters of many mineral springs are well known, and on this account they have long been employed for remedial purposes; but the precise effect of the various ingredients of this class, which exist to a minor extent in all river and spring waters, and the precise quantities in which they first begin to act injuriously, are by no means so accurately ascertained as could be wished. A definite quantity of saline ingredients in the drinking water is probably desirable, if not indispensable, to the perfect health of the consumers, and where, as in the case of rain water or water collected by distillation, the supply is deficient in this respect, it has been proposed to add a small quantity of saline matter, especially bicarbonate of lime, before using it for drinking purposes. Our knowledge of this question is, however, by no means either positive or precise.†

The waters of many wells and springs and even of brooks and rivers contain in solution salts of the alkaline earths in such quantities as to interfere with the formation of a lather with soap when the water is used for washing. Such waters are familiarly known as hard, while those which readily make a lather with soap are spoken of as soft. Water which owes its hardness merely to an excess of carbonate of lime is not disagreeable to the taste, and on being boiled softens very much. Water, the hardness of which is communicated by its passage through strata of magnesian limestone, often contains sulphates as well as carbonates of lime and magnesium; it does not soften so much in boiling as the former variety, and is more or less disagreeable to the taste. Water charged with a considerable excess of sulphate of lime, sometimes spoken of as selenitic, softens very little on boiling, and is still more disagreeable to the taste.‡ Different effects may reasonably be expected

* See, for example, the reports of GAGE, p. 93, who, however, speaks of "the use of the impure Mississippi and surface waters;" BIDWELL, p. 96, according to whom "one probable cause of the prevailing diarrhœa is the use of unfiltered water of the Mississippi river;" and REECE, p. 97, who attributed the diarrhœa of the 118th Illinois, while on transports on the Yazoo, to drinking the water of that river.

† BOUSSINGAULT—*Recherches sur le développement de la substance minérale dans le système osseux du porc*, Comptes Rendus, T. XXII, 1846, p. 336—showed experimentally that some growing pigs assimilated more lime salts than were contained in the food given them, less that contained in their excretions, and that the surplus must have been contained in the water drank: "De ce qui précède il résulte la preuve de l'intervention des substances salines de l'eau dans l'alimentation qui, sans leur concours, aurait été insuffisante." E. J. A. GAUTIER—*Chimie appliquée à la Physiologie*, &c., Paris, 1874, T. I, p. 157 *et seq.*—has attempted to show that an adult workman excretes more than a gramme (1.247 grm.) of calcium oxide and a small quantity of silica (.061 grm.) more than is contained in his daily allowance of bread and meat, and that the excess must be obtained from such vegetables and wine as he may obtain and the water drank; he concludes that the latter, "being the only constant element in the alimentation should be such that its mineral elements can compensate for the continual losses of disassimilation." This writer accordingly advises that distilled water, such as is often used on board ship, should have added to every litre .2 to .3 grm. of bicarbonate of lime, .025 to .3 of sea salt and a trace of silicates, p. 176. On the other hand, HENRI BUIGNET—Art. *Eau*, Nouv. Dict. de Méd. et de Chir. Pratiques, T. XII, Paris, 1870, p. 206—declares that the evil effects of water containing no salts have been greatly exaggerated; and GRIMAUD (de Caux)—*Aménagement et conservation des eaux pluviales pour les besoins de l'économie domestique*, Annales d'Hygiène, T. XIV, 1860, p. 469—in advocating the use of rain water for drinking purposes, boldly declares that it is an error to insist that water intended for ordinary drinking purposes ought necessarily to contain certain salts in solution.

‡ PARKES—p. 23, *op. cit.*, p. 599, *supra*—speaks of waters of the first class as chalk waters; they may contain from 7 to 20 grains of calcium carbonate per gallon. The second he speaks of as limestone or magnesian limestone waters; they usually contain from 4 to 12 grains of calcium sulphate and less carbonate, in the dolomitic districts much magnesium sulphate and carbonate. The selenitic waters may contain 6 to 20 grains of calcium sulphate, or even more; this water is not good for cooking or washing.

to result from the use of waters containing these different kinds of impurities, and experience seems to indicate that, while the first kind is quite wholesome, the second not unfrequently disturbs the bowels of those especially who are unaccustomed to its use, and the third may even, especially in high degrees of impregnation, produce such active and persistent purgation as to render its continued use injurious.

In the United States we have the testimony of Drake that in the great limestone tract of the Central Region, including the eastern half of Indiana, the western part of Ohio, the central section of Kentucky and middle Tennessee, the water of both wells and springs is hard, chiefly in consequence of the amount of carbonate of lime it contains in solution. In different parts of the formation the quality of the water varies considerably, and its chemical composition in many districts is not definitely known. According to Drake the best water of the region issues from fissures or seams in the limestone rocks or is drawn from wells sunk in them. It is drunk by the people of the most populous parts of the valley of the Ohio river and its tributaries. He seems half inclined to attribute to its use the dyspepsia, which in his time was common in these districts, as indeed it was at the same time in almost all parts of the United States, yet was obliged to declare that the ample development and general good health of the people who drink this water demonstrate that it is a salubrious beverage.* There are, undoubtedly, many districts in the eastern United States, especially on the slopes of the Appalachian chain, where the limestone water contains enough of the earthy sulphates to act as a laxative upon new-comers, although the natives drink it with impunity; and there are many wells and springs which contain so much, especially of the sulphate of lime, as to be quite unfit for habitual drinking. Throughout many districts of the Appalachian region, also, mineral springs of the most various kinds abound, charged with iron, alum, sulphur, sulphates and other substances. Some of these waters are highly purgative.†

According to Parkes,‡ dyspeptic symptoms accompanied by constipation, with occasional diarrhœa, are produced by the use of drinking water "containing a large quantity of calcium sulphate and chloride, and the magnesian salts." He states that water containing more than 8 grains of each substance, individually or collectively, appears to be injurious to many persons, and mentions two instances of well water containing respectively 50 and 58 grains per gallon, which was found to disagree with so many persons that no one would use it. Pinel,§ long ago, accused the water of a well in the Salpêtrière hospital of giving rise to chronic diarrhœa among those who drank it, on account of the great quantity of sulphate of lime and other earthy salts it contained. A similar accusation was made by

* DRAKE—p. 663, *op. cit.*, p. 601, *supra:* "The best kind of hard water is that of springs which issue from the fissures and seams of limestone rocks, or is drawn from wells sunk in them. Such is the water drunk by the people of the most populous parts of the valley of the Ohio River and its tributaries. Their ample development and general good health demonstrate that it is a salubrious beverage. Nevertheless, there is much dyspepsia within the specified region, and calculous affections appear to prevail more than elsewhere. On the other hand, goitre occurs much less frequently than in sandstone, slate, and coal districts."

† The literature of the mineral waters of the United States may be said to be in its infancy. I will not attempt to refer here to the scattered papers on the subject, but may name the works of JOHN BELL—*On Baths and Mineral Waters*, Philadelphia, 1831; J. J. MOORMAN—*The Mineral Waters of the United States and Canada*, Baltimore, 1867; and G. E. WALTON—*The Mineral Springs of the United States and Canada*, New York, 1873—as containing a good deal of interesting information on this head. Further studies are, however, very much needed.

‡ PARKES—p. 38, *op. cit.*, p. 599, *supra*—declares that a much less degree than the 8 grains mentioned in the text will affect some persons. Of the wells mentioned, one at Chatham contained calcium carbonate 19 grs., calcium sulphate 11, sodium chloride 13, total solids 50 grains per gallon. The other well contained calcium carbonate 22 grs., calcium sulphate 11, sodium chloride 14, total solids 58 grains per gallon.

§ PH. PINEL—*La Médecine Clinique*, 3me Éd., Paris, 1815, p. viii *et seq.*—observed that the water of a well used by the inmates of the Salpêtrière hospital contained a large quantity of sulphate of lime and other salts, and regarded its use as favoring "a certain disposition to chronic diarrhœa which is so often observed in the hospital." The water, analyzed by his student SCHWILGUÉ, was found to contain, in fifty litres, sulphate of lime 57 grammes, carbonate of lime 23.55, carbonate of magnesia 10.73, muriate of lime 6.25, muriate of magnesia 4.02, nitrate of potassa 5.33, muriate of soda 2.10, total 108.98 grammes per 50 litres. He points out that while this water contained 1.14 grammes of sulphate of lime per litre, the water of the Seine only contains .0629 grammes per litre of this salt.

Parent-Duchatelet against the waters of a well in the prison of St. Lazare.* These opinions have been repeated by many subsequent writers, and the use of selenitic waters for drinking purposes is commonly asserted in the text-books to cause diarrhœa. That such water will often act as a purgative, especially when first used, is, I suppose, sufficiently well established, but I suspect that a very much larger quantity of saline matter, than is commonly believed, must be present in a water before its continued use will be likely to produce any injurious effect upon the bowels. I would point out that some of the mineral springs of the United States which are thronged every summer with visitors, who drink the waters freely for their real or supposed healing virtues, rival the well, made famous by Pinel, in the quantity of sulphate of lime they contain; and yet although at first their effect is often decidedly laxative, they are so far from producing troublesome fluxes among those who drink them for some time that they are often recommended as possessing remedial effects, not only in dyspepsia but even in chronic diarrhœa.†

During the civil war I not unfrequently heard the opinion expressed by medical officers that the hard water of certain camp sites, especially in the Shenandoah valley and in the Central Region, was to blame for the prevailing fluxes, and this belief is occasionally mentioned in the reports contained in Section II.‡ But, while I am still quite willing to admit that there may have been localities in which, on the first arrival of troops, the water produced a laxative effect on account of its saline impurities, I am no longer so much impressed as I was in 1863 § with the importance of this cause.

Still more prone to disturb the bowels than waters containing earthy salts in solution are those impregnated with the salts of soda and potash. Such waters are sometimes obtained from artesian wells, and may be quite undrinkable, or if less highly charged may yet be capable of producing a purgative effect. They occur also in the great alkaline plains of the western territories of the United States and many of the mountain springs and streams of the Rocky Mountain region, in which sulphate of soda is a widely diffused ingredient that often exists in considerable quantities. The use of such water, charged besides with sulphur, is referred to by Poncet ‖ as possibly one of the causes of the diarrhœa

* PARENT-DUCHATELET—*Hygiène Publique*, Paris, 1836, T. I, p. 236, note—made a similar observation at the prison of St. Lazare. The sick list was large without apparent reason for it; the patients were for the most part suffering with chronic diarrhœa or diseases of similar character. The well water used for drinking purposes, like that of the well at la Salpêtrière, was found to contain "a very large proportion of sulphate of lime and other purgative salts." The observations of PARKES, on the two wells mentioned in note ‡, p. 605, are of a similar character.

† Thus, the water of the White Sulphur Springs of Virginia, one of the most popular summer resorts in that state, contains, according to the analysis of A. A. HAYES, of Boston, 67 + grains of sulphate of lime and 30 + of sulphate of magnesia, besides other salts, in 5,000 grains of the water. MOORMAN, p. 87.*op. cit.*, p. 605, *supra*. The use of this water is recommended by MOORMAN for the cure, among other diseases, of dyspepsia, *op. cit.*, p. 128, and chronic gastro-enteritis, p. 134. So, also, the water of the Yellow Springs, Montgomery county, Va., contains, according to the analysis of GILLIAM—*op. cit.*, p. 346—65+ grains of sulphate of lime and 21+ of sulphate of magnesia per gallon, besides other salts; we are told that from seven to eight tumblerfuls of it taken at intervals will usually produce "a mild cathartic effect;" yet we are further told that it is decidedly tonic in its effects, and that it is much relied on in chronic diarrhœa by those who have had most experience in its use—*op. cit.*, p. 348. It would be easy to multiply examples of this kind. According to PARKES—p. 20, *op. cit.*, p. 599, *supra*—it was decided by the Sanitary Congress at Brussels in 1853 that good drinking water ought not to contain more than 0.5 grammes of solids per litre, (= 35 grains per gallon.) I quite agree with him that this statement is of little use, because some kinds of solid matters are more likely to be injurious than others; but I cannot so well agree with his opinion that water containing more than 8 grains of sulphate of lime is from that fact alone likely to be injurious—*op. cit.*, p. 38.

‡ For example, PERRY—p. 70, *supra*—reporting from a camp near Harper's Ferry, says that the use of the limestone water of that region by the 16th Maine regiment "caused at first slight diarrhœas" among the men. So, also, LEE—p. 72—reporting from the same vicinity, accuses the lime water of aggravating the intestinal fluxes and causing a great deal of colic. So, also, according to the report of Medical Director MCPARLIN—Appendix to Part I, p. 110: "As early as the 15th of July [1862] Surgeon Thomas Antisell, U. S. V., Medical Director of the Second Corps, had expressed to me his hope that the corps might remain some little time in this 'red sandstone region, until the effects of the residence in the limestone strata of the valley passed off—diarrhœa and irritability of the whole lower bowels, arising from the excessive hardness of the water, and slight impregnation with sulphuret of iron. The water at Warrenton is soft, which, combined with the abundance of acid wild fruits, have completely checked the complaint.'" The observations which I shall hereafter present in connection with the effects of fresh fruits and vegetables in diminishing the prevalence of fluxes among troops, lead me to believe that in this case the abundance of wild fruits was of greater service than the change of water.

§ See J. J. WOODWARD—*Outlines of the Chief Camp Diseases*, &c., Philadelphia, 1863, pp. 210–11.

‖ PONCET—*Des maladies qui ont régné dans le corps expéditionnaire du Mexique*, Recueil de Mém. de Méd., de Chir. et de Pharm. Militaires, T. IX, 1863, p. 218—relates that during the early days of the occupation of Orizaba a form of acute diarrhœa resembling cholerine prevailed. Cases also occurred in which the diarrhœa was moderate; the patients had but two or three stools a day, generally retained their appetite, and but rarely had gastric embarrassment, except just after meals, when the stomach and belly became enormously distended with gas which was sometimes odorless, at

which occurred among the French troops at Orizaba, Mexico, in the year 1862. According to the opinion of Surgeon E. P. Vollum, U. S. Army, the use of alkaline drinking water is one of the causes of the mortality of children, at Salt Lake City, from bowel complaints,* and in a report by Assistant Surgeon J. H. Patzki, U. S. Army, it is suggested that one cause of diarrhœa at Fort Fetterman, Wyoming Territory, may be the use, for drinking purposes, of the alkaline waters of the North Platte river.† Dr. A. C. Peale, of the U. S. geological and geographical survey of the territories, has obligingly given me a memorandum, which I append in the foot note,‡ relating to some of the experiences of the field parties of the survey as to the effects of drinking alkaline waters in Colorado, New Mexico and Utah. Active purgation was produced in a number of instances, lasting in some of those affected only a few days, in others more than a week. I call attention particularly to the statement that, although the well water along the Rio Puerco, in New Mexico, is so strongly alkaline that whenever used by the traveller (Mr. Jackson) it produced diarrhœa, the inhabitants of the valley are not affected by it; an observation which corresponds to what is noticed in the case of hard waters. The actual effect upon the health of the persistent use of alkaline waters and the degree of impregnation which could be tolerated are subjects which afford an ample field for future scientific observation.

other times had the smell of sulphuretted hydrogen, ("d'acide sulfurique," probably a misprint for sulfhydrique.) This symptom occurred, no matter what the food or drink of the patient might be, ("quel que fût l'aliment ou la boisson.") PARKES—p. 39, *op. cit.*, p. 599, *supra*—has cited this narrative as a proof that "water containing much sulphuretted hydrogen will give rise to diarrhœa, especially if organic matter be also present," and states that the affection described "was traced to the use of water from sulphurous and alkaline springs; even the best waters of Orizaba contained organic matter and ammonia in some quantity." This presentation of the case, however, is not exactly correct. PONCET expressly declares his ignorance of the true cause of the trouble: "Nous ignorons la véritable cause de ces hypersécrétions." He suggests two possible causes: 1st, The mode of nourishment, especially the fact that the French continued their custom of taking but two meals a day, while the natives have long since learned to eat more frequently and less at a time. 2d, The nature of the waters. The springs at the village of Ingénio, situated to the west of Orizaba, are sulphurous and highly alkaline, "sources sulfureuses alcalisées à un haut degré," and the troops camped here furnished the first patients. With regard to the waters of Orizaba, our author remarks: "Les eaux d'Orizaba, les meilleures même, en contiennent peut-être une quantité suffisante pour produire quelques désordres intestinaux sur l'armée, et inactive pour les habitants qui la boivent journellement; elles renferment, à coup sûr, des matières organiques et de l'ammoniaque en assez grande quantité." Suggestions of this kind must not be too lightly assumed to be established facts.

* Page 341, Circular No. 8, cited p. 602, *supra*.

† *Op. cit.*, p. 351. He reports that this water is impure and somewhat alkaline: "There is no doubt that large amounts of the sulphates are dissolved. Tests for magnesia exhibit quite a quantity of that substance in the water, though the combination is undetermined. Iron is exhibited in large amount. Sulphur is shown to be present, not only by tests, but also by taste and odor. The organic impurities are not of much amount. Sulphate of soda, which is a very constant impurity in the waters of this section, exists also in the waters of the Platte. Of course, its flavor to one unaccustomed to it is disagreeable; but its influence upon the health of the garrison is not very marked. During 1873, 49 cases of acute diarrhœa and dysentery appeared on the reports, or about 11 per cent. of all cases taken sick. The fact that the season of greatest frequency of these diseases does not correspond to the season of low water, (December, 1872, to May, 1873, 10 cases; June to November, 1873, 39 cases, and similar proportions during preceding years.) does not disprove the effect of the water in their production. Though the water is more impure in winter and early summer, greater quantities of it are consumed in the hot season." But to this I may add that the total number of cases of diarrhœa and dysentery reported at this post during the four years ending June 30, 1874, was 132 out of an average annual mean strength of 233 officers and men, or 141 cases per 1000 of strength annually—*op. cit.*, p. 353. Now, diarrhœa to a much greater extent prevailed during the same period at posts where the purity of the water supply is beyond question.

‡ The following is Dr. PEALE'S memorandum, kindly furnished me December 18, 1877: "In October, 1876, Mr. Chittenden's division was in the desert-like plateau country between White River and Grand River in northwestern Colorado. One afternoon the party camped about five o'clock, after a long and dry march. There were six men in the party and all exceedingly dry. Although the water in the stream was strongly alkaline, all drank of it in greater or less quantity. Coffee was made for supper, but had a bitter taste, and was in very slight demand. Potatoes boiled, with their skins on, in the water, were so bitter that they could not be eaten. As little of the water as possible was used during the evening, but extreme thirst obliged every one to use it to some extent. By a little after midnight every man had been roused, and by morning all had had several passages. For breakfast the water was generally avoided, but the diarrhœa continued all the early part of the day until no member of the party had less than six passages and one had nine. All were much weakened, although the passages were accompanied by little or no pain. The stools were invariably of a very dark color. Mr. Beehler's division, the same year, was in the adjoining district, (on the North,) and on the trip from White River to Yampah River all the members of his party were affected with diarrhœa. Using the water for tea or coffee did not render the water any less liable to affect them. In 1874 in South Park, Colorado, Mr. Beehler notes that two men of his party were affected by the use of alkaline water near the salt-works. In the spring of 1877 Mr. W. H. Jackson, the photographer of the survey, was in New Mexico, and says that all along the Rio Puerco the well water is very strongly alkaline, and whenever used by him gave him diarrhœa. He abstained as much as possible from its use, taking it in the form of tea and coffee, when it did not seem to affect him. The surface water was not so noticeably alkaline. The water had a *soapy* taste. The people living along the river are not affected by it. Mr. Jackson also says that the water in the neighborhood of St. George, in southwestern Utah, gave him diarrhœa, and that all along the route from St. George to Los Angelos, Cal., the water is very bitter and invariably affects both men and animals travelling over the route. Animals suffer most, as men use the water more cautiously. Mr. Wilson states that in 1872 he camped one night at a locality south and east from the Unitah Mountains, where his party were obliged to use an inky-tasting mineral water that came from a stratum of rock near them. His entire party had diarrhœa, and the discharges were black. With some, the diarrhœa lasted several days, and others noticed the effects for more than a week. When the Union Pacific Railroad was being built through the Bitter Creek region, from Separation station to Green River, Wy. Ty., all the hands were affected by the water of the valley. The wells throughout this region are all strongly alkaline. It has been noticed that the riding and pack animals are always more affected than the men, as the latter are more cautious in its use. The men are, however, invariably affected to a greater or less degree, if they have to depend entirely on the alkaline water for drinking purposes."

The purgative properties of sea water are well known, and brackish waters so generally produce a laxative effect when first drunk, that their use has long been supposed to cause diarrhœa or even dysentery. Hippocrates* declared this opinion to be erroneous, and affirmed that the persistent use of saline waters is more likely to constipate than to loosen the bowels. In like manner, Rhazes† asserted that drinking brackish water at first relaxes, and afterwards constipates. But the old popular belief that such waters produce diarrhœa and dysentery has been again revived in modern times. Lempriere‡ mentioned that in his time the bowel complaints at Port Royal were attributed to the use of brackish water. Both Annesley and Twining§ believed that brackish water exercised a powerful influence in the production of dysentery. More recently, Norman Chevers|| has declared his belief that brackish water is a fertile cause of bowel complaints, especially of cholera and dysentery. According to Parkes,¶ the use of brackish water for drinking purposes formerly caused much diarrhœa at some of the Cape frontier stations. Now I do not doubt in the least the statement of the latter writer that the water of a certain well under his observation, having become brackish from the admixture of sea water, produced looseness of the bowels in almost all who used it;** nor do I doubt that this is the general effect of brackish waters when first drunk; but I distrust the assertion that their habitual use produces chronic fluxes or dysentery. I know of no instance in which these affections are said to have resulted from this cause in which it has been shown that the other causes of the intestinal fluxes were absent, and, indeed, in some of them the suspicion of other more dangerous contaminations of the drinking water itself has not been excluded.††

In a general way, then, my examination of this subject inclines me to the opinion that the effects of dissolved mineral substances in producing intestinal fluxes have been very greatly exaggerated. Of course it cannot be denied that, where other causes coexist, the purgative effect produced by the first use of certain waters may serve as the starting point for a serious flux; but where this is not the case most persons become accustomed to the use of waters containing a considerable quantity of impurities of this kind, they cease eventually to produce even a laxative effect, and it has yet to be shown by statistics that those who habitually make use of them are more prone to suffer from diarrhœa or dysentery than

---

* HIPPOCRATES—*loc. cit.*, p. 599, *supra*—attributed the same effect to hard water: "For such waters as are adapted for boiling, and are of a very solvent nature, naturally loosen readily and melt down the bowels; but such as are intractable, hard, and by no means proper for boiling, these rather bind and dry up the bowels. People have deceived themselves with regard to salt waters, from inexperience, for they think these waters purgative, whereas they are the very reverse; for such waters are crude, and ill-adapted for boiling, so that the belly is more likely to be bound up than loosened by them." Transl. of F. ADAMS, printed for the Sydenham Society, Vol. I, 1849, p. 198. The translator adds: "Coray appears to me to be unnecessarily puzzled to account for our author's statement, that saltish waters, although held to be purgative, are, in fact, astringent of the bowels. But, although their primary effect certainly be cathartic, is it not undeniable that their secondary effect is to induce or aggravate constipation of the bowels?"

† RHAZES—*loc. cit.*, p. 599, *supra*—clearly enunciates the view expressed in the note of ADAMS, just cited.

‡ WM. LEMPRIERE—*Pract. Obs. on the Diseases of the Army in Jamaica*, London, 1799, Vol. I—states that the wells at Kingston, Jamaica, "from their vicinity to the sea, furnish water of a brackish quality, that is very apt to disagree with the bowels," p. 90; and elsewhere that the bowel complaints at Port Royal "are attributed to the water, which is often brought in a brackish state" to that place, p. 125.

§ ANNESLEY—*Dis. of India*, London, 1828, Vol. II, p. 245: "We have frequently remarked the very powerful influence of brackish water, and water which has been kept for a considerable time shut up from the air, and in a stagnant condition, and particularly water taken from marshes, in the production of dysentery." TWINING—*Diseases of Bengal*, 2d Ed., Calcutta, 1835, Vol. I, p. 58, note: "When an extensive inundation of the sea has laid waste a large extent of some of the maritime districts, and filled the tanks, the poor natives are much distressed and obliged to go a great distance for fresh water. The next hot-weather generally dries up the salt-water in the tanks; and when they are again filled by the succeeding rains, the natives, from their indolence, apathy, and pressing necessities, drink the water strongly impregnated by the saline deposit on the sides of the tanks, and then a destructive dysentery rages in a whole district, and carries off many of those who had escaped from the inundation, and succeeding famine." But to what extent were such epidemics due to the famine, and what part was actually played by the brackish water? If the latter were the cause, it is strange that we do not possess more abundant modern testimony to that effect.

|| NORMAN CHEVERS—*The sanitary position and obligations of the inhabitants of Calcutta*, the Indian Annals of Med. Sci., No. 17, 1864, p. 70: "The land on which Calcutta is built, and, indeed all the country eastward to Dacca, is strongly impregnated with salt;" and he declares that "brackish water is a fertile cause of bowel complaints, especially of cholera and of dysentery, the most prevalent and intractable of all Calcutta diseases."

¶ PARKES—p. 40, *op. cit.*, p. 599, *supra*.

** PARKES—*loc. cit.* In this case he states that he found "the amount of chloride of sodium to be 253 grains per gallon."

†† Thus, in the Calcutta wells referred to by CHEVERS—note ||, *supra*—the probability of sewage contamination appears to have been overlooked

others. Of course, too, I readily admit the poisonous effects produced by water contaminated with certain metals, such as lead, copper, &c., but a discussion of these impurities and their effects would be foreign to my present purpose.

Organic matters of vegetable origin.—Vegetable impurities may exist in drinking water either in suspension or solution, and in various stages of decomposition. They abound in the waters of marshes and in stagnant ponds on whose borders a rank vegetation luxuriates. Surface pools or shallow excavations, dug in forests and filled by the rain, are sometimes highly charged with impurities of this kind, especially after they have been concentrated by evaporation during long spells of dry weather. As I have already mentioned, the Greek and Arabian physicians believed the use of such waters to produce fluxes as well as fevers. In modern times these views have to a great extent lost credit, yet they have been maintained by a few recent writers, as, for example, by Grellois,* who, however, has not adduced any very strong evidence in their favor. Still more general is the belief that, although the periodic fevers are not caused by drinking water contaminated by vegetable impurities, its use may give rise to intestinal fluxes. A few instances which appear to support this view can be found in literature. Thus Davy† has attributed an epidemic of dysentery in a regiment belonging to the English garrison of the island of Antigua, in 1845, to drinking rain water from tanks in which, in consequence of a prolonged drought, a considerable quantity of such impurities had collected, and Gore‡ has reported an instance in which vegetable impurities, washed from the surface into a shallow well, gave rise to a violent diarrhœa among those who drank the water, which ceased when the well was cleaned out and protected from further contamination. But there are not many instances where the use of such water appears to have caused fluxes in which the coexistence of organic impurities of animal origin is not probable.

---

* GRELLOIS—p 185, *op. cit.*, note ‡, p. 603, *supra*—in illustration of his opinion, so far as dysentery is concerned, cites particularly the case of the epidemic of dysentery which was so fatal in the Danish army in Scania during the year 1677. The same epidemic is also cited to sustain the same view by COLIN, p. 249, *op. cit.*, note **, p. 401, *supra*. An examination of the original account shows what slender support to the opinions in question is to be derived from this source. PAUL BRAND—*De dysenteria castrensi ejusque causa verminosa et curatione*, Acta Med. et Phil. Hafniensia. T. V, 1680, p. 26—a medical officer in the army at the time referred to, saw, or believed he saw, in the stools of the dysenteric subjects, great numbers of animalcula of divers forms and sizes, which wriggled about like eels, "animalcula quædam anguineo flexu gregatim perreptantia variæ magnitudiuis et formæ," and laments that he did not have a microscope to enable him to make a correct drawing of them. Here, he cries, is a beautiful illustration of the animated pathology! "observationes pathologiam animatam optime illustrantes," [see p. 369, *supra*, and note;] the atrocious pains of the disease are no doubt caused by these most ungrateful guests lancinating and mordicating the intestine of their host. Now whether these animalcula were derived from the stagnant water which the soldiers drank or the bad beer with which they were supplied, or whether they found their way into the system with the impure air breathed or the bad food used, he was not quite sure, but inclined to the opinion that the water was in fault, for, three years previously, the celebrated LEEUWENHOEK had shown him with the microscope a drop of water containing the most innumerable animalcula. In consequence of this opinion he had recourse to various vermifuges to cure his patients, especially to preparations of absinth, and with advantage. I suppose this narrative to have no value whatever as testimony that the water used by the Danish army had anything to do with their dysentery. OZANAM—*Hist. Méd. des Maladies Épidém.*, 2me Éd., Paris, 1835, T. III, p. 285—from whom GRELLOIS takes the story, [COLIN takes it from GRELLOIS,] says: "The cause of this epidemic has been attributed to the stagnant water and spoiled beer the soldiers drank, and to air charged with impure exhalations." [he omits to mention either the bad food or the animalcula,] but what evidence is there that the water had anything to do with the disease? Clearly the animalcula alone.

† JOHN DAVY—*On some of the more important Diseases of the Army*, London, 1862, p. 69 *et. seq.*: "In the island of Antigua, where there are few springs, and rain water collected in tanks is much used, dysentery has always been of common occurrence during a period of drought. * * * In 1845, a year of unusual drought, when during 51 days no rain fell, and during other 40 very little, four companies of the 71st Regiment, stationed at the 'Ridge' barracks in the same island, and using tank water—its dregs—in less than twelve months lost 52 men from dysentery and diarrhœa.* (* During the quarter ending the 31st October, out of a strength of 330, there were 141 cases of dysentery in hospital, of which 21 proved fatal.) I examined a portion of the water; I found it abounding in impurities, especially infusoria.—justifying the term dregs. The tanks, which had but little attention paid to them previously for a long while, were cleaned out, replenished as soon as the usual rains set in, and then yielding a purer water, the endemic subsided." I note in this case first that the notion that the infusoria are *per se* injurious is ridiculous. What the impurities really were is not shown; both vegetable and animal organic matter may accumulate in uncleaned tanks, but in this case it is not clearly shown that the condition of the tanks was a cause of the dysentery, or that the disease would not have ceased, as it did at its usual time, if the tanks had not been cleaned.

‡ PARKES—*Report on Hygiene for the year* 1864. Statistical, Sanitary and Medical Reports for the year 1863. London, 1865, p. 428. The facts were communicated by Staff Assistant-Surgeon A. A. GORE; the well was situated at Bulama, on the west coast of Africa. During August, 1864, its water produced violent diarrhœa in those who drank it. It was quite milky with vegetable impurities, which were separable by filtration. The well in question was merely a shallow hole dug at the site of a spring, and the impurities were washed in with the surface waters after rains. When filtered the water was quite harmless: "As soon as this was ascertained a good trench was dug round the well to arrest the surface-water, and an outlet trench to carry off this water was also provided; the edges of the well were raised so that no surface impurity could get in; the well was cleaned out and covered with a thatched roof. Next day the water was quite clean and without a particle of impurity, and the diarrhœa ceased. Dr. Gore mentions that in the recent epidemic of diarrhœa on the Gold Coast, the well water was said to have this milky appearance."

The ablest advocate of the view that vegetable impurities in drinking water cause intestinal fluxes, but not periodic fevers, is certainly Colin,* the greater part of whose interesting essay is occupied by the presentation of facts and arguments designed to prove the second of these propositions. His principal argument in favor of the first is drawn from the consideration that troops suffer more from fluxes during campaigns, when they are often compelled to use the stagnant waters of pools, surface wells and ditches which are impregnated with decomposing vegetable matter, than they do in garrison, where the water supply is usually good. But other potent causes of fluxes, having no connection with the drinking water, are too often also in operation during military campaigns, and, moreover, the water of surface wells and ditches as actually used by armies is too often contaminated by impurities of animal origin supplied by the troops themselves, that are far more to be dreaded than the doubtful effects of decomposing vegetable matter.

I may add that the few experiments which have been instituted for the purpose of ascertaining by direct observation the effects of the products of vegetable decomposition when imbibed with drinking water have yielded only negative results. Such was the issue of the elaborate investigation of Parent-Duchatelet and Andral† with putrid infusions of hemp, and of the less extended experiments of Minzi‡ with dew condensed in unhealthy localities in the vicinity of Rome and Terracina. On the whole, therefore, I do not hesitate to accept the opinion of Parkes§ that we have not, up to the present time, accumulated sufficient evidence to prove that the dissolved vegetable impurities ordinarily encountered in drinking water give rise to intestinal fluxes, and that even in the case of vegetable matters in suspension the testimony is by no means conclusive; in truth the opinions hitherto advanced as to the causation of fevers and fluxes by these impurities are to be regarded rather as ingenious conjectures than as sober deductions from well-established facts.

Organic matters of animal origin.—Much more abundant is the testimony which appears to connect impurities of drinking water derived from decomposing animal matter, whether in suspension or solution, with the production of intestinal fluxes; and although a great deal of this testimony is very far from conclusive, yet it is of a character to awaken grave suspicion with regard to the safety of using water thus contaminated, and to indicate the urgent necessity for further and more precise investigations.

---

* COLIN—*op. cit.*, note **, p. 401, *supra*. We should, however, be obliged to reject at once both the conclusions of COLIN, if we could place any confidence in the extraordinary results arrived at by Assistant Surgeon CHARLES SMART, U. S. A.—*On Mountain Fever and Malarious Waters*, The Amer. Jour. of the Med. Sci., Vol. LXXXV, 1878, p. 17—who claims to have found, by the process of WANKLYN and CHAPMAN, a quantity of "organic ammonia" in the snow-fall at Camp Douglas, Utah, which, on some occasions, was as great or even greater—*e. g.*, March 21, 1876, organic ammonia .60 parts per million, p. 30—than the percentage found by the authors of the process in the filthy water of Thames river at London bridge at high tide, which ranged from .35 to .59 parts per million—WANKLYN and CHAPMAN, *Water Analysis*, 4th Ed., London, 1876, p. 40. Dr. SMART has no doubts whatever as to the accuracy of his analyses, which he tells us "were carefully performed, and that the experience gained in conducting *over fifty* distillations for organic matter in potable waters superintended their performance," p. 30. Now, I call attention to the fact that all this organic matter, if it really had any objective existence, is not claimed to have produced either diarrhœa or dysentery, but "mountain fever," which Dr. SMART regards as a "malarial remittent fever with adynamic tendencies," p. 34. I shall have occasion hereafter, when discussing the etiology of malarial fevers, to refer to the arguments brought forward in this paper in favor of "the probable presence of malaria *in the snow*," p. 35.

† PARENT-DUCHATELET—T. II, p. 509 *et seq.*, *op. cit.*, p. 606, *supra*—in the course of his investigations as to the effects of the maceration of hemp on workmen and others—*Le Rouissage du chanvre considéré sous le rapport de l'hygiène publique*, (1832)—drank himself, in three doses, three centilitres of the infusion in a condition so putrid that it turned his stomach, ["ces trois doses me barbouillèrent un peu le cœur,"] but without experiencing the least indisposition from it. Similar results followed the ingestion of hemp infusion by others, and finally, at his request, ANDRAL experimented with the same infusion on seventeen patients whose digestive organs were in good order, and without producing any ill effect. ANDRAL himself reported: "I believe I may conclude from these trials that water in which hemp has been macerated so long that it exhales the most fœtid odor ("une odeur des plus fétides") can be given as drink without any kind of accident resulting from it."

‡ MINZI—*Sopra la genesi delle febbri intermittenti*, Rome, 1844; I have not obtained access to this work, and cite from COLIN, p. 272, *op. cit.*, p. 401, *supra*—collected during the month of August the dew from certain notoriously unhealthy localities in the vicinity of Rome and Terracina in sufficient quantities to enable himself and eight other persons to drink each several ounces of it. No effects were produced by this experiment. COLIN—p. 271, *op. cit.*—remarks that while some persons, like those experimented on by PARENT-DUCHATELET, have experienced no ill effects from drinking water containing decomposing vegetable matters, others not merely felt disgust, but suffered from nausea or even vomiting and intestinal troubles. I know not where to find the original account of these latter observations, to which no reference is given.

§ PARKES—p. 39, *op. cit.*, p. 599, *supra*.

It is well known that the use of tainted meat as food sometimes occasions violent intestinal catarrhs, and there is no doubt that the use of drinking water sufficiently impregnated with the products of decomposition from the dead bodies of animals or men will give rise to similar symptoms. Hence the water from wells in the vicinity of cemeteries* has long had an evil reputation. That this has been, in some cases, deserved I do not doubt, but the instances in which intestinal fluxes have been traced unmistakably to this cause are rare indeed.† Chemical analysis has indicated the contamination of the water of such wells with organic matter in a few cases; indeed, in some of these, as in the well water analyzed by Lefort,‡ the odor and taste sufficiently indicated the nature of the impurities present. But recent systematic investigations of the water of wells actually situated within the limits of cemeteries in Berlin, Carlsruhe and Dresden show that it is often quite impossible to detect in it any considerable quantity of organic impurity by chemical analysis, and that it is usually drunk with impunity by the keepers and their families.§ I am compelled, therefore, to agree with Pettenkofer,‖ that the actual evil effects of the impurities derived from this source have been very greatly exaggerated. The distance of the well from the cemetery affords no indication of the danger, but the character of the subsoil and the direction of its drainage must be taken into account; moreover, the disinfecting power of the soil itself must not be forgotten.

Some of the most striking illustrations of the morbific influence of well water thus contaminated, which pass current in medical literature, will not bear critical investigation. Among these, perhaps, the most interesting to the military surgeon is said to have occurred at Ciudad Rodrigo (1813) during the Peninsular campaigns, where it is alleged that the well water was contaminated in consequence of the burial within a short time of 20,000 bodies, and that those who drank it were attacked with malignant fevers and dysentery. I find this story repeated not only in the monographs on the danger of intramural interments, but in some of the best modern text-books on hygiene; it is usually credited to Sir James McGrigor, but that distinguished physician, in his sketch of the

* It would occupy more space than can be spared to attempt to present the literature of this subject. I may, however, refer to a few works, *e.g.*, E. CHADWICK—*A supplementary report on the results of a special inquiry into the practice of interment in towns*, London, 1843, p. 26; WM. LEE—*Report to the General Board of Health on interments in towns visited during* 1849–1850, London, 1851—who says of the churchyard at Newcastle-under-Lyme: "The drainage from it percolates through the walls into the street; the people inhale the putrid matter floating in the atmosphere, and drink water from wells polluted with decayed human remains," p. 4. Near this cemetery he found a public house the cellar of which was "two feet deep of horrible fluid with the churchyard odour, * * * and the water in a well, four yards from the public-house cellar, was full of flocculent animal matter with the same stench. The sequel is awful. The publican's wife had recently died of cholera, and he and two sons had had diarrhœa," &c., p. 5. See, also, WM. EASSIE—*Cremation of the dead*, London, 1875, p. 61 *et seq.* PARKES—p. 39, *op. cit.*, p. 599, *supra*—declares, in speaking of the influence of bad water in producing diarrhœa, "the animal organic matter derived from graveyards appears to be especially hurtful."

† See J. F. A. ADAMS—*Cremation and burial*, Sixth Annual Report of the Massachusetts State Board of Health, Boston, 1875, p. 300—who declares that in Massachusetts, "after a diligent inquiry, we have been unsuccessful in obtaining a single example of disease presumably induced by water contaminated by the proximity of burial-grounds." So, also, on p. 278: "In searching for cases of recent date of disease resulting from grave yard infection, we find that such are almost unknown to medical literature."

‡ J. LEFORT—*Remarques sur l'altération des eaux de puits par le voisinage des cimetières*; I cite from the report in the Bull. de l'Acad. de Méd T. XXXVI, 1871, p. 610—found in the commune of St. Didier (Allier) a well situated 50 metres from the cemetery which had a nauseous odor, very fetid taste, and contained a notable quantity of ammoniacal compounds.

§ ROTH und LEX—p. 22, *op. cit.*, p. 601, *supra*—state that the water of fifteen wells in Berlin churchyards proved on analysis to contain nitrates in smaller quantity than the mean found in the city wells. Two wells in churchyards at Carlsruhe contained, one more the other less nitrates than the mean of eleven city wells. An official investigation of the wells in the churchyards of Berlin showed that, with a few exceptions, the water was not only clear, odorless and tasteless, but also quite poor in organic constituents. See, also, with regard to this last investigation, Berlin Klin. Wochenschrift June, 1865, p. 254. FLECK—*Jahresbericht der Chemischen Centralstelle für Oeff. Gesundheitspflege*, Dresden, 1873; I have not seen this work, and cite from ADAMS, p. 280, *op. cit.*, *supra*—analyzed, in 1872, the water of 22 wells situated in nine of the Dresden cemeteries; he found a variable amount of organic contamination, but not on the whole more than in the other wells of Dresden, and remarks: "Of injurious physiological effects arising from the use of the water of the cemeteries of Dresden, there is no proof, as far as the author's knowledge extends. Moreover, it should, on the other hand, be mentioned that in each cemetery the well which is situated nearest to the grave-digger's house is used without regard to its quality by the grave-digger and his family, and up to the present time there has been no cause whatever for forbidding the use of the well. But, indeed, the composition of the cemetery-water does not differ essentially from that of the average well-waters of Dresden in respect to the decomposing organic matter, as may be seen by comparing with the above results the following determinations of the character of the water from various wells within the city." Then follow analyses of 17 city wells which sustain the opinion advanced. These analyses were repeated by FLECK, in 1873, with very similar results.

‖ MAX PETTENKOFER—*Ueber die Wahl der Begräbnissplätze*, Zeitschrift für Biologie, Bd. I, 1865, S. 48.

medical history of the Peninsular campaigns, speaks only of the evil effects of the aerial effluvia from these hasty burials. He presents no facts to show that the well water used was contaminated, nor does he express the opinion that it was. According to his narrative the dysenteries and fevers broke out, and were sent to hospital elsewhere, and the hospitals were subsequently moved to Ciudad Rodrigo, where a number of causes conspired to produce a great mortality. I find no proof that impure well water was one of these.* The statement of Parkes,† that the prevalent dysentery at Secunderabad, in the Deccan, appears to have been partly owing to the use of water which percolated through a large graveyard, is supported by better evidence, but even in this case the testimony is far from conclusive.

We have much more abundant and more satisfactory information with regard to the injurious effects of water contaminated with *decomposing fæcal matters*, and from the nature of the case it is probable that impurities of this kind are much more frequently present than those just discussed. In towns and villages where the water supply is from

* I find this story first, in the shape referred to, in the testimony of Dr. JAMES COPLAND before a committee of the House of Commons—*Report from the select committee on improvement of the health of towns*, ordered by the House of Commons to be printed June 14, 1842. Minutes of evidence, p. 156. He said: "It is fully ascertained and well recognized that the alluvial soil, or whatever soil that receives the exuviæ of animal matter, or the bodies of dead animals, will become remarkably rich in general; it will abound in animal matter, and the water that percolates through the soil thus enriched will thus become injurious to the health of individuals using it; that has been proved on many occasions, and especially in warm climates, and several very remarkable facts illustrative of it occurred in the Peninsula campaigns. It was found, for instance, at Ciudad Rodrigo, where, as Sir James Macgregor states, in his account of the health of the army, there were 20,000 dead bodies put into the ground within the space of two or three months, that this circumstance appeared to influence the health of the troops, inasmuch as for some months afterwards all those exposed to the emanations from the soil, as well as obliged to drink the water from the sunk wells, were affected by malignant and low fevers and by dysenteries, or fevers frequently putting on a dysenteric character." Now, Dr. COPLAND'S testimony, from which the above is taken, appears to have been given off hand, and with a good deal of "ex cathedra" positiveness. I do not, however, understand him to attribute any statement to Sir JAMES MCGRIGOR, except with regard to the number of bodies buried within a few months, which is quite correct. The rest represents simply his own inferences and opinions, for which he cites the testimony of no eye-witness. CHADWICK—p. 26, *op. cit.*, p. 611, *supra*—gives textually the extract I have cited, and merely speaks of it as a part of the testimony of COPLAND. But subsequent writers have not been so careful; thus, in the *Report on a general scheme for extramural sepulture, presented to both Houses of Parliament by command of Her Majesty*, London, 1850, p. 9, the whole story is attributed to Sir JAMES. The same is done by J. H. RAUCH—*Intramural interments in populous cities*, Chicago, 1866, p. 20. PARKES—p. 42, *op. cit.*, p. 599, *supra*—gives a somewhat different version: "The great loss by dysentery in the Peninsula, at Ciudad Rodrigo, was partly attributed by Sir J. MCGRIGOR to the use of water passing through a cemetery where nearly 20,000 bodies had been hastily interred." ROTH und LEX—p. 26, *op. cit.*, p. 601, *supra*—repeat this, but avowedly on the authority of PARKES. Now, so far as I have been able to ascertain, the only authority for this story is the loose testimony of COPLAND, which is certainly not sustained by the narrative of Sir JAMES MCGRIGOR—*Sketch of the medical history of the British armies in the Peninsula of Spain and Portugal during the late campaigns*, Medico-Chirurgical Trans., Vol. VI, 2d Ed., London, 1819, p. 422 *et seq.*—who relates that "dysentery appeared in the greatest number in the early part of 1813; but it had its origin, in the operations of the campaign of the former year." The army, during June and July, traversed Castile, exposed to a burning sun by day, and bivouacking during the night in arid unsheltered plains. They felt at times every vicissitude of heat and cold, were not regularly supplied with food, often indulged in unripe fruit and bad wine. "About the 20th July, the army began to make a retrograde movement; and the hospitals, particularly those at Salamanca, containing some thousand men ill chiefly of diarrhœa, dysentery, or remittent fever, were suddenly broken up, and the sick hurried off to the rear to Ciudad Rodrigo, which was the nearest hospital station to the frontier of Portugal." It will be observed that the men were taken sick with these diseases elsewhere, and were sent while sick to Ciudad Rodrigo. "The situation of this place is by no means favourable for an hospital station; it proved a source of great mortality to us; however we had no choice. The town is composed chiefly of ruins, with very narrow streets and some of them without a single inhabitant. It had been so much the object of contest, and alternately the site of the hospitals of all the contending armies, that nearly 20,000 bodies were calculated to have been put into the earth either in the town or under its walls in the course of a few months. Independently of these circumstances, the situation of Ciudad Rodrigo is unhealthy; it may therefore be imagined that its atmosphere was not the purest, and the surprise will not be great, that among the many conveyed to its hospitals from the front, a considerable mortality ensued notwithstanding every effort of the medical department ably conducted by Dr. Neale." It will be observed that Sir JAMES blamed the air, not the water, nor do I find in his able narrative any allusion to the water supply at Ciudad Rodrigo, or any evidence that it was contaminated in consequence of the interments mentioned.

† PARKES—p. 41, *op. cit.*, p. 599, *supra:* "Its constant prevalence at Secunderabad, in the Deccan, appears to have been partly owing to the water which percolated through a large graveyard. One of the sources of water contained 119 grains of solids per gallon, and in some instances there were 8, 11 and even 30 grains per gallon of organic matter, *(Indian Report*, p. 44.)" The authority cited is the *Report of the Royal Commission on the Sanitary State of the Army in India*, London, 1863, Vol. I, p. 44, where I find the analyses cited as above, but nothing is there said about the graveyard. In the stational report—Vol. II, p. 356—I find it mentioned that "there are four burial grounds used by the British troops, all within the station," but I find no hint that drinking water owed its organic matter to this source. If, then, the paragraph cited from PARKES is intended as more than a mere conjecture, he must have been in possession of some additional evidence, which he does not cite, and until this is accessible it is impossible not to regard his opinion with a certain degree of reserve. I may point out as a further reason for caution, that, while the medical statistics of the post—Vol. II, p. 351—show a great prevalence of dysentery during the official year 1858-9, the figures representing no less than 430.+ cases and 30.+ deaths per 1,000 of strength among the European troops, the figures for the official year 1857-8 represent only 49.+ cases and 2.+ deaths per 1,000 of strength, though the graveyards were, I suppose, in the same place. Further particulars with regard to the composition of the well water at Secunderabad will be found in the official report on *Water Analysis in the Madras Presidency*, for 1871, p. 44, and Appendix, p. 68, from which it appears that several of the wells are situated near graveyards, and it is stated by the analyst, Dr. HASTINGS, in the case of one well, No. 29, that it contains a large excess of organic matter, and receives in all probability drainage from the neighboring graveyard. Yet precisely this well is recommended by him for use in cholera times: "No. 29 well contains a large excess of organic matter, receiving in all probability part of the drainage from the neighbouring graveyard. It has the further disadvantage of being close to a line of barracks; but it possesses the great advantage, that being within the barrack-square, it can in cholera times be easily secured against the possibility of the introduction into it of choleraic discharges. The water of this well is not fit for drinking purposes; but it would be a much safer drinking water if properly purified by boiling, &c., and secured against the possibility of contamination by choleraic or other discharges, than the water of any other well not thus secured; no matter how pure previous analyses may have shown it to have been." p. 69.

wells, the contamination may take place by filtration from adjoining sewers, or privy vaults, or by overflow during heavy rains or floods; and the surface wells and rivulets, which so often afford the only drinking water of camps, are peculiarly exposed to similar impurities. Here the danger consists not merely in the presence of decomposing animal matter, but in the probable existence of specific contagia derived from the dejecta of the sick. Recent investigation has rendered it highly probable that both cholera and typhoid fever may be propagated in this way,* and the same has often been asserted to be true of diarrhœa and dysentery, but the evidence brought forward is far from conclusive, although there is enough to warrant grave suspicion.

The old observation of Read,† (1770,) who believed he had traced an epidemic of dysentery to the use of well water contaminated by adjacent latrines, is not an isolated one, but appears to be supported by several recent incidents of a similar character. I may refer, in illustration, to the observations of Oakes,‡ who traced an outbreak of dysentery at Cape Coast Castle, on the west coast of Africa, to the passage of sewage from a cess-pool into one of the tanks; and to the account given by Kraft§ of the prevalence of intestinal catarrhs and dysentery in Prague, after the spring floods of 1862 had washed sewage and surface impurities into the wells. Greenhow|| concluded, from his investigation of the districts of England in which alvine fluxes produce the greatest mortality, that a high death-rate from these disorders always coexisted either with the tainting of the atmosphere by the products of organic decomposition, especially of human excrement, or with the habitual drinking of impure water. Sewage contamination most probably explains the presence of the organic impurities in the water of the canal de l'Ourcq, which appears from the narrative of Champouillon¶ to have caused an outbreak of dysentery in a French regiment in

---

* See PARKES—p. 44 *et seq.*, *op. cit.* The relation of the drinking water to typhoid fever will be referred to in the chapter on fever.

† READ—*Obs. sur la dyssenterie qui a été traitée à l'hôpital militaire de Metz pendant le mois de Juillet*, 1781, Jour. de Méd. Militaire, T. I. 1782, p. 181—has related that during August and September, 1770, one of two regiments lodged in the barracks in the Chambierre quarter of Metz suffered greatly from dysentery, while the other had but few cases. On inquiry it was found that the former obtained its drinking water from two wells which proved to be contaminated with fæcal matters filtered from the neighboring latrines, while the latter drank from two other wells not so contaminated. The impure wells were closed, and the disease speedily diminished. In 1781 dysentery broke out, in the month of July, in two regiments lodged in the same barracks. The wells were again closed, with advantage.

‡ PARKES—p. 41, *op cit.*: "On the West Coast of Africa (Cape Coast Castle), an attack of dysentery was traced by Assistant-Surgeon Oakes to the passage of sewage from a cess-pool into one of the tanks. This was remedied, and the result was the almost total disappearance of the disease."

§ KRAFT—*Bericht über die in Folge der Ueberschwemmung von 1. und 2. Februar 1862 in Prag beobachteten Krankheitszustände*, Prager Vierteljahrschrift für die Prakt. Heilk., Bd. III, 1862, S. 141. This observation is the more significant because the resulting fluxes occurred so much earlier in the year than they usually do.

|| GREENHOW—*Reports on the prevalence and causes of diarrhœa at Coventry, Birmingham, &c.*, Second Report of the Medical Officer of the Privy Council, for 1859, Appendix, p. 65—concludes, from the evidence which he presents in detail, that "the excess of mortality has in all the places been coincident with one or other of two definite local circumstances: a. The tainting of the atmosphere with the products of organic decomposition, especially of human excrement. b. The habitual drinking of impure water," p. 160. In like manner BUCHANAN—*Report on the results which have hitherto been gained in various parts of England by works and regulations designed to promote the public health*, Ninth Report of the Medical Officer of the Privy Council for 1866, p. 46—concluded from his investigations that "diarrhœa is another disease which appears to have been reduced by purification of air and water." He gives, in support of this statement, the death-rate from diarrhœa before and after the completion of works for the improvement of the drainage and water supply in 24 towns. The conclusion cited has been justly criticised by VIRCHOW—*Canalisation oder Abfuhr*, Virchow's Archiv, Bd. XLV, 1869, S. 296—who has correctly pointed out that, although in twelve of the towns in BUCHANAN'S table a diminution of diarrhœa followed the sanitary works, in twelve others there was actually an increase in the mortality of the disease, and that the percentage of the change in these latter cases is as great—in two cases even greater—than in the former. VIRCHOW further criticises the method of these English investigations, especially the nomenclature employed: "And what does diarrhœa signify? Was it dysentery, that is an infectious disease? Does not a part of it belong to phthisis? Ought not many of the cases to be counted with typhus? In the last connection it is certainly not unimportant that Worthing, Penzance, Chelmsford, Carlisle, Rugby, which have so much typhus, show all of them an increase in the diarrhœa mortality. Certainly it is to be concluded from all this that the English nomenclature is as yet very bad, and that their statistical figures as yet repose on a very uncertain foundation." I may add, however, that in subsequent portions of his report BUCHANAN gives the figures of dysentery separately for all the towns in the table referred to except Cardiff and Ely. These figures are in most of the cases quite small; in more than half of them less than 1 death per 10,000 of population annually. I note that in six of the towns the mortality from dysentery increased after the sanitary works; in two it remained unchanged, and in fourteen it diminished.

¶ CHAMPOUILLON—*Quelques Obs. relatives au régime alimentaire du soldat*, Rec. de Mém. de Méd., de Chir. et de Pharm. Militaires, T. XXVII, 1871, p. 230—states that in the year 1852, during the month of August, the 19th light regiment suffered greatly from dysentery, while the 44th regiment of the line had only a few cases of diarrhœa. They both occupied the caserne de Reuilly, (Paris,) and both drank the water of the canal de l'Ourcq, which contained much organic matter. But on inquiry it was found that the men of the 19th regiment mixed their drinking water with brandy, which merely precipitated the organic matter on the sides of the vessels where it putrefied, so that the mixture became quite offensive on standing; while those of the 44th mixed their water with red wine or made coffee with it, and in both cases the tannin seemed to exert an antiseptic influence. Red wine having been supplied to the 19th regiment in lieu of brandy the disease abated almost immediately.

1852; and similar impurities must have existed in the muddy canals of the plains of Peï-ho, if it be true, as stated by Falot,* that the use of their water for drinking purposes produced dysentery among the allied troops in China.

Oldekop† has testified that the water of the Volga at Astrachan, which he accuses not merely of producing a purgative effect when first used, but also of occasioning choleraic symptoms and chronic diarrhœas, is impregnated with sewage; and when Ilisch‡ declared that the water of the Neva at St. Petersburg, the drinking of which is said to give rise to diarrhœa, is rich in organic substances, he probably had a similar contamination in view. An observation reported by Greenhow§ seems to show also that water, without any direct admixture of sewage, may be so contaminated by the absorption of sewer gases as to become capable of generating diarrhœa in those who drink it; and Davy|| has related an incident which seems to show that the use of water contaminated by the excreta of the human skin may give rise to bowel complaints and dysentery. It seems probable, moreover, that the use, for drinking purposes, of water contaminated with the fæcal discharges of animals may give rise to diarrhœa, as in the case of the village ponds described by Cox and the well analyzed by Schweizer,¶ but in such cases it sometimes happens that the probability of contamination with impurities of human origin is also very great, as, for example, in the case of the water which, according to Orabona,** produced an outbreak of dysentery on board the brig Le Génie.

The foregoing are some of the more striking of the observations brought forward in support of the opinion that water impregnated with decomposing animal matter, and especially with sewage, gives rise to diarrhœa and dysentery. Others have been adduced

---

* A. Falot—*Relation méd. d'une campagne en Chine de* 1859 *à* 1862, Montpellier Thesis of 1863, which I have not been able to see, and cite from Barrallier, p. 719, *op. cit.*, p. 603, *supra*. He points out also that the Chinese who drank the same water, but always first boiled it, were very rarely attacked. This, however, does not correspond with the observation of Dudgeon, *vide infra*.

† F. Oldekop—*Die Lepra caspica*, Virchow's Archiv, Bd. XXVI, 1863, S. 117—represents the water as being also yellowish and turbid.

‡ Ilisch—in the Verhandlungen des Cholera-Congresses zu Weimar, p. 14, which I have not been able to see, and quote from Roth and Lex, S. 24, *op. cit.*, p. 601, *supra*. The following extract is from the latter citation: "In Petersburg ist es bekannt, dass das Trinkwasser, welches dort allgemein aus der Newa bezogen wird und reich an organischen Substanzen ist, namentlich auf Fremde eine diarrhöische Wirkung äussert." I regard both this statement and that of Oldekop with distrust, for reasons which will be given further on.

§ Greenhow—Appendix, p. 153, *op. cit.*, p. 613, *supra*. The observation referred to relates to an outbreak of diarrhœa in the New Bailey prison at Salford, which proved to be due to drinking water from a cistern. This "communicated with the common sewer by means of an untrapped waste-pipe, allowing free passage of the sewer gases into the cistern. * * * The cistern was covered over with boards which confined the gases so as to favour their absorption by the water."

|| Davy—p. 69, *op. cit.*, p. 609, *supra*—relates that the troops stationed at Morne Bruce, in the island of Dominica, were very subject to bowel complaints and dysentery. They were supplied with drinking water by an open conduit defiled by washing clothes in it: "As soon as it was covered over, the impurities excluded, the occurrence of the disease was arrested; from that time at least it ceased to be endemic." But what kind of dirty clothes were washed? Did they include children's diapers or the bedclothes of dysenteric subjects soiled with the discharges? Without particulars of this kind, carefully observed, the value of the observation is lost.

¶ W. I. Cox—*Epidemics and their every day causes*, The Sanitary Review, Vol. IV, 1858, p. 254—relates that in a village of 30 or 40 cottages, observed by him, the inhabitants "use no other water than that afforded by surface pools; the majority of which are, during the summer and autumn, covered with vegetable life, slimy, and bubbling with the liberated products of decomposition. They are all uncovered, sunk below the general level of the ground. Hundreds of donkeys, pigs, and geese, graze close to the brink." These people suffered from choleraic diarrhœa, while a neighboring village remained free. The water of the largest pool contained "five grains of organic matter in the imperial gallon." E. Schweizer's analysis will be found reported in Oesterlen's Zeitschr. für Hygieine, &c., Bd. I, 1859-60, S. 166—*Merkwürdiges Vorkommen von Buttersäure im Wasser eines Brunnens*. The use of the water of this well produced serious diarrhœa not merely in the persons who drank it, but in domestic animals, some of which died. The water was clear and colorless, but contained considerable quantities of butyrate of lime, showing contamination by organic matter. The source of these impurities proved to be a neighboring ditch filled with vegetable garbage, the fæces of animals, &c., [in short, a dungheap, I suppose.] Here, too, I may mention the account given by Rambaud—*Obs. sur la fièvre putride et maligne qui a régné à l'hôpital militaire de Sedan, pendant l'hiver de l'année* 1776 *à* 1777, Jour. de Méd. Mil., T. II, 1783, p. 480—of an epidemic which he attributed to the use for drinking purposes of water contaminated by stable manure. He speaks of the disease as a fever, but the absence of head symptoms and the frequent bloody stools, signalized in the narrative, incline me to agree with Estienne—Rec. de Mém. de Méd. de Chir. et de Pharm. Militaires, T. XV, 1824, p. 83—who calls it a putrid dysentery. The garrison had just occupied new barracks, and no cause was found for the outbreak but the use of water recently dug in a place which had been used as a depot for the manure of the cavalry horses. The rains of autumn and the commencement of winter had washed much putrid and alkaline matters from the old dung-heaps into these wells. So soon as attention was drawn to this cause the use of the wells was forbidden, and, as the soldiers continued to drink from them, sentinels were placed which rendered their use impossible; but it is worthy of note that, "in spite of these precautions, the disease continued during a great part of the winter."

** I cite Barrallier—p. 719, *op. cit.*, p. 603, *supra*: "Orabona, in his Études méd. sur la côte de Zanzibar, reports that the epidemic which raged on the brig Le Génie was provoked by the abuse by the sailors of the crew of the water of McTony, a source supplied by a brook whose waters flowed over a black and muddy slime, mingled with detritus of all kinds, and disturbed unceasingly by the Arabs during their religious ablutions, and by the trampling of horses and other domestic animals."

of a far less convincing character. Especially has the use of the waters of certain rivers been accused on insufficient evidence. Thus the opinion of Foucaut and Gayme, that the dysentery of Cochin China is caused by drinking the water of the rivers of that country, which are said to abound in organic matters of both vegetable and animal origin, has been controverted by Frontgous and Bourgarel, and we have the more recent testimony of Antoine and Lenoir* that the use of rain water, distilled water, and even of water brought from France in iron tanks, has vainly been resorted to by the crews of ships visiting that unhealthy region with the hope of escaping its endemic fluxes. In like manner the conclusion of Cornuel, that the dysentery he witnessed at Guadeloupe was caused by drinking the water of the rivers of that island, seems rudely shaken by the subsequent testimony of Dutroulau,† who has shown that at St. Pierre, on the neighboring island of Martinique, where the prevailing dysentery was likewise attributed to the river water, the French garrison was for several years supplied with rain water for drinking purposes without any diminution in the ravages of the disease. In view of these observations, which show the futility of any effort to prevent dysentery by the use of rain water, or even of distilled water, for drinking purposes, it is not surprising that the employment of boiled water should likewise fail to protect. We have the recent testimony of Dudgeon‡ that, although boiled water is universally employed by the Chinese for drinking purposes, diarrhœa and dysentery are common among them.

Both in Europe and our own country fears have been expressed that the water of rivers may be so contaminated by the sewage of towns seated on their banks as to render their use farther down the stream injurious. But the English investigations seem to render it highly probable that when organic impurities are thus discharged into a running stream

---

* A. FOUCAUT—*Essai sur les eaux du Cambodje*, Archives de Méd. Navale, T. IV, 1865, p. 225—found by analysis a considerable quantity of organic matters in the water of the Cambodje, and concluded from his study of the subject that "the local river and other waters in the province of My-thô are of bad quality on account of the large quantity of organic matter they contain;" and that "the use of these waters is one of the principal, though not the only cause of dysentery among the Europeans," p. 241. This opinion is sustained by J. B. L. GAYME—*De la dysenterie endémique dans la Basse-Cochinchine*, Montpellier Thesis, No. 10, 1866, p. 10 *et seq.*, also p. 18 *et seq.*, who declares that these waters "contain in abundance vegetable and animal débris," which, on account of the high temperature of the region, speedily enter into putrid decomposition, p. 18. These views have been controverted by A. FRONTGOUS—*Considérations sur la dysenterie observée en Cochinchine pendant les années* 1863-64, Montpellier Thesis, No. 30, 1866, p. 14, and A. C. A. BOURGAREL—*De la dysenterie endémique dans la Cochinchine Française*, Montpellier Thesis, No. 100, 1866, p. 27. F. ANTOINE—*Essai sur la diarrhée endémique de Cochinchine*, Paris Thesis, No. 256, 1873, p. 55—in reference to this discussion, declares that whenever this water "has been replaced by rain water, or ships have continued during their sojourn in Cochin China to use water brought from France, the intestinal derangements have not been the less frequent." J. M. H. LENOIR—*De la diarrhée chronique de Cochinchine*, Paris Thesis, No. 124, 1874, p. 16—gives two examples in illustration of the truth of this assertion. The first was communicated by a friend: On board the Tarn, only distilled water, or water brought from Toulon in iron tanks, was used for drinking purposes by the officers and crew; yet while the ship was at Saïgon numerous grave cases of flux occurred. The second fell under his own observation, when he visited Cochin China on the Corrèze; the same precautions were vainly enforced. The commanding officer, the surgeon and several other officers suffered from the disease.

† CORNUEL—*Mém. sur la dysenterie observée à la Basse-Terre, (Guadeloupe,)* Mém. de l'Acad. Royale de Méd., T. VIII, 1840, p. 103—expresses himself quite strongly: "J'ai pu remarquer que, la dysenterie ne se rencontrait que dans les lieux où l'on boit l'eau des rivières. A la Grande-Terre, à Marie-Galante, aux Saintes où il n'y a point de rivières, on ne boit que de l'eau de pluie ou de mare, et la dysenterie y est fort rare." This testimony is often cited as conclusive, but we learn from A. F. DUTROULAU—*Traité des Maladies des Européens dans les Pays Chauds*, 2me Éd., Paris, 1868, p. 563—that "the inhabitants of Fort-de-France, who drink only rain water, are persuaded when they come to St. Pierre that the diarrhœa by which they are often attacked is due to the use of the river water drunk there. At St. Louis the same accusation is directed against the river water, charged, it is said, with marsh matters during the rainy season, and brackish during the dry season." Nevertheless he assures us "that at St. Pierre the soldiers, whom it has been desired to remove from the influence of the river water, have drunk rain water for several years, but dysentery has none the less continued its ravages in the garrison." Moreover, in 1848, two French ships of war, the Brandon and the Embuscade, while at this place, had violent epidemics of dysentery on board. During the whole period the crew of the first drank nothing but distilled water, and the second, water brought from France, while at the same time the merchant ships in port, which took no such precautions, escaped.

‡ JOHN DUDGEON—*The diseases of China, etc.*, The Glasgow Med. Jour., Vol. IX, 1877, pp. 174 and 309: "But whatever be the water, and wheresoever the supply, it is invariably boiled by the Chinese," p. 191. If this statement be literally true, it seems to explain why, in spite of the contamination of the drinking water with sewage, typhoid fever should be so rare as it is said to be, p. 179 *et seq.* On the other hand, this precaution seems to have exercised no control whatever over the spread of cholera, p. 332, or of the alvine fluxes. "In summer, diarrhœa and dysentery are very frequent, caused chiefly by eating the early unripe fruits and vegetables, and in too great a quantity, and probably also by exposure at night and sudden and severe vicissitudes of temperature." It is true, DUDGEON further expresses the opinion that dysentery among the Chinese is less severe and less apt to be complicated by hepatic inflammation than among Europeans in China, but this contrast between natives and strangers usually exists in tropical climates, whether the natives drink boiled water or not. It would also appear from this paper that periodic fevers, alvine fluxes and small-pox are the chief diseases among the Chinese—p. 320 *et seq.*—which is in accord with the observations of WILSON—p. 337. The frequency of diarrhœa and dysentery among the Chinese is denied by FALOT—see note *, p. 614, *supra*—and the reason given that they use boiled water; but I presume the testimony of DUDGEON, who lived and practiced medicine among them, corresponds better with the facts.

they are speedily oxidized and become harmless.* Assistant Surgeon Willson,† of the 3d Michigan volunteers, attributed an outbreak of diarrhœa and dysentery in that regiment during March, 1862, to drinking the water of the Potomac river between Alexandria and Washington, where it is contaminated with the sewage of the latter city. I feel much doubt as to the correctness of this opinion. At the time referred to in his narrative the Army of the Potomac was shipped on transports for the Peninsula, and no similar complaint was made by any of the numerous other regiments compelled to drink Potomac water at the same time.

On the whole, it must be admitted that the evidence relied upon to connect impurities of animal origin in the drinking water with the production of the alvine fluxes is by no means so strong as that which attributes typhoid fever to a similar origin. The subject is surrounded by many difficulties, chief among which is the circumstance that other more potent causes of dysentery undoubtedly exist, as shown by the frequent occurrence of that disease at times and places where no fault can be found with the drinking water. Nevertheless, the opinion that impure water may, under certain circumstances, produce alvine fluxes is wide-spread among modern physicians,‡ and I confess I regard it with great favor. If it be true that in some forms of dysentery the discharges from the bowels are contagious, the use of drinking water contaminated with sewage in which such discharges are mingled would certainly offer a ready means for bringing the specific poison into contact with the intestinal mucous membrane of healthy individuals and thus of propagating the disease.

* I refer particularly to the *Report of the Royal Commission on Water Supply*, London, 1869. The commissioners expressed the opinion mentioned in the text in the following striking language: "The organic compounds dissolved in the water appear to be of very instable constitution and to be very easily decomposed, the great agent in this decomposition being oxygen, and the process being considerably hastened by the motion of the water. Now, as such waters always contain naturally much air dissolved in them, the decomposing agent is ready at hand to exert its influence the moment the matter is received into the water; in addition to which the motion causes a further action by the exposure to the atmosphere; and when, as in the Thames, the water falls frequently over weirs, passes through locks, etc., causing further agitation and aeration, the process must go on more speedily and more effectually. The effect of the action of oxygen on these organic matters, when complete, is to break them up, to destroy all their peculiar organic composition, and to rearrange their elements into permanent inorganic forms, innocuous and free from any deleterious quality. This purifying process is not a mere theoretical speculation; we have abundant practical evidence, which we shall hereafter refer to, of its real action in the Thames and other rivers," p. LXXIV, *Report*. See, especially in support of these conclusions, the testimony of PARKES, *Minutes of Evidence*, 3,180 to 3,188, p. 119; HAWKSLEY, 5,676 to 5,683, p. 287; ODLING, 6,451 to 6,462, p. 353; MILLER, 7,088, p. 437, and others. It must be added that, on the other hand, FRANKLAND maintained before the commission that sewage once introduced into water is decomposed with extreme slowness, so that it is very doubtful when it is got rid of, if ever,—6,222 to 6,426, p. 340 *et seq.* Two years later, before the Select Committee on the Metropolis Water (No. 2) Bill—*Special Report, ordered by the House of Commons to be printed*, July 25, 1871—his testimony was still more positive. He declared that sewage once introduced is not got rid of in the Thames, or any river in England, and that "168 miles run would not get rid of above a third of it," *Minutes of Evidence*, p. 103. See, in support of the views of the commissioners, the observations of C. F. CHANDLER—*Water supply of cities*, Reports and Papers presented at the Meetings of the American Public Health Association, in the year 1873, New York, 1875, p. 542—with regard to the water of the Hudson river.

† G. B. WILLSON, letter from, in the Boston Med. and Surg. Jour., Vol. LXVI, 1862, p. 198: "After embarkation, at 10 A. M., on the 17th," (of March, 1862,) "we lay between Washington and Alexandria at anchor till afternoon of the 18th. The water of the Potomac, always muddy and dirty, is at this point pretty well mixed with the drainings of sewers and filth of every kind from Washington, which at the present time, between citizens and other civilians and soldiers, must have a population of over 100,000. This was the only water our men had to drink from the time we embarked, and in less than twelve hours it began to show its effect in diarrhœa and dysentery. Between that time and our landing at Fortress Monroe, I think I must have prescribed for as many as 150 cases of diarrhœa and dysentery, and some 30 or more of our men are yet suffering from the same complaint, contracted or first developed on the boat." A curious supposed cause of water contamination is mentioned by Medical Director Brinton, Appendix to Part I, p. 29, who says of the troops of the Army of the Tennessee at Pittsburgh Landing: "Many of them had been for weeks suffering from the diarrhœa peculiar to the Tennessee River. This is said to result from the large amount of animal decomposition which takes place on the mussel beds or shoals, a few miles above Pittsburgh Landing. Whether this explanation be or be not correct, it is certain that almost every one drinking the water of the river suffered from a profuse diarrhœa which resisted obstinately the ordinary therapeutic means." The above statement, communicated to me verbally by Surgeon Brinton, was mentioned in my *Outlines of the Chief Camp Diseases*, &c., Philadelphia, 1863, p. 212. I have, however, since that time satisfied myself that the opinion is erroneous. In answer to an inquiry addressed to Dr. LAWRENCE SMITH, of Louisville, Kentucky, I have received a letter from General E. KIRBY SMITH, dated March 14, 1878, in which that distinguished gentleman says: "I know of no causes which would tend to make the waters of the Tennessee in the vicinity of the Mussel Shoals laxative in quality. I have waded for days in the Shoals in my conchological trips, drinking freely of the river water, with a tendency to diarrhœa at the time, without having been affected. The inhabitants along the river do not attribute such qualities to the water. From the rapidity of the current and the rocky bottom, the water is in more constant motion, better aerated, and purer than at other points. The mussels are living and healthy. I saw no evidences of impurity imparted to the waters by them; on the contrary, I am convinced they make the water of the river purer and healthier." Dr. J. BERRIEN LINDSLEY, secretary of the Tennessee State Board of Health, in transmitting this letter remarks: "I may add that a similar acquaintance with the mussel beds and shoals on the Cumberland river, fully confirms the views expressed by Professor Smith."

‡ Though usually mentioned by the more prudent rather as a suspicion to be investigated than a fact established, for example, note the caution with which VIRCHOW has expressed himself on this subject—*Kriegstyphus und Ruhr*, Virchow's Archiv, Bd. LII, 1871, S. 30: "Unreines, mit organischen, in Zersetzung begriffenen Stoffen vermischtes Trinkwasser steht mit Recht im Verdacht, sowohl Abdominaltyphus, als Ruhr hervorzurufen." J. B. FONSSAGRIVES—*Hygiène et Assainissement des Villes*, Paris, 1874, p. 296—speaks much more positively: "En ce qui concerne la dysenterie, on n'a plus à démontrer combien l'usage alimentaire d'eaux abondant en matières organiques est susceptible de produire cette maladie;" but he does not cite a single observation in proof, though, when he comes to typhoid fever, a few lines further on, he finds them readily enough.

On the other hand, we may suppose that decomposing animal matters of a non-specific character may, if imbibed with the drinking water in sufficient quantities, give rise to ordinary intestinal catarrhs, which, in accordance with the amount of poison, or the susceptibility of the individual, may or may not assume the characters of dysentery. But all this is to a great extent conjectural, and founded rather upon the analogy of typhoid fever than on actual observations with regard to dysentery. Further investigations, undertaken with special reference to these questions, are much to be desired. Most of those hitherto recorded are loosely made, and few of them will bear even gentle criticism. An outbreak of diarrhœa or dysentery occurs at a particular place, the drinking water happens to be bad, and this is forthwith assumed to be the cause.

But if the fæcal contamination of water is ever a cause of dysentery, certainly the necessary conditions are too often supplied by military camps in time of war. The graphic language of Medical Inspector Summers* shows that, as late as the summer of 1863, the great western army under General Grant had not yet learned the lesson which Moses† taught the Israelites, when he made it a religious duty to bury their excrement beneath the soil; and I know of no reason for believing this particular army to have been less cleanly than the others. Certainly, I myself often witnessed such scenes as Dr. Summers has described, in the vicinity of the camps of the Army of the Potomac, before Washington and on the Peninsula. It is true that army regulations directed sinks to be dug in the vicinity of every camp,‡ and it was generally directed that each day's deposits should be covered with earth. But it was long before the men learned to use the trenches exclusively, and they were too often so badly managed that it was disgusting to use them.§ The brush and timber in the vicinity of the camps usually bore positive testimony to the common neglect of the regulations on this important subject. Where the water supply was derived wholly or in part from shallow surface wells, these were not unfrequently so situated that every rain must have washed into them more or less of the fæcal matter that polluted the soil. Where camp sites were long occupied, additional sources of surface contamination were afforded by the offal of cattle slaughtered for food, which was too often imperfectly buried, and without due regard to any relation between the situation of the place of burial and the wells. The same remark applies to the burial of dead horses, but I believe rarely to dead men, who were, I think, more faithfully and discreetly buried than in any other war of similar magnitude.

That these sources of water contamination exercised, in proportion as they existed, an injurious effect upon the health of our troops I do not for a moment doubt. That this was one of the means of the general spread of typhoid fever is, to say the least, highly probable, in view of well-known facts with regard to the diffusion of that disease by means

* *Supra*, p. 95; and yet in the very same report the writer seems to attribute the fluxes of these filthy camps to the fact that the water was hard.

† *Deuteronomy*, Chap. XXIII, 12–14: "Thou shalt have a place also without the camp, whither thou shalt go forth abroad: And thou shalt have a paddle upon thy weapon; and it shall be, when thou wilt ease thyself abroad, thou shalt dig therewith, and shalt turn back and cover that which cometh from thee: For the Lord thy God walketh in the midst of thy camp, to deliver thee, and to give up thine enemies before thee: therefore shall thy camp be holy: that he see no unclean thing in thee, and turn away from thee." Our modern trowel-bayonet is well fitted for the office of the Hebrew's paddle, and it is to be hoped will be so used in any future war; meanwhile its aid is said to be occasionally required on the frontier.

‡ *Revised U. S. Army Regulations* of 1861, § 522, 536 and 539. The official directions were: "A portion of the earth dug out for sinks to be thrown back occasionally." Some intelligent officers insisted that this should be done daily, but that proper practice was by no means universal. Compare my remarks on this subject in my *Outlines of the Chief Camp Diseases*, etc., Philadelphia, 1863, p. 49.

§ See also, in this connection, the testimony of O. C. GIBBS, Surgeon 21st N. Y. vols.—Army Correspondence, Med. and Surg. Reporter, Vol. IX, 1862–3, p. 83—with regard to the camp of his regiment near Sharpsburg, Md., in October, 1862: "It is supposed that we are to remain but a short time here, and soldiers go to stool wherever convenience dictates. The consequence is that a stench from fæcal evacuations poisons the whole atmosphere." This regiment of 280 men had 35 to 50 men on sick call daily, nearly all with diarrhœa. So, too, Medical Director MCPARLIN reported to General MEADE, June 5, 1864; see Appendix to Part I, p. 161, with regard to the Army of the Potomac near Cool Arbor: "Very few regiments have provided sinks for the men, and their excreta are deposited upon hill sides, to be washed thence into the streams."

of infected water. I suspect also that it was not without its influence upon the spread of the fluxes so common among the troops. In the camps before Yorktown, along the Chickahominy, and in other situations where surface wells were commonly used, their water was very generally accused of producing diarrhœa and dysentery. Several complaints to this effect will be found in Section II.* If this opinion was well founded, I do not doubt that the mischief was done rather by the animal impurities just referred to than by decomposing vegetable matters from the surface. But it would be difficult now to determine the extent of the injury arising from this source, and no analyses were made that can be referred to as showing the extent of the contamination in any particular case.†

Drinking cold water.—No discussion of the relation of water to the etiology of dysentery would be complete that did not consider the action of pure water if drunk too cold and in excessive quantities. Long ago, Aretæus ‡ mentioned drinking cold water among the causes of ulcerative dysentery, but this opinion was by no means generally shared by the ancient or mediæval writers, and when, in the last century, the learned Ackermann § discussed the opinion of Aretæus, it appeared to him quite extraordinary. Of late, however, this view has again been brought forward, especially by some of the French writers, Catteloup, Savignac, Dutroulau, Barrallier and Lubrez.‖ It is asserted that, particularly in tropical climates, the ingestion of large quantities of cold water by those who are heated and sweating, as, for example, soldiers on the march, is often followed by cramps, diarrhœa with or without vomiting, or even by dysentery. These results are particularly likely to occur if the ingurgitation of large draughts of cold water is followed by rest in the shade, especially if the surface be simultaneously chilled by a cool breeze; if, on the other hand, the drinker continues his march, or other exercise, he usually escapes. Two explanations have been offered for the accidents in question: The cold drink may simply aid the cool breeze and rest in the shade in producing a sudden suppression of perspiration, with consequent internal congestions; or the direct lowering of temperature in the stomach and adjacent parts, the heat of which is abstracted by the mass of cold water, may produce functional disorders of the solar plexus of nerves, or of the circulation of the abdominal viscera; in either case, the mischief is due to the introduction of a mass of liquid at a low temperature; any other cold liquid, *e. g.*, beer, would act in the same manner.

‡ ARETÆUS—*De Causis et Signis Morb. Diut.*, Lib. II, Cap. 9, Ed. Boerhaave, p. 60: The word used is ψυχροποσία, drinking cold water. CELSUS—Lib. IV, Cap. 15—on the other hand, recommends drinking cold water as a cure for dysentery. He declares that it "astringes the ulcers and thereby institutes the beginning of a cure."

§ ACKERMANN—*De Dys. Antiq.*, Leipsic, 1777, pp. 100 and 101: "Hoc vero maxime mirum est, quod Aretæus, qui in enarrandis dysenteriæ caussis maximo pæne inter majores nostros studio elaboravit, frigidæ adeo aquæ infestam vim in creando diro hoc atque hominibus tam molesto morbo accusaverit." He hastens to express his opinion that ARETÆUS is quite in error, unless his remark be restricted to marsh water or other impure water.

‖ CATTELOUP—*Rech. sur la dys. du Nord de l'Afrique*, Rec. de Mém. de Méd. de Chir. et de Pharm. Militaires, T. VII, 1851, p. 11—pictures the soldier, fatigued by a long march under the sun of Algeria, reeking with sweat, quenching his imperious thirst with the first water he meets. If it is impure, "it is necessarily injurious to the digestive organs, but pure fresh water taken without moderation can itself become a cause of diarrhœa." SAVIGNAC—*Traité de la Dysentérie*, Paris, 1863, p. 45—states the case still more strongly: "The imbibition of a considerable quantity of water, above all when the body is violently heated and in active diaphoresis, a frequent cause of intestinal derangements in all countries, is one which most directly determines dysentery in those where it is endemic." So also DUTROULAU—*Traité des Maladies des Européens dans les Pays Chauds*, 2me Éd., Paris, 1868, p. 561: "If you interrogate patients as to the cause of their dysentery, many will reply that it occurred because they drank cold water while their bodies were heated or sweating;" and a similar opinion is expressed by BARRALLIER—p. 720, *op. cit.*, p. 603, *supra*. For the most recent presentation of this view, see J. M. LUBREZ—*Essai sur l'Étiologie de la dysenterie*, Paris Thesis, No. 297, 1877, p. 17 *et seq.* See also an essay by JULES ARON—*Relation d'une épidémie de dysentérie saisonnière*, Rec. de Mém. de Méd. de Chir. et de Pharm. Militaires, T. XXXIII, 1877, p. 392—who, in describing an outbreak of dysentery among the 4th dragoons at Joigny during August and September, 1876, makes the practice of drinking large quantities of cold water, on returning heated from the military exercises, play a considerable part in the etiology of the disease among the soldiers.

The accidents resulting from this cause were investigated in 1841 by Guérard,* who collected a considerable number of observations in support of his views. According to him, these accidents may be grouped as functional lesions of the nervous system, affections of the digestive apparatus and of the respiratory passages. Under the first head he mentions pain in the stomach, faintness, headache, vertigo, spasmodic phenomena of various kinds, and even sudden death; under the second, symptoms resembling cholera morbus, gastritis, gastro-enteritis, dysentery and peritonitis; under the third, hæmoptysis, pleurisy and pneumonia. Christison † thought it worth while to point out that some of these phenomena may be mistaken for poisoning; an error which indeed led to judicial inquiries in Paris during the hot summers of 1822 and 1825.‡

In the United States accidents of this kind, first alluded to, so far as I can learn, by Franklin, have been described especially by Rush and Watts.§ Here the nervous phenomena particularly have attracted attention; the patients were seized with dimness of sight, vertigo, fell to the ground, breathed with difficulty, the face was suffused with blood, and not unfrequently death ensued. Now I do not doubt in the least that Watts was right when he ascribed the cases he observed not to the cold water drunk but to *coup de soleil;* and, although it would doubtless be going too far to deny all possibility of injurious effects from the copious use of cold drinks, yet I suspect that the majority of the effects they are supposed to cause should properly be attributed to exposure to heat. The sagacious Drake,‖ who accepted from others the opinion that the accidents ascribed to cold drinks in the eastern cities were really produced by them, vainly sought for cases of a similar character in

* A. GUÉRARD—*Mém. sur les accidens qui peuvent succéder a l'ingestion des boissons froides, lorsque le corps est échauffé;* read to the Acad. royale de Méd., November 30, 1841, Annales d'Hygiène Publique, T. XXVII, 1842, p. 43. A learned essay, in which a considerable number of observations by various authors are cited in support of the views maintained. Among others he mentions an incident related by QUINTUS CURTIUS—*De Rebus Gestis Alexandri Magni*, Lib. VII, Cap. 5, Tauchnitz Ed., Leipsic, 1872, p. 283—according to whom, when the army of Alexander, under a burning sun, reached the river Oxus, so many of those who drank intemperately of its water died, that the loss was greater than that general had previously experienced in any battle. I do not, however, with GUÉRARD understand the mortality in this case to have occurred because the water was cold. The army had just marched through a desert in which for some time they had experienced great suffering from almost total deprivation of water. It was its sudden and intemperate use by men who had long been without it that produced the mortality, not merely its temperature. Under such circumstances the sudden free use of drink is almost as dangerous as the free use of food by starving men.

† ROBERT CHRISTISON—*A Treatise on Poisons*, Amer. Reprint of 4th Ed., Philadelphia, 1845, p. 98. He describes particularly the apoplectic and cholera-like cases. The first might be confounded with narcotico-acrid, the second with pure irritant poisons.

‡ See GUÉRARD—p. 38, *op. cit., supra.* A large number of persons, after swallowing ices and iced drinks in the cafés of Paris during the hot summer of 1825, were attacked by symptoms resembling cholera morbus. Poison was suspected and vainly sought for by chemists appointed by the government. The whole subject was ultimately investigated by a commission of which ORFILA was a member. This body concluded that the accidents were merely due to the sudden action of cold on the stomachs of heated individuals. According to GUÉRARD similar accidents occurred in Paris in the summer of 1822, which was also very warm.

§ B. FRANKLIN—*On the art of swimming, in answer to some inquiries of M. Dubourg,* Life and Writings, Philadelphia, 1840, Vol. II, p. 382: "I once knew an instance of four young men, who, having worked at harvest in the heat of the day, with a view of refreshing themselves, plunged into a spring of cold water: two died upon the spot, a third the next morning, and the fourth recovered with great difficulty. A copious draught of cold water, in similar circumstances, is frequently attended with the same effect in North America." B. RUSH—*An account of the disorder occasioned by drinking cold water in warm weather, and the method of curing it,* Med. Inquiries and Observations, Philadelphia, 1789, p. 123: "These accidents," he remarks, "seldom happen" unless the temperature exceeds 85° Fah. Three circumstances usually concur: The patient is extremely warm; the water is extremely cold; and a large quantity of it is swallowed. A few minutes after swallowing it the patient is affected with dimness of sight, staggers, falls to the ground, breathes with difficulty, his face is suffused with blood, the extremities become cold, the pulse imperceptible, and death ensues in four or five minutes unless relief is obtained. In less severe cases acute spasms occur in the breast and stomach, which are "so painful as to produce syncope, and even asphyxi." Cold punch, beer, and even toddy under the same circumstances, may produce the same effect. The remedy is liquid laudanum. JOHN WATTS, Jr.—*Remarks on the supposed effects of drinking cold water; illustrated by cases which occurred during the hot weather of the summer of* 1818, The Medical and Surgical Register, New York, 1818, p. 81. The cases described, thirteen in number, were all admitted into the New York hospital with symptoms resembling apoplexy. The patients were generally common laborers; some of them recently arrived foreigners: "It was stated that they had been at work, exposed to the sun all the morning, and that they had drank more than their usual quantity of ardent spirits; that after dinner they returned to their work, and with the additional excitement produced by eating, felt an increasing thirst, which obliged them to go frequently to the pumps, and to drink very largely of cold water." The symptoms which followed resembled those described by RUSH. Two of the thirteen patients died. This occurred during the last two days of June and the first of July, 1818. No rain had fallen for some time, and the thermometer in the shade stood at 92°-93° Fah. Numerous other instances were said to have occurred at the same time in various parts of the city: "It may even be feared that some persons have fallen victims to the injudicious and extravagant administration of laudanum; since it was so frequently recommended, and officially, too, by the Board of Health," &c., &c. But WATTS judiciously pointed out that these symptoms differ in nothing from those of "coup de soleil" unaided by the supposed action of cold water, p. 89 *et seq.;* he insists upon the impunity enjoyed by "the multitudes who, while perspiring at every pore, freely drink large draughts of soda water, much colder than the water of our pumps," and concluding that the cases he describes were not caused by the use of water as was supposed, exclaims, "we feel a moral gratification in vindicating the character of that salutary beverage." Yet these cases are cited by both GUÉRARD and CHRISTISON as illustrations of the noxious effects of cold water.

‖ D. DRAKE—*Principal Diseases of the Interior Valley of North America*, Cincinnati, 1850, p. 661.

the interior valley of the United States, and mentioned that in New Orleans, Mobile and other towns near the Gulf coast, ice was regularly imported from New England, and ice water drunk by multitudes in the hottest weather with impunity.

At the present time the free use of ice water has become so general throughout the United States as to astonish Europeans. Ice-water tanks in the railroad cars, depots and public places of all kinds, as well as in the hotels, bar-rooms and private houses, afford an almost unlimited supply, which is freely indulged in during the hottest weather of our most tropical summers. Iced soda water is exposed for sale in the towns at almost every drug shop and confectioner's store, and so greedily purchased that its manufacture has become a considerable branch of industry. Yet no proportionate multiplication of the accidents which have been attributed to cold drinks has followed; on the contrary, in proportion as a knowledge of the phenomena of heat apoplexy has become more widely diffused, the number of cases in which evil effects are attributed to their reckless use becomes smaller and smaller. So far as diarrhœa and dysentery are concerned, I have never myself seen a case which could be fairly ascribed to the abuse of cold drinks, and think their role in the etiology of these diseases has been very greatly exaggerated.

ALCOHOLIC DRINKS.—Here the injurious effects of the abuse of fermented drinks as well as of spirits are to be considered. Already Aretæus* mentioned the unaccustomed use of *malt liquors*, and the various beverages employed as a substitute for wine, among the causes of dysentery. In modern times, beer and ale, especially of inferior quality or soured, as is so frequently the case with the stuff furnished to troops by the sutlers in time of war, have been very often accused by military surgeons† of causing diarrhœa and dysentery. But it seems probable that even the excessive use of these drinks, whether of good or bad quality, is seldom of itself to blame. On the other hand, most drinkers of malt liquors will remember occasions, the digestion being already somewhat disordered, when a moderate quantity of good quality has appeared to produce a purgative effect; and in such conditions of the digestive organs excessive draughts, especially if the liquor is bad or sour, would be still more apt to disorder the bowels. Where other causes of diarrhœa or dysentery coexist, the intestinal disturbance thus produced may, of course, initiate serious disease. The various kinds of mead, root beer, cider,‡ and even the non-astringent wines, under like

* ARETÆUS—*De Causis et Signis Morb. Diut.*, Lib. II, Cap. 9, Boerhaave's Ed., p. 60—specifies in the passage referred to, among the drinks which may thus prove injurious, κυκεών, ἢ βυτέων πόμα; for the latter expression, the reading βρυτέων πόμα is preferred by ADAMS in the Sydenham Society's Edition, London, 1856, p. 110. According to ACKERMANN—*De Dys. Antiq.*, Leipsic, 1777, p. 97—κυκεών or κυκεών πόμα, latinized cocetum, was a sort of thick soup, concerning the composition of which opinions differ, some saying that it was made of wine and flour, others that it also contained cheese and honey. It was rather used as a concentrated food than as a drink. HOMER mentions it in several places, *e. g.*, Circe set it before the companions of Ulysses—*Odyssey*, Book X, Lines 233–5 and 290. Concerning the drink ρυτέων or βρυτέων, ACKERMANN—*op. cit.*, p. 99—states that the name was applied by the Greeks to a drink made by fermenting grape-skins in water, as well as to fermented drinks made from barley, and also drinks prepared from divers herbs and roots. ADAMS—*op. cit.*, p. 353—translates it "zythus (ale)." The reader may consult on this subject the commentary of ADAMS on the article Ζύθος in PAULUS ÆGINETA, Lib. VII, Sect. 3, Transl. of Sydenham Society, Vol. III, London, 1847, p. 125, to which I will only add that DIOSCORIDES—Lib. II, Cap. 109 and 110, Paris Ed., 1549—describes the medicinal effects of two kinds of drink made from barley, zythum and curmi, without attributing to either the capability of disordering the bowels.

† The reader will recall that PAUL BRAND—*loc. cit.*, note *, p. 609, *supra*—mentioned bad beer among the possible causes of the dysentery of the Danish army in Scania, (1677,) and that the dysentery from which ROLANDER suffered—note ‡, p. 370, *supra*—seemed to be due to the same cause; both these writers imagined that to produce such effects the beer must have contained animal parasites. I will not detain the reader by enumerating the authors who have expressed the opinion that the diarrhœas and dysenteries of soldiers may be due to the abuse of these drinks; a single striking passage from VIRCHOW will suffice. Sketching the various causes which gave rise to fluxes among the German army invading France in 1870, he writes—*Kriegstyphus und Ruhr*, Virchow's Archiv, Bd. LII, 1871, S. 33: "Crowded together in narrow freight cars, provided with no special arrangements for ventilation, the soldiers proceeded almost without interruption hundreds of miles on a stretch. Heated and thirsty they partook indiscriminately of all possible kinds of refreshments offered to them at the stations. All kinds of beer, good and bad, wine, fruit juices and lemonade, fresh fruits, many sorts of bread and meat, coffee, broth, and hundreds of other things were given them and hastily devoured. What wonder, then, that even at this early period so many diarrhœas originated?"

‡ SAVIGNAC—*Traité de la Dysentérie*, Paris, 1863, p. 44—is particularly severe in his remarks on cider, which he says is largely drunk in the north of France. He accuses its excessive use of producing the most brutal drunkenness (l'ivresse la plus crapuleuse) and of provoking violent diarrhœa. Even in moderate quantities it may cause brisk purgation. It is especially dangerous if sour. He actually goes so far as to suggest that its general use accounts for the frequency which he assigns to gastric cancer in Normandy!

circumstances may act in the same way. Indeed, similar evil results occasionally follow the use of non-fermented drinks, such as lemonade and other beverages flavored with fruit juices, especially if stale or made of damaged fruits.

The intemperate use of *distilled liquors* has also long been accused of causing dysentery, especially in tropical climates. Annesley and Martin in India, Catteloup in Algeria, Dutroulau writing of the French Antilles, Savignac and Barrallier,* may be mentioned among those who have taught this view. On the contrary, Twining† suggested that the apparent influence of this cause in India is due rather to the fact that intoxicated persons more recklessly expose themselves to the heat of the sun and sudden changes of temperature than to the direct action of alcoholic drinks, and stated that dysentery occurs very frequently in Bengal among persons of the most exemplary temperance. Haspel,‡ from his experience in Algeria, was led to regard the opinion that the abuse of alcoholic liquors is a common cause of dysentery as a very grave error, and pointed out that during epidemics of dysentery it is common for drunkards to imbibe more than usual without being attacked. Sir John Pringle§ expressed the opinion that spirits drunk to excess tend rather to weaken the constitution than to produce any of the common camp diseases. An official statement, published in the Fort St. George Gazette,‖ shows that during the year 1849 the proportion of cases of dysentery among the soldiers in the Madras Presidency who were temperate drinkers was considerably less than among those who altogether refrained from alcoholic drinks or the intemperate; the excess in the proportion of cases among the intemperate as compared with those who practiced total abstinence was very small. The statistics by which this statement is supported cannot be regarded as conclusive, but they are highly

* ANNESLEY—*Dis. of India*, London, 1828, Vol. II, p. 243: "Among the numerous exciting causes of dysentery to which the European soldier is liable in India, there is none whose influence is so marked as indulgence in the intoxicating liquors of the country. The sick-list of a regiment is invariably increased after pay-day, when the men have the means of this indulgence in their power; and the consequence is generally an attack of dysentery, proceeding commonly from the excitement of the mucous surface of the digestive organs, and the derangement of the biliary and other secreting functions, occasioned by these beverages." Sir JAMES RANALD MARTIN—*Influence of Tropical Climates*, 2d Ed., London, 1861, p. 429—sweepingly enumerates "excesses in the use of wine, spirituous liquors or tobacco" (!) among the predisposing causes of dysentery in India. CATTELOUP—p. 11, *op. cit.*, p. 618, *supra*, remarks: "No one can doubt that the immoderate use of these drinks (liqueurs alcooliques) which are often adulterated and drunk without caution, can secondarily produce dysentery." DUTROULAU—p. 563, *op. cit.*, p. 618, *supra*—especially blames the liquor called tafia, produced by distilling the molasses and other waste products of the manufacture of sugar: "This alcoholic liquor is the cause of the death of a multitude of wretches. Its action on dysentery is incontestable." See also SAVIGNAC—p. 43, *op. cit.*, p. 620, *supra*, and BARRALLIER—p. 719, *op. cit.*, p. 603, *supra*. Both these writers particularly blame tafia.

† TWINING—p. 58, *op. cit.*, p. 608, *supra*. ANNESLEY, *loc. cit.*, expresses similar views, but only as one of the modes in which strong drinks produce dysentery: "When the soldier becomes excited by the use of spirituous liquors, he is utterly indifferent to all the consequences of exposure to the direct rays of the sun, to the cold dews and condensed exhalations of the night: and, negligent of the necessary protection from currents of air, and fogs, and rain, he often exposes himself to each of those causes of disease, sleeping sometimes in the open air and upon the damp ground, without any substance intervening sufficient to protect him from the chilling influence of the cold, damp earth on the one side, and the comparatively cold, moist, and unwholesome atmosphere on the other."

‡ A. HASPEL—*Maladies de l'Algérie*, Paris, 1850, T. I, p. 56 *et seq.*

§ PRINGLE—p. 87, *op. cit.*, p. 600, *supra*: "For as to the abuse of spirits, and of fruit, and drinking bad water, however generally they have been accused, I will venture to affirm, that those three causes together never occasioned the tenth part of the sickness of the army, in any of our campaigns. First, as to spirits, it may be observed, that even when drunk to excess, they tend more to weaken the constitution than to produce any of the common camp-diseases; or if some actually sicken after drinking, we may be assured that many more are preserved by taking those liquors in moderation."

‖ I have not obtained access to this journal, and cite from E. J. WARING—*Statistical notes on some of the diseases of India*, Indian Annals of Med. Science, Vol. III, 1855–6, p. 473: "In an Official Return published in the Fort St. George Gazette, Madras, (February 28th, 1851,) are details respecting the influence of intemperance on the sickness and mortality amongst the European troops, serving in the Madras Presidency, during the year 1849. The troops included in this Return, are the 15th Hussars, H. M. 25th, 51st, 84th and 94th Regiments, and the 1st Madras Fusiliers. From this the following Table is collated:—

DYSENTERY.	Admissions with dysentery.	Deaths from dysentery.	Percentage of admissions to strength.	Percentage of deaths to strength.	Percentage of deaths to admissions.
450 Teetotallers	52	3	11.555	0.666	5.769
4,318 Temperate	344	31	7.966	0.717	9.302
942 Intemperate	112	15	11.889	1.592	12.500

This return tends to show, that too much stress has been laid by some writers on the influence of intemperance on the production of Dysentery, there being very slight difference in the ratio of admission to strength between the intemperate man and the teetotaller. The man who holds the middle course appears to be the least liable to the invasion of this disease."

suggestive, and the attempt of Parkes* to explain them away can by no means be regarded as disposing of the question.

It would be easy, but not profitable, to cite opinions on both sides of the question under consideration. It is a part of the larger question as to the injurious effects of alcoholic drinks on the human frame, which has long been discussed with a degree of bias seldom encountered in scientific discussions, except when the matter in view has also a moral or religious as well as a scientific aspect. On neither side of this question are the opinions advanced so well supported by evidence as to make the opposite view untenable. It is true that the intemperate are often attacked by dysentery, sometimes just after a debauch, and especially in tropical climates; it is also true that perfectly temperate persons are often attacked, especially in tropical climates, and no adequate statistics have been collected to prove which class is most liable. It must be conceded that the absence of such statistics, in view of the moral bias which would make so many persons zealous to collect the facts, if they existed, renders it highly improbable that there is any direct connection between the use or abuse of ardent spirits and the causation of dysentery. And yet it is so well established that habitual intemperance impairs the general health of the drunkard, and that dysentery, when it occurs epidemically, is especially prone to seize upon those whose general health is impaired by any cause, that it is probable that drunkards may be somewhat more subject to attacks during the epidemic prevalence of the disease, and still more so that, as is often alleged, the disease is more fatal to patients of this class, when attacked, than to temperate persons. Moreover, these opinions are in harmony with what we best know of the effects of habitual intemperance upon the health. The fatty or cirrhosed liver so common in old drunkards certainly offers mechanical conditions which may occasion passive congestion of the intestinal mucous membrane, and although this does not of itself give rise to diarrhœa or dysentery, it is undoubtedly favorable to the action of the other causes of those diseases. Moreover, the habitual drunkard is not only more subject to the exposures from which a temperate and prudent person would secure himself, but has less resisting power to oppose to the evil consequences of disease when once established.

Errors of diet.—The relation of errors of diet to the causation of diarrhœa and dysentery has next to be considered. The Greek physicians† laid great stress on the effects of different kinds of food; some relaxed, others constipated the bowels; some were more

* Parkes—p. 285, *op. cit.*, p. 599, *supra*—remarks: "It has been supposed, from some statistics for 1847, published in the 'Fort George Gazette,' that teetotallers were more subject to dysentery, but the error was committed of not estimating sufficiently the influence of a particular station (Secunderabad), where it so happened a number of teetotallers were stationed during an outbreak of dysentery. The conditions of the station were to blame, not the habits of the men." This criticism appears to me highly unsatisfactory: Were there no temperate drinkers or drunkards in the garrison of Secunderabad? I may add that, not having seen the Fort St. George Gazette, I am unable to reconcile the discrepancy between Waring and Parkes as to the date of these observations. Similar statistics collected in other years, and elsewhere, are much to be desired.

† Little bearing directly upon this subject is to be found in the genuine writings of Hippocrates, but much in the spurious or doubtful treatises which have been attributed to him. In *De Victus Ratione*, Lib. II, § 39–56, [Ed. Littré, VI, 535 *et seq.*,] the different articles of food are discussed at length, and several spoken of as relaxing the bowels, producing flatulence, purgation, etc. In the same treatise, § 74, [*Id.*, 615,] diarrhœa and dysentery are particularized among the evil consequences which may follow plenitude resulting from an excess in the quantity of the food as compared with the amount of exercise. In *De Affectionibus*, § 47, [*Id.*, 255,] certain kinds of food are said to cause flatulence, irritation, gripings and loose stools, while others constipate, and elsewhere where cholera and diarrhœa are spoken of as resulting from excess in wine or of the table, § 27, [*Id.*, 239.] In *De Salubri Victus Ratione*, § 7, [*Id.*, 85,] meat diet is said to cause diarrhœa. Galen—*Methodus Medendi*, Lib. VIII, Cap. 5, [Ed. Kühn, X, 571,]—mentions diarrhœas arising from crudities in the aliment, and declares that they sometimes give rise to ephemeral fevers. In *De Probis Pravisque Alimentorum Succis Liber*, Cap. 1, [*Id.*, VI, 749 *et seq.*,] he remarks that among the diseases produced by the use of bad food [succi pravi alimentum] during the famines, which for several years had afflicted the nations conquered by the Romans, febrile affections, diarrhœas with offensive acrid stools, dysenteries and tenesmus had prevailed. These diseases especially affected the country people who had been stripped of their best food to supply the towns, and compelled to live on such coarse roots, herbs and other miserable food as they could get. In this treatise the effects of various kinds of food are discussed at length. A still more elaborate discussion of the different articles which may be used for food will be found in *De Alimentorum Facultatibus*, [*Id.*, VI, 453 *et seq.*] Aretæus—*loc. cit.*, p. 620, *supra*—mentions "the administration of acrid things, such as myttôtos, onions by themselves, garlic, food of old and acrid flesh, by which dyspepsia (ἀπεψία) is produced," among the causes of dysentery—p. 353, Adams' Transl. So also Archigenes—in Ætius, Tetrab. III, Serm. I, Cap. 43, Lyons Ed., 1549, p. 599—affirmed that dysentery might arise from crudities, as well as from unaccustomed and acrid food, (a cruditatibus, perigrenoruinque et acrium ciborum acceptione.)

readily digested than others; some provoked flatulency. Indigestible or acrid food, or a mere excess in the quantity of food, might give rise to apepsia and diarrhœa; and protracted diarrhœa was a recognized cause of dysentery. Indeed, the use of indigestible, acrid or bad food is mentioned among the immediate causes of dysentery by Aretæus, Archigenes and Galen. Among the articles regarded as dangerous by Aretæus, cyceon, a thick soup composed of wine, honey, cheese and flour, and myttôtos, an acrid mixture of which garlic and black olives were the chief ingredients, are particularly specified.* These articles of diet, extensively employed in antiquity, have long since gone out of use; but the effect of certain fungi in producing cholera morbus and diarrhœa, insisted upon by Galen,† is confirmed by modern experience, and has recently been investigated by Letellier and Speneux.‡

The Roman § and Arabian physicians paid no less attention than the Greeks to the effects of particular kinds of diet. There is a striking passage in the Canon of Avicenna,‖ in which it is represented that alvine fluxes may be caused either by a deficiency or excess in the quantity of food otherwise good, as well as by the unwholesome qualities of certain articles of diet. Thus, fluxes are produced by acrid articles such as onions, or by those endowed with venomous properties such as fungi; but special dangers attach to substances that readily putrefy. These are not only themselves prone to become speedily corrupted in the alimentary canal, but when taken with other food communicate to the whole mass their own corruption, and the fermenting contents of the bowel cry out to nature for expulsion from the body. So important did these alimentary causes seem to Avicenna that he devoted a special chapter to the treatment of the fluxes they produce; an arrangement which was long after followed by medical writers.¶

The notion that certain kinds of food are prone to undergo in the digestive canal fermentations of a more putrid character than those which characterize normal digestion had been insisted upon by Galen,** who taught, further, that the same phenomena might result even with wholesome food, if from any cause the digestive processes of the individual were enfeebled; that in these conditions of impaired digestion unwholesome food was

---

* With regard to *Cyceon*, see note * to p. 620, *supra*; according to ACKERMANN, *loc. cit.*, it enjoyed the reputation of being a particularly concentrated form of food used to restore the fatigued, and as a first course in feasts. *Myttôtos*, (μυττωτός.) according to ACKERMANN—*op. cit.*, p. 95—was known by the Latins generally as moretum, though it was probably referred to by PLAUTUS—*Mostellaria*, Act. I, Scene 1, Line 45, Tauchnitz Ed., Leipsic, 1869, T. III, p. 88—under the name alliatum. Its composition is given by DIOSCORIDES—Lib. II, Cap. 182, Paris Ed., 1549, fol. 120—who remarks, in treating of garlic: "Factum ex eo, et nigra oliva intritum, quod myttoton vocant." According to ACKERMANN it was used as food chiefly by slaves and rustics, though the better classes sometimes employed it by the advice of their physicians.

† GALEN refers to this subject in several places; I need cite only *De Probis Pravisque Alimentorum Succis Liber*, Cap. 4, [Ed. Kühn, VI, 770.] where he declares that of the various kinds of fungi, (μύκητες,) mushrooms (βωλίται) are not known to have proved fatal, but that even they, when not cooked, sometimes cause cholera. The other fungi have caused death to some persons, and brought others into danger of death by cholera and diarrhœa.

‡ LETELLIER et SPENEUX—*Rech. sur les principes toxiques des champignons*, Annales d'Hygiène, T. XXVII, 1867, p. 71. According to these writers a number of the species of mushrooms are poisonous, the most dangerous being the *hypophyllum crux militense* of Paulet; of ten victims of poisonous mushrooms, nine owed their death to this. Its administration produces vomiting, pain and diarrhœa, succeeded by cold perspiration, syncope and coma. They found in it two poisonous principles which are identical with those in other poisonous species. The first extracted by water and alcohol, is an acrid non-volatile substance which, when given to cats, produced vomiting, pain, diarrhœa, tenesmus and even bloody stools. The second, extracted from the juice of the plant by a process similar to that used to extract alkaloids generally, is an uncrystallizable substance which acts as a narcotic poison, and resembles narceine in its action. They proposed to call it amanitine, and regard it as a glucoside. Tannin in watery solution is the only antidote, and should be given after, or during the use of oily emeto-purgatives.

§ See, for example, CELSUS, Lib. II, Cap. 19 to 30; note particularly Cap. 28, "De his, quæ facile intus corrumpuntur."

‖ AVICENNA—*Canon*, Lib. III, Fen 16, Tract. 1, Cap. 2, Venetiis, apud Juntas, 1595, p. 809—commences his chapter on the alvine fluxes with the words: "You should know that every flux of the belly results either from the alimentary matters and food (ex cibariis et cibis) from the surrounding air, or the organs, (ex membris.") Toward the close of this chapter he gives the account of the modes in which the food may cause fluxes, from which I have abstracted the remarks in the text—pp. 812 and 813. With regard to the treatment, see Lib. III, Fen 16, Tract. 2, Chap. 8, *op. cit.*, p. 826, De cura fluxus ventris facti propter cibos. Compare with these passages the remarks of GALEN—*De Sympt. Causis*, Lib. III, Cap. 1, [Ed. Kühn, VII, p. 205 *et seq.*]—on indigestion, the occurrence of crudities, the corruption of the food, the consequent formation of vicious humors and their consequences.

¶ See note to p. 273, *supra*.

** GALEN expresses these views more or less fully in various places, but nowhere more distinctly than in the chapter cited in note ‖, *supra*. To quote from this exposition a single passage, he declares that in interpreting the symptoms which arise from this cause it behooves the physician not only to determine whether indigestion exists, "but also wherefore, whether on account of imbecility of the digestive faculty or on account of immoderate abundance, or of some bad quality of the food," [*Id.*, 212.] Among the consequences to be dreaded, if the conditions referred to are neglected, he especially specifies lientery.

particularly to be dreaded, and that the crudities and vitiated juices arising from these processes were fertile sources of disease. Among the kinds of food which were liable to produce such results, Galen appears to have regarded the seasonable *fruits* of summer and autumn with particular disfavor. It may be conceded that Ackermann,* in his attempt to vindicate the wholesome character of these grateful articles of diet, correctly affirms that neither Galen nor the other ancient physicians anywhere in so many words attribute dysentery to their use; yet it cannot be denied that Galen carried his prejudices against them so far as to declare his belief that they constitute one cause of the great mortality in the autumn which had been insisted upon by Hippocrates.† He seems to have in some way connected their employment with the causation of the autumnal fevers; a notion which Arnold of Villanova, in his commentary on the Regimen of the School of Salerno;‡ extended to embrace the pestilential fevers generally, including small-pox and the other exanthemata. It is true, as Ackermann has correctly pointed out, that Galen himself recommended the use of apples in the treatment of dysentery, and that other ancient physicians, such as Alexander of Tralles, advised damsons, grapes and other fresh fruits for the same purpose.§ But the cautious medical use of this kind of food, which the last-named writer advises on account of its laxative properties, by no means warrants the assumption that its indiscriminate or excessive employment by well persons was believed to be harmless.

Subsequent physicians continued to express the Galenical prejudice against fresh fruits, but came gradually to regard dysentery as the chief evil consequence of their use.

---

* ACKERMANN—p. 122 *et seq.*, *op. cit.*, p. 620, *supra*. He relies still more upon the circumstance that "omnes enim pæne medici antiqui sive mala, sive pruna, aliosque fructus, qui ad pomorum classem referri solent, iis, qui intestinorum difficultate exercerentur præcepere."

† HIPPOCRATES—*Aphor. III*, 9, [Ed. Littré, IV, 489:] "In autumn diseases are most acute and most mortal on the whole. The spring is most healthy and least mortal," Vol. II, p. 717, Adams' Transl., cited p. 608, *supra*. In his commentary on this passage GALEN—*Comm. III in Aphor. Hippoc.*, § 9, [Ed. Kühn, XVII, B, 576,]—explains the autumnal mortality by saying that at this season it is both hot and cold during the same day; that it follows the summer heat by which the strength of men has been prostrated; that its chill air drives back the humors which were tending to the skin, and that, besides such causes which are common to all, the autumnal fruits are abundantly offered to those who will use bad diet, and that depraved humors accumulate in such persons who use them freely. In *De Alimentorum Facultatibus*, Lib. II, Cap. 2, [Ed. Kühn, VI, p. 560.] he explains that the perishable nature of the summer fruits favors their fermentation in the digestive organs, and that they are all to be regarded as unwholesome, "sunt autem omnia hæc pravi succi," and in another chapter of the same treatise—Cap. 6, [*Id.*, 569,]—he counsels abstinence from them, for the unwholesome humors which they generate may accumulate in the veins, and there putrefying occasion malignant fevers. These passages must satisfy even those who are unwilling to admit the authenticity of the treatise *De Probis Pravisque Alimentorum Succis*, Cap. 1, [*Id.*, 755 *et seq.*,] in which GALEN relates that he himself frequently suffered from febrile attacks, requiring bloodletting, in the autumn in consequence of his free use of summer fruits, was once in danger of an abscess between the diaphragm and the liver from the same cause, and that he only enjoyed habitual good health after he resolved to refrain from them. He adds that he had persuaded a number of friends to follow his example, with equal benefit to them. PAULUS ÆGINETA—Lib. I, Cap. 53, Transl. of Adams, printed for Sydenham Soc., Vol. I, London, 1844, p. 73—states the objection to fruits somewhat more moderately when he says that in autumn "too much fruit ought likewise not to be taken, being hurtful not only by the quantity, but also by the quality of the chyle which it supplies, and by engendering flatulence."

‡ ARNOLDUS DE VILLANOVA (died, 1313)—*Commentum super Regimen Salernitanum*, Opera Omnia, Basel, 1585, p. 1907. The old verse ran: "Autumni fructus caveas, ne sint tibi luctus," "Take care of autumnal fruits lest they be a sorrow to thee." On which he comments that grapes, peaches, figs and the like engender blood that is prone to putrefy, especially if they be received into an unclean stomach and a body full of ill humors such as generally occur in autumn, and thence ill diseases are engendered, such as small-pox, morbilli and pestilential fevers. There is a curious English translation (not very accurate) of this commentary entitled *The Schoole of Salernes most learned and juditious Directorie*, &c., London, 1617. HÆSER—*Lehrb. der Geschichte der Med.*, Bd. I, 2te Aufl., Jena, 1868, S. 284—thinks the common opinion probable that the Regimen of the School of Salerno was addressed to Robert, son of William the Conqueror, who visited Salerno for the treatment of a wound in 1101.

§ ACKERMANN—p. 123, *op. cit.*, p. 620, *supra*. GALEN—*De Alimentorum Facultatibus*, Lib. II, Cap. 21, [Ed. Kühn, VI, 597,]—says that apples may be given with bread for the purpose of strengthening the digestive organs of those who have but little appetite and digest slowly, as well as those who suffer from vomiting, diarrhœa and dysentery. For these purposes he recommends particularly those apples which possess a certain degree of astringency. On the other hand, ALEXANDER of TRALLES—Lib. VIII, Cap. 9, Basel Ed., 1556, p. 458-9—recommends laxative fruits. The passage referred to relates to the treatment only of the variety of dysentery in which the ulcers are seated in the rectum. For this he advises a regimen intended to keep the stools soft and unirritating. He declares that he has known persons to be cured by the abundant use of damsons or grapes; but he cautions against the unnecessary use of such articles of diet on account of their tendency to fermentation. ACKERMANN—p. 125, *op. cit.*, *supra*—relates, in support of his interpretation of the views of this author, an anecdote in which he is represented as giving fruit freely in an acute bilious disease epidemic in Rome; ("bilioso morbo acuto grassante;") but in fact, the disease in question was simply tertian intermittent fever, and the observation referred to has no direct bearing on the dysentery question. It will be found in the chapter in which ALEXANDER of TRALLES treats of tertian fever—Lib. XII, Cap. 6, Ed. cited, p. 733. He relates that he often administered fruits and vegetables of various kinds, especially pompions, (πεπόνες,) with advantage just before the commencement of the paroxysms, but that most of the Roman physicians never even named them except as generators of bile. On one occasion, after he had prescribed pompions to a patient laboring under this fever, a physician who stood by exclaimed: "Man, why do you wish to kill rather than cure this sick person? Read GALEN on Aliments, where he clearly says that eating pompions makes people bilious." He then says that he was at much trouble to explain to those who could understand him, that GALEN did not say that pompions generated bile, but that they caused cholera, (cholera morbus,) that is vomiting, and goes on to express his own opinion that they do not even have this effect if moderately used. The passage in GALEN referred to will be found in *De Alimentorum Facultatibus*, Lib. II, Cap. 4, [Ed. Kühn, VI, 564.]

Fabricius Hildanus* very clearly sets forth the reasoning upon which this opinion was based when he declared that the season of autumn, in which these fruits abound, is also that in which experience, as well as Hippocrates, shows that dysentery chiefly prevails. It would be unprofitable to multiply citations in illustration of the extent to which this opinion found acceptance. For a long time it encountered no serious opposition. It was acknowledged that the use of fruits in excess, especially if unripe, was a common cause of diarrhœa and dysentery, even by those who, like Sennertus,† correctly held that it was not the exclusive cause of these diseases, and pointed out that dysentery occurs also among infants at the breast and grown persons who never use fruit, and that it may prevail as an epidemic in the spring before fruits make their appearance.

The first whose protest against this general belief secured a favorable hearing from medical men was undoubtedly Degner,‡ who based his opinions as much upon unfounded speculative reasons as upon the observations he brought forward to show that fruits may be freely indulged in without danger, and that, although their abuse may give rise to simple diarrhœa, it is not chargeable with the production of dysentery. His speculations did not long survive, but his observations were confirmed by others, and the innocence of fresh fruits, so far as the causation of dysentery was concerned, was affirmed by Sir John Pringle, Tissot, Zimmermann, Donald Monro and many others.§ Tissot relates that a regiment of Swiss, stationed in southern France, having been attacked by dysentery, the

* G. Fab. Hildanus—*De Dysenteria*, (1602,) Opera, Frankfort, 1646, p. 670—"Experientia enim docet, uti quoque Hippocr. et alii scriptum reliquerunt, autumni tempore, cum hujusmodi fructus maturescunt, dysenteriam imprimis grassari." But he gives an explanation of the mode in which they act, which is quite consistent with the Galenical teachings when he declares that they do mischief, "quia facile corrumpuntur, et in humorem causamque morbificam dysenteriæ convertuntur." Hildanus gives *(loc. cit.)* quite a list of authorities to whom he appeals in support of these views; but an examination shows that he has confounded together the more ancient writers who declare autumnal fruits injurious, and the more modern ones who say that they produce dysentery.

† Sennertus—*Pract. Med.*, Lib. III, Pars II, Sect. 2, Cap. 7, Opera, Paris, 1641, T. III, p. 125—names, in a general way, among the causes of dysentery, "such a nature of the food and things swallowed that they can be readily converted into acrid and eroding humors, (humores acres et mordaces.") He admits that the common opinion is right, that fruits, especially if not ripe, belong to this class, "cum experientia doceat, multos ab esu fructuum ut prunorum, nucum, avellanarum et similium, præcipue non satis maturorum in dysenteriam incidisse." Yet he declares his belief that the cause of dysentery ought not always to be referred to the use of such fruits, since even those who altogether abstain from them have fallen into dysenteries. Then he adds the noteworthy observation that the epidemic dysentery of 1624 began in some of the towns in the neighborhood of his practice in the month of May, before there was any fruit at all, and greatly diminished, or altogether disappeared, towards the close of autumn, when all the fruits were ripe and in daily use. Moreover, during the same epidemic he himself treated dysenteries afflicting suckling infants and persons who wholly abstained from the use of fruits. Sennertus had a special prejudice against eating grapes and drinking must, for which he gives the following reasons: "Nam non solum fermentationem in humoribus excitant; verum sæpe etiam ex nebulis, rubigine et carbunculo, araneis, aliisque vermibus multa inquinamenta uvis et musto insunt, quæ humores inficiunt et concitant, ut diarrhœæ et hinc dysenteriæ causæ sint, præsertim si corpus dispositum sit."

‡ Others had previously taken the same ground, but without securing a general hearing. Thus, Peter Rommel—*Dysenteria contumax uvis recentibus et musto curata*, Ephem. German., Dec. II, Ann. 10, Obs. 192, p. 370—after relating a case of dysentery which was cured by the diet Sennertus accused of causing the disease, viz: eating grapes and drinking must, declared that common experience shows that fruits of all kinds, cucumbers, plums, &c., are eaten daily and in abundance without any injury whatever to the health. And Sam. Carl—*Spec. Theor. Med.*, p. 297, cited by Degner, *loc. cit.*, *infra;* I have not been able to see the original—had pointed out that in vintage time the intemperate use of grapes occasionally causes diarrhœa, but is never known to produce dysentery. Degner—*Hist. Med. de Dys. Bilioso-Contagiosa*, &c., (1738.) Ed. novissima, Utrecht, 1754, p. 248—thought that the acid fermentation of the fruit was so contrary in its nature to the alkaline fermentation which he supposed to arise from the miasma that produces dysentery ("ortæ e miasmate bilioso-dysenterico") that it could not possibly cause that disease; a similar suggestion had been already made by Rommel, *loc. cit.* Degner cites the observations of Rommel, Carl and some others, confirms them by his own, and declares: "Summer fruits sweet, fresh and ripe, do not readily injure anybody, but, rather on account of their friendly vegetable acid, are most grateful to our systems, and truly a divine gift to those who rightly use them."

§ Pringle—*Obs. on the Dis. of the Army*, 1st Ed., London, 1752, p. 24—observed in 1743 that the dysentery appeared earlier than usual among the English troops in Flanders, and remarked: "Now, as its usual time is not before the latter end of summer, or beginning of autumn, its cause has been unjustly imputed to eating fruit in excess. But, the circumstances here contradict that opinion; for the sickness began and raged before any fruit was in season, except strawberries, (which, from the high price, the men never tasted,) and ended about the time the grapes were ripe; which growing in open vineyards were eat by every body." In another passage—p. 109 *et seq.*—he cites Degner, and adopts his theoretical explanation of the innocence o fruit in this connection. Tissot—*Avis au peuple sur sa santé*, (1761.) Chap. 24, § 338, Œuvres, T. III, Lausanne, 1788, p. 13—says that unripe or bad fruit may sometimes occasion diarrhœa, constipation, diseases of the nerves and of the skin, "but never an epidemic dysentery. Ripe fruit of any species, especially summer fruits, are true preservatives against this disease." He relates several striking incidents in support of his opinion, among them the one mentioned in the text. J. G. Zimmermann—*Von der Erfahrung in der Arzneykunst*, Theil II. Zurich, 1764. Buch IV. Cap. 6, S. 255 *et seq.*—repeated the opinion of Tissot as to the injury that unripe fruit might do: "Aus dem Misbrauch des rohen Obstes entstehen Herzweh, Coliken, Durchfälle, Verstopfungen und allerley Nervenkrankheiten," but insists that it cannot produce dysentery; he cites Degner in support of the latter opinion. The subsequent experience of Zimmermann during the epidemic of 1765 confirmed him in these views: see *Von der Ruhr unter dem Volke im Jahr* 1765, Zurich, 1767, Cap. III, S. 37 *et seq.*, for the statements made in the text. He also mentions—*op. cit.*, Cap. VI. S. 128 *et seq.*—that during the epidemic of 1765 fresh grapes liberally administered proved an excellent remedy for dysentery. Donald Monro—*An Account of the Diseases which were most frequent in the British Military Hospitals in Germany from Jan.*, 1761, *to the return of the troops to England in March*, 1763, London, 1774, p. 58, note—speaks of the opinion that fruit causes dysentery as a "vulgar error," and cites Pringle and Tissot.

officers purchased the crop of a vineyard for the men, and thus presently cured the sick and preserved the well from the disease, which speedily disappeared. Zimmermann, in the epidemic of 1765, saw dysentery appear among the poor in the month of June, when, indeed, the early cherries were ripe, but much too dear for them to buy, and he observed that that year fruit was unusually scarce; while Tissot had previously shown that there was but little dysentery during 1759 and 1760, years in which fruit was unusually abundant.

Since the commencement of the present century, although from time to time the excessive use of unripe or spoiled fruit has been accused of at least irritating the bowels and favoring the occurrence of dysentery in the predisposed, or during the epidemic prevalence of the disease, most of the physicians who have particularly examined the subject express views which agree substantially with the observations of Degner.* Trousseau† has contributed an observation not unlike that recorded by Zimmermann. In the year 1859 France was visited by a severe epidemic of dysentery; during that year fruits were quite scarce, while in 1858 they were extraordinarily abundant and dysentery was very rare.

In the course of our own civil war it was found that, so far from the use of fresh fruits or vegetables favoring the production of diarrhœa or dysentery, it manifestly diminished the frequency and severity of the diseases. Medical officers report that when fresh vegetables were issued to the troops, or obtained by foraging, the number of soldiers on sick report with fluxes promptly diminished, and that the same result was observed when the men had an opportunity to plunder orchards and vegetable gardens or even to pluck green corn in the fields.‡ Undoubtedly what happened in these instances was partly due to the fact that a wide-spread scorbutic taint existed among our troops, so that the fruits and vegetables owed their beneficial influence to their antiscorbutic virtues. Nevertheless,

* Thus, for example, A. A. MALIK—*Abhandlung über die Ruhr*, Prague, 1828, S. 40—while he admitted that the use of ripe fruit is often not injurious, even that many physicians have employed it in the treatment of dysentery with benefit, held that unripe fruit is often a cause of the disease, and declares that during the epidemic of 1827 on the Nawarow and Jessency estates it particularly attacked children who ate wild berries: "Dass diese Beschuldigung aber auch zum Theil anerkannt werden müsse und wahr sey; zeigen meine Beobachtungen, dass sie am leichtesten bei jenen Kindern sich einstellte, die sich viel in Wäldern aufhielten, und übermässig viel Waldobst, als Heidel-, Preissel- und Brombeeren genossen." NAUMANN—*Handb. der med. Klinik*, Bd. IV, Abth. 2, Berlin, 1835, S. 38—brings forward this observation in support of his opinion that overloading the stomach with green, sour or unsound fruit "acts injuriously upon the intestinal canal, and at least is able to favor the predisposition to dysentery," and remarks: "Aus diesem Gesichtspunkte vermag der Genuss mancher Obstarten, z. B. der halbreifen Birnen, der Pflaumen und Stachelbeeren, als Schädlichkeit einzuwirken." VIRCHOW—*Hist. etc. zur Lehre der Unterleibsaffektionen*, Archiv, Bd. V, S. 350 *et seq.*—maintains the danger of the use of unripe fruit, or of any fruit under certain conditions, remarking that he himself has repeatedly seen fatal dysentery result from the thoughtless use of fruit during convalescence from typhoid fever. BARRALLIER—p. 718, *op. cit.*, p. 603, *supra*—remarks: "We do not completely adopt the opinion of Zimmermann, for it is evident that, if acid fruits under ordinary circumstances can only be accused of provoking diarrhœa, they may become injurious in the course of a dysentery." He thinks, however, that the saccharine (mucoso-sucrés) fruits are perfectly harmless. More moderate views are expressed by BAMBERGER—S. 395, *op. cit.*, p. 578, *supra*; SAVIGNAC—p. 42, *op. cit.*, p. 620, *supra*; DUTROULAU—p. 563, *op. cit.*, p. 618, *supra*, and many others; yet perhaps the majority of modern writers express themselves with caution as to the safety of unripe and bad fruit or condemn it altogether, and several, as SAVIGNAC, for example, think it best to avoid acid fruits during the endemic or epidemic prevalence of dysentery.

† TROUSSEAU—*Considérations clin. et thér. sur la dyssenterie*, (reported by Legrand du Saulle.) Gaz. des Hôpitaux, An. XXXIII, 1860, p. 37; see also *Clinique Méd. de l'Hôtel-Dieu de Paris*, 2me Éd., Paris, 1865, T. III, p. 159.

‡ See, for example, in Section II, the remarks of CALHOUN, p. 73; FORBES, p. 74; and HAMILTON, p. 96. CALHOUN has elsewhere—*Rough notes of an army surgeon's experience during the great rebellion, No.* 15, The Med. and Surg. Reporter, Vol. IX, 1862-3, p. 424—related more fully his experience with regard to the benefits obtained by the second division, 3d Corps, in August, 1862, from the free use of green corn roasted: "That diarrhœas and dysenteries ceased, as if by magic." So also Medical Director J. F. HAMMOND, of the 2d Army Corps—Appendix to Part I, p. 65—says of the diarrhœa which prevailed in the Army of the Potomac on the Peninsula: "A surgeon of brigade reported to me that he had cured some of his cases of diarrhœa with raw Irish potatoes in vinegar." J. C. HUBBARD, Surgeon 41st Ohio volunteers—*Sanitary report*, Cincinnati Lancet and Observer, Vol. V, 1862, p. 527—states that during the summer of 1862 camp diarrhœa in his regiment "was often relieved by the free use of berries and other subacid fruit, and I am of opinion that the improvement of the health of the men in this respect is attributable to the comparatively free access we have to these fruits and fresh vegetables since our arrival to the richer and better cultivated region of North Alabama." S. K. TOWLE, Surgeon 30th Massachusetts volunteers—*Notes of practice in the U. S. A. General Hospital, Baton Rouge, La., during the year* 1863, Boston Med. and Surg. Jour., Vol. LXX, 1864, p. 59: "During the early fall of 1862, I had a large number of serious cases of chronic diarrhœa, many of them exhibiting symptoms of scurvy. The only vegetables within my reach, in any considerable amount, were green oranges; and, as they were very grateful and palatable to the taste of the patients, I bought with my hospital fund large quantities of the fruit, and soon became convinced that few articles of medicine or food did as much good." A. D. COSBY—*On the use of large doses of calomel in diarrhœa and dysentery*, Atlanta Med. and Surg. Jour., Vol. VIII, 1867-8, p. 155—relates his experience with the camp diarrhœa of the 17th Kentucky volunteers, 1862, as follows: "The chronic cases on hand, when I joined the regiment, that did not recover during the spring, were cured by green corn in the summer, without any further medication. The green corn was scraped from the cob and boiled done in water, a piece of fat pork being thrown in to season it. Thus the regiment was delivered from that terrible army scourge." On the other hand, unripe fruits, vegetables, etc., are mentioned among the causes of camp diarrhœa by several reporters in Section II: *e. g.*, CHAMBERLAIN, p. 67; BARKER, p. 68; PERRY, p. 70; VOLLUM, p. 71; REAMER, p. 78; TAYLOR, p. 87; TUTTLE, p. 90; and BIDWELL, p. 96.

such observations are in harmony with those which show the innocence of fresh fruit under circumstances in which scurvy can have played no part, and the old experience of Alexander of Tralles* finds a parallel in the successful treatment of summer fluxes with watermelons and peaches by some of the New England physicians during 1869.† To explain such observations it is by no means necessary to deny that indigestion, vomiting or diarrhœa may at times be produced by the excessive use of green or spoiled fruit. But the dangers from this source are altogether insignificant when compared to the benefits to be derived from the proper use of this kind of food even under ordinary circumstances, and especially in the case of armies in times of war, when so many conditions conspire to favor the development of a scorbutic taint among the troops.

More serious dangers attach to the use of *animal food* in which, from imperfect methods of preservation or length of keeping, *putrefaction has fairly commenced.* Spoiled oysters, lobsters, crabs and fish are particularly obnoxious, but spoiled meat, whether fresh or salted, produces similar effects with an energy corresponding to the degree to which putrefaction has advanced and the resisting powers of the individual.‡ The effects vary from simple vomiting and purging to a brisk gastro-intestinal catarrh which, in extreme cases, may be accompanied by a cholera-like collapse. The severer forms of these accidents are, however, comparatively rare, because such decomposed animal food appears to most persons so revolting that they refuse to swallow it.

An illustration of the production of diarrhœa by the use of food in which putrefaction had commenced was afforded during the year following the war by the so-called Horsford marching ration,§ which consisted essentially of parched wheat in lieu of bread, and a

---

* See p. 624, *supra.*

† See the articles entitled *Watermelon vs. Diarrhœa*, Boston Med. and Surg. Jour., Vol. IV, 1869, by S. G. WEBBER, p. 34; C. E. BUCKINGHAM, who recommends peaches also, p. 73; H. C. BICKFORD, p. 116; and B. E. COTTING, p. 146. The last writer reports nine cases of cholera morbus and acute diarrhœa treated successfully by the free use "of the pulp of ripe watermelons."

‡ I will not attempt to go into the literature of this subject, but refer the reader to the work of R. CHRISTISON—*Treatise on Poisons;* I cite the 1st Amer. Ed., Philadelphia, 1845, Part II, Chaps. 22 and 24, p. 477 *et seq.*—for a pretty good introduction to the earlier observations. He treats quite fully of poisonous mussels and oysters, and of poisoning by diseased and decayed animal food: "These poisons are formed in three ways, by morbid action local or constitutional, by ordinary putrefaction, and by modified putrefaction," p. 487. The symptoms described are vomiting, purging, &c. See also WHARTON and STILLÉ'S *Medical Jurisprudence*, 3d Ed., Vol. II, Philadelphia, 1873, § 535-6, p. 482 *et seq.*, and A. S. TAYLOR—*On Poisons*, 3d Ed., London, 1875, Chap. 54, p. 532 *et seq.* Already, in the last century, G. VAN SWIETEN—*Kurze Beschreibung und Heilungsart der Krankheiten welche am öftesten in dem Feldlager beobachtet werden*, Vienna, 1752, S. 107—declared that camp dysentery arises when the troops eat meat or fish beginning to putrefy, or mouldy bread, or bread made from mouldy flour, ("geschimmeltes, oder von geschimmelten Getraid gemachtes Brod.") A translation of this little work by JOHN RANBY, Surgeon General to the British Army, was reprinted in America, Philadelphia, 1776, for the use of the Continental medical officers during the Revolutionary War.

§ Prof. E. N. HORSFORD, formerly Rumford Professor in Harvard University, Mass., has the credit of having devised this "Marching Ration," and secured its trial by persistent and ingenious representations of its value, in spite of the unfavorable report of a board of officers to whom the question of its adoption was referred. In a communication to the Secretary of War, dated Jan. 23, 1865, he especially claimed for it that it was "more palatable, more healthful, less perishable and less expensive than the existing marching ration." Indeed, he went so far as to assert in another part of the same communication "that it is substantially imperishable." Feb. 18, 1865, the Commissary General was directed by the War Department to purchase 500,000 of these rations for trial. In a communication to the Commissary General, dated March 15, Prof. HORSFORD explains that his "bread ration consists of ninety parts of roasted wheat coarsely ground, ten parts of finely crystallized, not powdered, white sugar and a trace of salt in each hundred parts. Eight ounces avoirdupois is a day's supply." The price charged for this ration of 8 oz. was 8⅓ cents per ration. In the same communication Prof. HORSFORD adds: "The meat ration I call 'roasted whole beef.' It is cooked by coagulating by dry heat the albumen at the surface of the individual mouthfuls into which the total lean meat is cut. It includes in addition to the mass of lean meat ordinarily served, the liver, heart, tongue, and kidneys, together with the meat and nutritive juices detached and extracted from the raw bones of the entire carcass, and the juices of the scrap lean meat adhering to the lump fat. The juices are carried down in vacuo, the lean meat all roasted, and dried down till the pieces are fixed, leaving still about one-fifth of the water of the normal lean meat, the former incorporated with the latter, and with the seasoning resolved into a homogeneous whole of small mouthfuls. These are pressed into forms and varnished with gelatine. * * * Each ration will weigh about three ounces, and occupy about four cubic inches, and be the full nutritive equivalent of ten ounces of first class fresh lean beef." The price charged for the ration of three ounces of this material was 33 cents. These rations, delivered to the Commissary at New York, were ordered by General GRANT to be placed in depot at New Orleans, subject to the orders of General SHERIDAN, for use in the department of Texas. They were actually shipped from New York at various dates between May 25 and July 1, 1865, and having been received by Col. M. P. SMALL, the commissary on duty at New Orleans, portions were sent by him to different parts of Texas during July, August and September, and earnest efforts were made to secure their use by the troops. But the "substantially imperishable" ration had already begun to undergo putrefactive changes. The soldiers for the most part refused to eat it, and those who were induced to make the attempt not merely found it disagreeable in taste and insufficient in quantity, but suffered from diarrhœa produced by its use. Capt. H. F. HAWKES, post commissary at Ringgold Barracks, Texas, reported to Col. SMALL, Nov. 5, 1865: "Captain LEWIS informed me that on being issued to the troops at Edenburg it produced diarrhœa. * * * Of that sent to Rome, a portion was issued to the troops by Lieut. JOHNSTON until its issue was forbidden by Surgeon EAGLE, Medical Director and Inspector of the 2d Brigade, 2d Div., 25th A. C., as diarrhœa was becoming so prevalent that his hospital was filled with patients." He adds that some of the cases containing these rations were inspected and condemned as "mouldy, rotten, and unfit

special form of compressed beef. A large quantity of this food, purchased in the spring of 1865, was sent to the commissary depot at New Orleans for issue to the troops serving in the department of Texas, where it arrived during the summer of the same year. The parched wheat soon spoiled and became full of vermin; the beef underwent putrefactive changes, and, as a consequence, the marching ration was tried to but a limited extent. When actually used it produced diarrhœa, and this result occurred not only when the whole ration was eaten, but in some instances followed the employment of the spoiled parched wheat only. That greater mischief did not occur appears to have resulted from the refusal of the troops to use this putrid food to any very great extent.

In connection with the injurious effects of damaged animal food I may refer to the consequences of the use of meat containing the trichina spiralis. Such food is well known to produce violent gastro-intestinal catarrhs with other serious symptoms.* It has been suggested that this cause may have played an important part in the production of intestinal fluxes during the civil war,† but I know of no observations showing that this was actually the case. In this place, also, may be mentioned the attacks of vomiting and purging that occasionally follow the use of cheese, and are sometimes so violent as to give rise to suspicions of poisoning. In November, 1864, Surgeon F. V. Hayden, U. S. Volunteers, forwarded to the Surgeon General's Office for chemical examination a large piece of cheese from which a distinguished general officer and his staff had eaten freely at dinner, and which, from the violence of the vomiting and purging produced, was believed to be poisoned. A careful chemical examination by Dr. B. F. Craig showed the error of this view.‡ The exact conditions under which cheese assumes this poisonous character and the nature of the changes that occur are as yet unknown.§

---

for issue. To be buried immediately and dropped from the returns." In an endorsement, dated Nov. 28, 1865, Col. SMALL remarks: "Similar reports from different points in this military division have been received regarding the condition and issue of this peculiar ration, all of the same tenor, viz: the meat rotten and mouldy, the bread filled with weevil and worms and unfit for issue. The Horsford meat and bread ration on hand at this depot, in a dry storehouse, and not exposed to the weather either by transportation or otherwise, was found upon examination to be unfit for issue, and the following is the report made: Inspection report: Condition of meat ration 'mouldy, rotten, and totally unfit for issue to troops; if possible, to be sold, otherwise to be thrown away or buried. Bread ration is full of weevil and other worms, should have been packed in air-tight tin cases; to be sold, as it is only fit to be fed to hogs or cattle.'" The quantity thus condemned at New Orleans, Nov. 13, 1865, was 127,500 of the bread rations, 129,200 of the meat rations. Surgeon D. MACKAY, 29th U. S. colored troops, writes, Nov. 13, 1865, that as post surgeon at Ringgold Barracks he had "the Bread ration tested to its fullest extent. In no case have I known it to produce anything but injurious results. It is perfectly inadmissible in affections of the alimentary canal." Surg. BENJ. DURHAM, Jr., U. S. Vols., Chief Med. Officer 3d Div., 25th Army Corps, writes, Nov. 15, 1865, to the commissary at Brazos Santiago, Texas: "I decidedly protest against any attempt to issue this beef to the troops, for you will find it spoiled, and I recommend that it may be immediately removed from your storehouses lest it should disadvantageously affect other desiccated rations. I also request, if this is condemned, that (as a sanitary measure) it be taken out in a lighter and thrown into the gulf. Unless properly buried it should not be left on the island." Asst. Surgeon O. F. ROGERS, 117th U. S. colored troops, writes from Ringgold Barracks, Dec. 7, 1865, that the Horsford bread ration "produces colic and diarrhœa in a great proportion of the men." Capt. CHAS. H. MORSE, 117th U. S. colored troops, writes, Dec. 9, 1865, of the bread ration: "In my own case, and in the case of the men of my company, it produced diarrhœa." Asst. Surgeon B. HOBBS, 116th U. S. colored troops, reports, Dec. 8, 1865, that during the few days that Horsford's marching ration was issued under his observation, "there was a great increase of sickness in the command," especially of "bowel derangements." The unfortunate results of this experiment are well calculated to suggest caution to future aspirants in the same direction.

* On the subject of the trichina spiralis, see F. KÜCHENMEISTER—*On Animal and Vegetable Parasites of the Human Body*, Transl. of Syd. Soc., London, 1857, Vol. I, p. 233 *et seq.*; C. DAVAINE—*Traité des Entozoaires*, Paris, 1860, p. 672 *et seq.*; T. SPENCER COBBOLD—*Entozoa*, London, 1864, p. 334 *et seq.* The last two authorities may be especially consulted for the literature of the subject.

† GEORGE SUTTON—*A report on trichinosis as observed in Dearborn Co., Indiana, in* 1874, Trans. of the Indiana State Medical Society, 1875, p. 126—after referring to the mortality among our troops during the civil war from intestinal fluxes, remarks: "When we take into consideration the imperfect manner in which meats are often cooked in the army; the hurried manner in which the meals are prepared and eaten—meat often eaten almost raw during the excitement of battle—the large amount of pork which enters into the rations of the soldiers, with the gastro-enteritis which trichinous pork is known to produce, it makes it more than probable, we think, that many of these cases of diarrhœa and dysentery arose from trichina."

‡ Dr. CRAIG, then chemist of the Surgeon General's Office, reported, November 14, 1864: "I do not find in the cheese any of those mineral poisons whose presence would account for the effects produced by it, but from its taste and smell I believe it to have entered into a peculiar condition of putrefaction which is known to occur in cheese and to confer upon it poisonous properties."

§ On this subject PARKES—p. 249, *op. cit.*, p. 599, *supra*—remarks merely: "Sometimes cheese becomes sour, particularly if made from sheep's milk, and may cause diarrhœa." L. PAPPENHEIM—*Handb. der Sanitäts-Polizei*, 2te Aufl., Bd. II, Berlin, 1870, p. 71—states that the so-called cheese-poison ("Käsegift") occasionally develops in the most unaccountable way in the whole product of cheese factories, which for years have been producing a wholesome article. In such a case brought to his own notice, he searched in vain for any known poisonous substance which might have been accidentally introduced during the process of manufacture. He suggests that some microscopic fungus developed in the cheese may be the cause of the trouble; (see also S. 451;) but this is a pure speculation, for which there is no evidence whatever. See, for an introduction to the older literature of the so-called poisonous cheese, CHRISTISON—Part II, Chap. 24, p. 494 *et seq.*, *op. cit.*, note ‡, p. 627, *supra*; also WHARTON and STILLÉ, § 534, p. 481, and TAYLOR, p. 534; both cited in the same note.

In a general way it must be admitted that the ingestion of large quantities of any food difficult to digest may give rise to vomiting or diarrhœa. But here the condition of the individual is often more important than the character of the food, for that which is readily disposed of by robust digestive organs is often wholly unmanageable by individuals whose digestive organs are for any reason impaired.

Two articles of the army ration issued to our troops, hard bread and beans,* were often accused of provoking indigestion and camp diarrhœa during the civil war. The hard bread appears to have acquired its bad reputation chiefly from the fact that fragments of it were frequently recognized in the stools of those suffering with chronic fluxes; and perhaps in such cases it may actually have acted as an irritant, especially when bolted without sufficient mastication. But the experience of sailors, and of the army in time of peace, seems to show conclusively that hard bread is of itself a wholesome article of diet, and that it may be used without injury when combined with other food in sufficient quantity and variety. Nor is there good reason for believing that beans deserved the blame which was thrown upon them. From the earliest times they have had the reputation of producing flatulency, but have been charged rather with constipating than relaxing the bowels.† Galen relates that a sort of bean soup was in his time used by the gladiators, and in our own army, in times of peace, bean soup has always been popular.

Modern chemistry fully confirms the opinion, long entertained, as to the high nutritive value of beans by discovering in them nearly twice the percentage of nitrogenous matter found in ordinary wheat flour.‡ The microscope shows that the starch-containing cells which make up the substance of the grains have much thicker cellulose walls than the cells of wheat. These walls are slowly soluble in the digestive juices, and hence, if beans are eaten in large quantities, a portion of their substance is apt to escape undigested with the fæces, where the undissolved cells can be recognized with the microscope, and the starch grains give the characteristic iodine reaction.§ But the same thing occurs also, though to a less degree, with other starch-containing grains, including wheat flour;‖ and in the case of beans the undigested portions do not appear to give rise to any intestinal irritation, provided the beans are thoroughly boiled and the skins strained out. This latter precaution is certainly important, especially in cooking for troops in time of war; if it be neglected, the greater part of the skins pass through the alimentary canal unaltered, and

* In illustration of the opinion that hard bread was a cause of camp diarrhœa, see, in Section II, the remarks of VOLLUM, p. 71; TIBBALS, p. 74; MOTTRAM, p. 97, and TOWNSHEND, p. 98; see also J. R. BLACK—*Camp diarrhœa*, The Cincinnati Lancet and Observer, Vol. VII, 1864, p. 275. For a sweeping condemnation of hard bread, in which it is accused of producing not only diarrhœa, but "paralytic tendencies, a disposition to fibrous depositions in the heart and lungs, pains in the extremities and back, and derangements of the ear and eye," with a suggestion that "erysipelas and hospital gangrene" may have a similar origin, see p. 28 of the essay of SALISBURY, cited p. 373, *supra*. This writer errs, in part because he attributes the symptoms of scurvy to the use of hard bread, instead of blaming the absence of other articles of food; in part his statements are purely imaginative. With regard to beans, see, in Section II, the remarks of MARTIN, p. 73; WOOD, p. 74, and BRADT, p. 100; see also J. T. CALHOUN—*loc. cit.*, p. 626, *supra;* also C. F. W. HAASE, Surgeon 5th N. Y. S. M.—*Camp life*, Amer. Med. Times, Vol. III, 1861, p. 181—who attributes much of the diarrhœa at that early period of the war to the use of beans, asserting that whenever desiccated vegetables were substituted the number of cases greatly diminished.

† Thus, in the Hippocratic treatise, *De Victus Ratione*, Lib. II, § 45, [Ed. Littré, VI, 513,] we are told that beans are nourishing, binding and flatulent, and it is explained that they are flatulent because the pores are not able to take up all the abundant nourishment they furnish. GALEN—*De Alimentorum Facultatibus*, Lib. I, Cap. 19, [Ed. Kühn, VI, 529,]—mentions that in his day beans were used in manifold ways, liquid soups and thick pastes being made from them, and they were also prepared with barley broth; this latter form of soup he says was used by the gladiators. He adds that, however cooked, beans are flatulent, even if boiled for a long time. See also the commentary of Dr. ADAMS on PAULUS ÆGINETA, Lib. I, Cap. 79, Vol. I, p. 125, Ed. cited *supra*, p. 624.

‡ A. PAYEN—*Précis Théorique et Pratique des Substances Alimentaires*, 4me Éd., Paris, 1865, p. 331—assigns from 24 to 30 per cent. of nitrogenous matter to different kinds of beans. The analyses cited by PARKES—p. 235, *op. cit.*, p. 599, *supra*—give from 22 to nearly 39 per cent., while according to the same writer—p. 206, note *—wheat flour contains on an average about 14 per cent. of nitrogenous matter.

§ PARKES—*loc. cit.*—makes a similar statement with regard to peas; "About 6.5 per cent. of the ingested pea passes out unchanged, and starch-cells, giving a blue reaction with iodine, are found in the fæces." But his further statement that "much flatus is also produced by the sulphuretted hydrogen formed from the legumin," is, I suppose, rather an inference than a matter of observation. An exceedingly small quantity of sulphuretted hydrogen will give its odor to a large quantity of other gases; see the analyses of flatus by RUGE—note * to p. 489, *supra*.

‖ The bran of wheat is certainly more irritating than even the skins of beans; neither should be given as food to persons suffering under alvine fluxes.

undoubtedly, in the case of those whose digestive organs are at all sensitive, produce more or less irritation. It was probably the common observation of this circumstance, in patients suffering under camp diarrhœa, that led to the unfavorable opinions so many medical officers formed with regard to the use of beans as food during the civil war, and it is very likely that in those whose bowels were already deranged the undigested skins aggravated the disorder. But it must not be forgotten that the skins pass unaltered through the alimentary canal in healthy individuals also, and usually with impunity, as any one can satisfy himself by observation, although they are in this case concealed in the fæcal mass and not noticed unless specially searched for.

Even if the food was unobjectionable, *bad cooking* was looked upon as a cause of diarrhœa by many surgeons, and the common practice of making fried messes with mixtures of meat and hard bread,* etc., was very generally condemned. Errors of this kind undoubtedly favor the development of dyspepsia, and thus render the subject more susceptible to the inroads of diarrhœa and dysentery, but there is no evidence to show that they can of themselves give rise to alvine fluxes. The sutler's pies and cakes came in, too, for their share of blame,† though it is probable enough that by introducing some variety into the monotony of the ration they did on the whole more good than harm. Sudden changes in diet were also sometimes charged with producing diarrhœa, particularly the mild epidemics already spoken of as occurring in the case of recruits and regiments newly mustered into service.‡ It is not unlikely that alimentary conditions had something to do with the production of these outbreaks, but the complete change of the mode of life in other respects could not have been without its influence.

In all cases the ingestion of indigestible food acts at first merely by producing an irritation of the mucous membrane, which, if severe enough, brings on vomiting, purging, or both, and so gets rid of the obnoxious substance. The relief thus afforded is very generally complete, and at the same time the experience serves as a warning against a repetition of the offense. Occasionally the first irritation is so severe as to initiate an intestinal catarrh that may persist with variable issue; most frequently the catarrh resulting from this cause is of a transitory character; in either event the resulting flux usually manifests itself in the form of cholera morbus or diarrhœa, and seldom or never assumes that of dysentery unless other causes coexist. If the ingestion of unsuitable food be persisted in, its action may in some cases keep up and intensify the inflammatory process until grave diarrhœa or even catarrhal dysentery results. But the usual mode in which intestinal diseases are produced by this cause is by no means so simple: it is, namely, through the production of dyspeptic and scorbutic conditions, local debility or other disorders of the digestive functions on the one hand, and slowly produced modifications of the general nutrition on the other, that the flux is ultimately brought on, or the system rendered susceptible to the action of other causes which are yet to be considered.

Dyspeptic conditions and constipation.—In certain debilitated conditions of the digestive functions the alimentary mass, or some part of it, undergoes various fermentative changes which even may, in extreme cases, assume a more or less putrefactive character.

* As to this practice, see the remarks in Section II of Schell, p. 70; Vollum, p. 71; and Martin, p. 73; see also J. R. Black, *loc. cit.*, p. 629, *supra*.

† See, in Section II, the remarks of Brown, p. 77; Sanborn, p. 94; Bidwell, p. 96; and Bache, p. 99; with which compare the remarks of Virchow, cited p. 620, *supra*.

‡ See the remarks on these initial outbreaks, pp. 285–6, *supra*. The opinion that change of diet was a cause is expressed in several of the reports in Section II, *e. g.*, by Chamberlain, p. 67; Barker, p. 68; Day, p. 69; and Leonard, p. 70.

In proportion as the restraining antiseptic influence of the normal secretions is diminished these fermentative and putrefactive changes more and more approximate those which would occur in the same substances kept at the same temperature out of the body. Much remains to be learned with regard to the minor degrees of these processes, but it is pretty generally recognized that in extreme cases the starchy and saccharine ingredients of the food may pass into lactic- or acetic-acid fermentation, that the fat-acids may be set free from the fatty ingredients of the food and ammoniacal compounds liberated from its nitrogenous elements. That some of the products of these abnormal processes, even when the food itself is wholesome, may act as irritants to the intestinal mucous membrane and give rise to vomiting, diarrhœa, or both, was already confidently believed by the Greek physicians.* Since their time the matter has been made the subject of many studies, yet our own knowledge with regard to it is still very unsatisfactory.

Virchow has suggested† that the ammoniacal compounds set free by putrefactive changes in the nitrogenous matters of the food are especially liable to give rise to dysentery. Not merely is the temperature of the body favorable to the occurrence of these changes, when they are not restrained by the normal antiseptic secretions, but the mucus of the intestines and the detached epithelial cells it often contains may, in his opinion, act as ferments, as the mucus and epithelium of the urinary bladder do in the case of retained urine. The modified secretion of the inflamed mucous membrane, when intestinal catarrh already from any cause exists, is a still more active ferment; and in either case the intensity of the result is favored by whatever produces retention of the intestinal contents and thus affords time for the completion of the putrefactive process. In this manner he explains the influence of previous constipation in the production of dysentery, which had been insisted upon by Cleghorn, Chalmers, Cullen and Annesley;‡ the retained fæces enter into a putrid decomposition, and the ammoniacal compounds set free act as powerful local irritants, capable of setting up a brisk inflammation of the mucous membrane, or, when this already exists, of intensifying it until it assumes the diphtheritic character. Several circumstances show that this view is true for a certain class of cases: The catarrhal and diphtheritic inflammation, the ulceration, sloughing and perforation of the mucous membrane in contact with the fæcal mass that accumulates above the point of obstruction in cases of stricture, peritoneal bands, volvulus, etc.; the experimental production of dysentery by injections of ammonia;§ and the fact that constipation often immediately precedes the occurrence of dysentery, are especially significant in this connection. But it would be exceedingly unsafe to assume that considerations of this kind represent the whole etiology of dysentery. While it is true that constipation often precedes dysentery, this is by no means universally the case, nor is it true even in the majority of instances. A preceding diarrhœa of several weeks' duration, by which the intestinal canal is thoroughly emptied out, is even more common, and the scybala, of which so much has been said, are by no means of such frequent occurrence as has sometimes been assumed.‖

If constipation stood in any direct causal relation to dysentery it might be expected that it would occur most frequently in those districts in which dysentery prevails, and at about the same season as dysentery or a little earlier. Now the systems of reports pursued in the United States Army require every soldier excused from duty even for a day to be

* See, especially, GALEN—*loc. cit.*, note ‖, p. 623, *supra*.
† VIRCHOW—*Hist. etc. der Unterleibsaffektionen*, Archiv, Bd. V, S. 325-333 u. 352 *et seq.*
‡ See note ‡, p. 353, *supra*. § See p. 480, *supra*. ‖ See p. 353, *supra*.

placed on sick report. A soldier suffering merely from constipation, who receives a purgative from the regimental surgeon, is reported as a case of constipation if excused from duty. The number of such cases reported among the white troops during the five years ending June 30, 1866, was 145,960.* These figures do not include any of those occurring in the hospital population, and of course represent only the more serious cases of constipation; yet the number is so large that their distribution by season and region must give a very just idea of the actual distribution of constipation among our troops. Now it is worthy of note that the ratios deduced from these figures do not show any agreement in the regional distribution of constipation with that of dysentery during the war. So far from this being the case, it was precisely where diarrhœa and dysentery were most frequent that constipation was least so; its average annual ratio per 1,000 of strength during the time specified being 132 for the Pacific, 70 for the Atlantic and 60 for the Central Region; whereas the fluxes were least frequent in the Pacific and most common in the Central Region. Nor did the fluctuations of the ratios from year to year in either region agree at all with those of diarrhœa and dysentery. It is true that the monthly fluctuations so far harmonize that the ratios of constipation for the summer months were somewhat larger than those for the winter months, but they by no means follow the peculiar curves of diarrhœa and dysentery in any region, and, moreover, as compared with these, the variations were very small.

These circumstances would seem to show that other more influential causes were at work in the production of the intestinal fluxes of the civil war. Moreover, while in certain cases the explanation of Virchow seems to offer the best interpretation of the observed facts, there are others which show that neither constipation nor fæcal retention is a necessary condition even for the putrid fermentation of the alimentary mass. Not only when no constipation exists, but during the actual progress of diarrhœa, divers fermentations may occur in the intestinal contents, and it is probable that various irritating substances may thus arise: as yet ammonia and its compounds are the best known of these, but it is by no means likely that they are the only ones.

Is it now probable that, besides the irritants of the intestinal mucous membrane which may be contained in the ingesta or produced from them by chemical changes in the alimentary canal, the body of the sick man may itself furnish diseased secretions capable of exercising an irritant action? The Greek physicians affirmed the truth of this view: They held that vicious humors arising in any part of the body might find their way to the alimentary canal, accumulate there and by their irritative action give rise to diarrhœa and dysentery. Either phlegm, yellow bile or black bile might act in this way.† Long after the ancient conception of yellow bile as one of the four humors had disappeared from

* The number reported among the colored troops was 17,201. The ratios deduced in this case agree no better with the ratios of diarrhœa and dysentery than those for the white troops. Thus, in the year ending June 30, 1864, the ratio per 1,000 of strength for constipation among the colored troops was 154 for the Atlantic and 102 for the Central Region, while the cases of diarrhœa and dysentery were more numerous in the Central Region. The following year the cases of diarrhœa and dysentery were more numerous in the Atlantic Region, but now the cases of constipation were more numerous in the Central, the ratios being 87 per 1,000 of strength for the former and 98 for the latter. Compare these ratios and those for constipation mentioned in the text with the ratios for diarrhœa and dysentery given in Section 1 of this Chapter. Further particulars and ratios with regard to constipation will be given in the Third Volume of the Medical History of the War.

† See, for example, the passages in GALEN, cited note ‡, p. 335, *supra;* also, on the Greek doctrine of the origin of diarrhœa and dysentery by a flux of humors, note *, p. 341, *supra;* with regard to dysentery from black bile, note †, p. 392, *supra.* The Arabians adopted the Greek opinion on this subject. AVICENNA—*Canon*, Lib. III, Fen 16, Tract. 1, Cap. 2, Venitiis, apud Juntas, 1595, T. I, p. 810—went so far as to fix the time necessary for each of these humors to produce ulceration: yellow bile required 14 days, phlegm a month, black bile 40 days. In striking contrast to these old views may be cited the observations of UFFELMANN—S. 241, *op. cit.*, p. 388, *supra*—on a woman laboring under a biliary fistula, who suffered a smart attack of dysentery accompanied by fever. By the second day of the disease the fistula, which had been discharging bile freely, became perfectly dry, and so continued until the 9th day, when, the fever having subsided and the appetite begun to return, the first traces of restored biliary secretion were recognized at the orifice of the fistula. A similar suppression had previously occurred to the same patient during an attack of pneumonia, but in this instance the secretion when restored was of the normal brownish color, while after its suppression in dysentery it was at first decidedly greenish, and only regained its usual appearance after the lapse of several days.

medical literature and bile came to be regarded merely as a secretion of the liver, it was a common belief that the irritant action of a morbid bile poured out into the intestine was an important factor in the causation of dysentery. The prominence given to this view by Degner and the modifications it subsequently experienced have been sketched in a previous portion of this Section.* But in a large proportion of the cases of dysentery the secretion of bile is very greatly diminished or altogether suppressed. In the so-called bilious cases,† even where copious vomiting and purging of bilious matters occur in the early stages, there is no evidence that the bile itself acts as the irritant that initiates the disease;‡ much rather does it appear probable that the excessive secretion, when it really is excessive, results from an irritation affecting the liver simultaneously with the gastro-intestinal inflammation, or propagated to the liver through the biliary passages from the intestinal canal. This "bilious complication" is quite as common in connection with mild gastro-intestinal catarrhs as with dysentery; the ordinary cholera morbus of the summer months furnishes a familiar example. It is probable that in many of these cases there is no actual increase of the hepatic secretion, but the digestive process being interfered with, and the passage of substances through the alimentary canal hastened, the bile secreted is voided before it has time to undergo the metamorphoses that occur in the normal condition, and hence appears to be more abundant than it really is: We possess no exact information as to this point, and further investigations, guided by modern knowledge of the physiology of the hepatic secretion, are greatly to be desired.

The excessive secretion or abnormal character of the bile is then to be regarded merely as a complication of diarrhœa or dysentery; we have no satisfactory evidence that it ever acts as its cause; nor have we any evidence that this role is played by any other normal or abnormal secretion that finds its way into the alimentary canal, with the single exception of urea, which is sometimes vicariously excreted by the intestine. Whenever the kidneys fail to separate the urea accumulating in the blood, it is thrown off by other organs, especially by the skin and the intestinal mucous membrane. Amidst the fermentations going on in the alimentary canal urea speedily breaks up into carbonate of ammonia, which acts as a local irritant, just as ammoniacal compounds set free by the putrefaction of nitrogenous matters in the alimentary canal may do. That this condition actually occurs in certain cases of Bright's disease of the kidneys, and that diarrhœa, catarrhal dysentery, or even the severest forms of diphtheritic dysentery may be caused by the irritant action of the carbonate of ammonia thus set free, appears to be established beyond question. But Treitz§ has altogether exaggerated the frequency with which dysentery is produced in this way, and his speculation that exposure to cold produces dysentery by checking the kidney secretion and causing urea to be separated by the intestinal mucous membrane is unsupported by actual observation.

---

* See p. 394, *supra*. † See p. 395, *supra*.

‡ BARRALLIER—p. 724, *op. cit.*, p. 603, *supra*—speaks, perhaps inadvertently, as if the contrary had been proven: "Les travaux de Bouisson (de Montpellier) ont démontré l'action réelle de la bile sur les actes morbides qui se passent dans le tube digestif; il résulte de ses expériences que lorsqu' une grande quantité de ce liquide arrive dans les intestins, les digestions sont troublées, et que les malades sont pris de coliques et de diarrhée," &c. Now certainly F. BOUISSON—*De la Bile*, &c., Montpellier, 1843, p. 128—does make the statement that these are the effects of an increased quantity of bile, (polycholie;) but he no more attempts to prove by experiment this old belief than to prove the actual existence of polycholie by observation.

§ See p. 386, *supra*. This view appears to be an amplification of a suggestion previously made by VIRCHOW, p. 355, *op. cit.*, p. 631, *supra*. Speaking of the decompositions of the contents of the alimentary canal in dysentery, he says: "Without the presence of the fæcal masses, a part of the material for the decomposition would be wanting; the processes of decomposition would not attain the intensity, (Höhe;) their products the acrimony, (Schärfe;) nor the irritation the local duration and mechanical increment (Steigerung) necessary to generate a genuine fully-developed dysentery. But the decomposing substances are of a more or less alkaline nature, and if it should be generally established, as C. Schmidt (Charakteristik der epidem. Cholera, 1850, S. 96, folg.) incidentally mentions, that urea is mingled with the intestinal secretions in dysentery, it would be very simple to explain the preponderating occurrence of ammonia among the products of decomposition."

PORTAL CONGESTION.—In this connection a few words may be said with regard to a condition which has been thought to play a considerable part in the production of the intestinal fluxes in consequence of its direct influence upon the circulation of the blood in the intestinal mucous membrane: I refer to congestion of the portal system of bloodvessels. Attention was first directed to the real and supposed morbid influences of anomalies in the portal circulation by George Ernest Stahl,* (1698,) since whose time various speculations, which need not here be discussed, have been advanced with regard to the consequences of these anomalies.† The present state of our knowledge of this subject is briefly as follows: The portal circulation, while it shares the physiological characters of the general circulation, undoubtedly offers certain peculiarities which favor the development of local congestions. The absence of valves in the veins that unite to form the portal trunk and in the branches of the latter, as well as the fact that these branches ramify through a second system of capillaries in the substance of the liver, introduces a special series of mechanical conditions which must be considered in studying the disturbances of this portion of the circulation. Moreover, as the movement of the blood through these vessels is normally assisted by the intermittent pressure of the respiratory movements, of the intestinal contents, and of the contraction of the abdominal muscles, it may be impeded by various thoracic disorders as well as by disorders of the abdominal viscera.

Abdominal congestion may result on the one hand from a dilatation of the cœliac axis, the mesenteric arteries or any of their branches, in consequence of which a greater supply of blood is received by the abdominal viscera or some portion of them; on the other hand it may be the consequence of some mechanical retardation of the venous current. The so-called active congestion, resulting from arterial dilatation, takes place under the influence of the vascular nerves, as a reflex action set on foot either by some distant irritation or by nutritive disturbances in some portion of the abdominal organs themselves. The mechanism by which it is effected seems to be simply a relaxation of the circular muscular fibres of the arteries involved. A general abdominal plethora produced in this

* The essay of J. P. GAETKE, sub presidio G. E. STAHL—*Diss. med. inaug. de vena portæ porta malorum hypochondriaco-splenetico-suffocativo-hysterico-colico-hæmorrhoidariorum*, Halle, 1698; I cite a reprint, Halle, 1726—contains his doctrine on the subject. It treats in Sect. I of the anatomical relations of the portal circulation, insisting particularly on the absence of valves and the distribution of the branches of the portal vein in the substance of the liver. In Sect. II the physiology of the portal circulation is discussed; the motion of the blood in these vessels is not caused by the impetus of the heart, but partly by the mechanical impulse of the respiratory movements, partly by a special tonic motion, resembling the peristaltic motion of the intestine, which has its seat in the mesentery, and by which the blood is constantly propelled forward. Sect. III treats of the diseases of the portal circle: "De passionibus, venæ portæ familiaribus." Here he included not only lesions of the vessel and its branches or vitiation of the contained blood, but all the affections of the annexed viscera which he believed to result therefrom. These he treats under four heads: I, Lesions of the capacity of these vessels; 2, of the consistency of the contained blood; 3, of the motions of the blood, especially those of a passive character; and 4, lesions and alterations of a more active character in the motion of the annexed parts, especially of the intestines, the mesentery and the spleen. Sect. IV deals with the therapeutic measures adapted to the foregoing lesions. An interesting account of these views of STAHL will be found in the essay of VIRCHOW, cited p. 631, *supra*. According to him they are also fully elaborated in the essay of ALBERTI—*Tract. de hæmorrhoidibus*, Halle, 1722—a copy of which I have not been able to see.

† I may merely refer in this connection to the doctrine of obstruction of the abdominal viscera or infarctus propounded by J. KÄMPF—*Für Aerzte und Kranken bestimmte Abhandlung von einer neuen Methode, die hartnäckigsten Krankheiten, die ihren Sitz im Unterleibe haben, besonders die Hypochondrie, sicher und gründlich zu heilen*, Dessau und Leipzig, 1784—in an essay remarkable alike for the extraordinary language often used and the confusion of ideas which frequently characterizes the speculations of its author. According to his formal definition of the term infarction—Cap. 1, S. 22—he meant it to embrace preternatural obstructions of the portal vein and its branches, and anomalies in the contents of these vessels, and hence of course the consequences of these conditions in the spleen, alimentary canal and mesentery as well as in the liver. He subdivided infarctus into two kinds: In the first the obstructing material was diseased blood; in the second diseased serum mingled with lymph, or, as he called it, *pituita*. Of each of these he made five genera; and as his conception of infarctus embraced also abnormal accumulations in the hollow cavities of the affected organs, and especially of the intestines, descriptions of the most diverse intestinal contents, including undigested food of the most various kinds, are mingled with his fanciful accounts of pituita and black bile. Some of the cases reported in this work have already been referred to (note ‡, p. 365, *supra*) as examples of tubular diarrhœa; perhaps others were of the same nature, but it is not always possible to identify the conditions described. As the universal remedy for infarctus and its accompanying evils, KÄMPF lauded the use of what he called visceral clysters, (die Viszeralklistire,) brewed from a mixture of herbs, among which I note taraxacum, valerian, myrrh, arnica, verbascum, millefolium, dulcamara, conium maculatum, &c., on the selection of which for particular cases and the detailed mode of preparation he laid superstitious stress. This singular book appears to have been intended more for popular than for professional use, but it long found a certain number of followers in the profession as well as out. As late as 1853 O. KOHLRAUSCH—*Ueber sogenannte Infarkten*, Müller's Archiv für Anat. Phys., &c., Jahrg., 1853, S. 151—thought it worth while to publish an essay, illustrated by several figures, to show that the masses in the stools, still known as Infarkten, were composed chiefly of undigested vegetable cells and other debris from the food, along with fungi, (Schimmelfasern,) &c. VIRCHOW—S. 299. *op. cit.*, last note—gives a graphic account of the doctrine of KÄMPF, to which the reader is referred.

way would only be an exaggeration of the physiological conditions that occur during the time of digestion. Virchow* has suggested that extreme dilatation of this sort affecting the cœliac axis may explain some of the cases of transitory pulsation in the epigastric region, which can occasionally be felt by the physician as well as by the patient. But a recognizable plethora of this kind is far less frequent than an arterial hyperæmia of individual parts, *e. g.*, of the gastro-intestinal mucous membrane or some portions of it produced in the same way; this may occur without inflammation, but very generally accompanies some degree of the inflammatory process, and is to be looked upon rather as one of the phenomena of inflammation than as its cause.

Passive congestion or venous hyperæmia of the abdominal organs, which is the condition generally understood when portal congestion is spoken of, may result in some cases from preternatural dilatation of the portal vein itself, or more frequently of the veins which unite to form it, in consequence of relaxation of their circular muscular fibres,† or of anomalies in the nutrition of their walls similar to those which occur in varicose veins;‡ but local disturbances, as for example hæmorrhoids, much more frequently arise in this way than general abdominal congestion. Portal congestion may also be produced by whatever interferes with the propulsive powers that carry on the portal circulation. Here, in addition to the resistances which the venous circulation elsewhere encounters, special resistances are introduced by the passage of the blood through a second set of capillaries in the liver. Diminished energy of the cardiac contractions, by which the chief motive force of the circulation is furnished here as elsewhere, or of the respiratory movements and other muscular actions that normally assist the portal circulation, may be followed by passive congestions in the abdominal viscera, although the normal resistance remains unchanged; such congestions occur chiefly in individuals who have from any cause fallen into an extreme condition of marasmus.§ Moreover, while the propulsive powers remain normal or nearly so, portal congestion may be produced by mechanical obstructions, such as result from valvular disease of the heart, aneurism of the aorta, tubercles of the lungs or other diseases of the thoracic viscera that offer mechanical obstacles to the general circulation; or from diseases of the liver itself, as cancer, cirrhosis, amyloid and fatty degeneration, parenchymatous inflammation, etc., by which the motion of the blood through the organ is impeded.‖ That mere functional disturbance of the liver, giving rise to congestion of that organ, may in like manner interfere with the portal circulation and so determine abdominal congestion is probable enough; but the popular opinion which regards these congested conditions as a direct cause of diarrhœa and dysentery is not supported by evidence.

Experiments on animals, such as those of Cohnheim,¶ show that passive hyperæmia produced by the mechanical obstruction of venous trunks gives rise to œdematous infiltration of the congested tissues, and that it may cause hæmorrhage into the tissues, but not

† KÖLLIKER und VIRCHOW—*Ueber einige an der Leiche eines Hingerichteten angestellte Versuche und Beobachtungen*, Würzburg Verhandlungen, Bd. I, 1850, S. 319—in the body of a decapitated criminal, examined 35 minutes after death, obtained by the use of galvanism no contraction of the portal vein, and only a little in a branch of the superior mesenteric vein, although the great saphena vein and its branches and the lymphatic vessels of diverse regions were still very contractile; whence VIRCHOW concludes—S. 295, *op. cit.*, p. 631, *supra*—that it is doubtful whether the muscular coat of the portal vein exercises any considerable influence on its calibre. According to the same author—S. 297, *op. cit.*—the varicose dilatations, referred to in the text, occur chiefly in the veins of the stomach, spleen and rectum.

‡ See VIRCHOW—S. 297, *op. cit.* § See VIRCHOW—S. 289, *op. cit.*

‖ To these causes VIRCHOW—S. 293, *op. cit.*—adds external compression, such as is produced by tight corsets, &c.

¶ J. COHNHEIM—*Ueber venöse Stauung*, Virchow's Archiv, Bd. XLI, 1867, S. 221: "Es entwickelt sich Oedem oder Hydrops, aber keine Phlegmone." Compare the account of passive or mechanical hyperæmia given by E. WAGNER—*Manual of General Pathology*, Amer. Transl., New York, 1876, p. 183 *et seq.* According to the latter writer chronic catarrh is a consequence of the venous hyperæmia of the intestinal mucous membrane. VIRCHOW—S. 310, *op. cit.*—in making the same statement remarks, however, that it is not every catarrh of the intestine that produces diarrhœa.

inflammation. An examination of the symptoms of the unmistakable portal congestion that results from cirrhosis of the liver shows that neither diarrhœa nor dysentery is a necessary consequence of this condition. Ascites is a very frequent sequel, but inflammatory affections of the mucous membrane of the alimentary canal are by no means invariable concomitants. Indeed Frerichs has shown that in the bodies of those dead of cirrhosis it is much more common to find catarrhal tumefaction, erosion and ulceration of the mucous membrane of the stomach than similar lesions of the intestine. He tells us that the bowels are generally costive, particularly in the early stages; even in the later stages diarrhœa does not occur in the majority of cases. Still rarer in the experience of Frerichs was the occurrence of diarrhœa in cases of chronic hepatic hyperæmia and portal obstruction resulting from valvular disease of the heart and embarrassment of the pulmonary circulation.* In the face of such facts how unreasonable it would be to assume that transient congestions of the portal circulation can play any conspicuous part in the direct causation of the intestinal fluxes. And yet in the case of marked cirrhosis diarrhœa occurs so much more frequently than it would be likely to do in healthy persons, that we may well suppose with Murchison,† that the congested condition of the mucous membrane in this disease is favorable to the action of the causes of intestinal inflammation, and perhaps in this way the occurrence even of transient portal congestion may favor indirectly the development of diarrhœa or even of dysentery. Nor do I doubt that the pre-existence of chronic venous congestion is likely to determine an unfavorable progress in the inflammatory process when it has once been developed by other causes, and perhaps the more transient congestions may produce to a less degree a similar tendency.

Constitutional condition of those exposed.—The influences which do not appear to act directly upon the alimentary canal, but seem to cause the alvine fluxes or to favor their development by an action upon some other part of the body or upon the constitution generally, have next to be considered; and here first the constitutional condition of those exposed requires attention. Mere exhaustion, from fatigue, over exertion and loss of sleep, as during long marches, sieges and battles of several days' duration, produces a condition favorable to the inroads of several diseases, among which diarrhœa and dysentery are conspicuous. In like manner almost any constitutional disorder of a debilitating character, however produced, favors the development of these diseases among those exposed to their causes. The observations of Finger,‡ during the Prague epidemic, as to the frequency with which dysentery attacked patients already laboring under lung-phthisis, cancer, typhus, secondary syphilis and Bright's disease of the kidneys, and its great mortality in these complicated cases, were abundantly confirmed by our own experiences in the civil war, during which also the relation of pre-existing diseases to the development of diarrhœa was found to be of a very similar character. The frequency with which the different abnormal constitutional conditions were followed by fluxes varied considerably, some seeming to be

* F. T. Frerichs—*Clinical Treatise on Diseases of the Liver*, Transl. of New Syd. Soc., Vol. II, London, 1861, p. 45. Catarrhal conditions of the stomach were observed in 26 out of 36 subjects dead of cirrhosis. The mucous membrane of the large intestine is said to have been "softened and of a livid hue" in 13 cases; "in 5 cases, there were superficial catarrhal ulcerations. The small intestine was rarely implicated, and never more than very slightly." Persistent diarrhœa had occurred in but ten of these 36 cases; in two of these, however, tubercular ulceration of the intestines coexisted, p. 47. In Vol. I, London, 1860, of the same work, I read—p. 366—that in 20 cases of hepatic hyperæmia arising from obstruction to the circulation of the blood ("Stauungshyperæmie") "transient diarrhœa" was observed in 4 cases only. "The bowels, as a rule, are confined."

† Charles Murchison—*Clinical Lectures on Diseases of the Liver*, etc., Amer. Reprint, New York, 1868, Lecture 7, p. 248: "Gastritis and enteritis also frequently occur in the course of cirrhosis, the congested mucous membrane being excited to inflammation by causes which would otherwise be inert."

‡ S. 134, *op. cit.*, p. 552, *supra*.

much more favorable to their occurrence than others. Among those which appeared to exercise the most considerable influence in this direction during the civil war, tuberculosis, typhoid and typho-malarial fevers, the malarial fevers and chronic malarial poisoning, and the scorbutic taint, may be particularly mentioned.

The victims of tuberculosis were liable not merely to the form of diarrhœa that results from tubercular disease of the intestines,* but to simple catarrhal inflammations of the intestinal mucous membrane and diphtheritic dysentery. The frequency with which this class of cases proved fatal is well illustrated by the autopsies recorded in this chapter. In typhoid and typho-malarial fevers the peculiar enteric lesion characteristic of the disease was not merely associated in numerous instances with a catarrhal inflammation of the large intestine, but the flux set on foot was prone to persist after the fever had run its course, and a chronic dysentery based on follicular ulceration of the colon occurred in some cases, while in others acute diphtheritic dysentery supervened.† These complications will be discussed more fully in the chapter on camp fevers.

Still greater appeared to be the influence of the constitutional condition induced by the action of malaria, whether manifested by actual malarial fever or as a chronic malarial poisoning. Evidence has been presented in a former portion of this chapter which renders it highly probable that malaria *per se* cannot be regarded as an exciting cause of either diarrhœa or dysentery,‡ yet seems to show that when the causes of the alvine fluxes operate on a great scale, as in the case of armies, they are peculiarly prone to smite those who are debilitated by the malarial influence; hence we have seen that, while in the territory of the United States the distribution of the mortality of these diseases among the civil population has been on the whole greater in the non-malarial than in the malarial districts, the reverse was the case in our armies during the civil war. Nothing need be added here to what has already been said with regard to the relations existing between malaria and the fluxes.

But unquestionably of still greater moment, in connection with the etiology of the fluxes, were the various constitutional conditions resulting from insufficient or improperly selected alimentation, and which, on account of their general character, may be conveniently embraced under the head of *the scorbutic taint.* The subject of the relation of this taint to the alvine fluxes is so intimately allied to the general subject of scurvy that a detailed discussion must be postponed to the chapter on scurvy in the next volume. I shall here merely append in a foot note§ references to some of the medical officers who have testified

* See p. 578, *supra.* † See p. 287, p. 403 *et seq.*, and p. 496, *supra.*

‡ See p. 398 *et seq.* and p. 414 *et seq.*; compare also the remarks on pp. 287 and 496. Of the frequent association of the prevalent fevers of malarial districts with diarrhœa and dysentery, when the causes of these diseases also prevail, I of course entertain no doubts. To the testimony already brought forward to this effect (p. 398 *et seq.*) I may add that of CLEGHORN—*Obs. on the Epidemical Diseases in Minorca*, 4th Ed., London, 1779, p. 134; J. HUNTER—*Obs. on the Diseases of the Army in Jamaica*, London, 1788, p. 218; JAMES LIND—*Essay on Diseases incidental to Europeans in Hot Climates*, 5th Ed., London, 1792, p. 64 *et seq.*; and GILBERT BLANE—*Obs. on the Diseases of Seamen*, 3d Ed., London, 1799, p. 449. To the list of those who have held that the malarial fevers and dysentery have a common cause I may add the names of ROBERT JACKSON—*Outline of the History and Cure of Fever*, Edinburgh, 1798, p. 322—who "was convinced of the truth of it, from his own observation, in the late American war;" JAMES BANKIER—*Essays on the Origin, etc., of Dysentery.* Madras, 1835, p. 28; J. A. LIDELL—*Diseases of the Isthmus of Panama*, N. Y. Jour. of Med., Vol. IX, 1852, p. 78—who regarded malaria as the predisposing cause of the disease as seen among the laborers constructing the Panama railroad; and C. D. GRISWOLD—*Camp dysentery*, Boston Med. and Surg. Jour., Vol. LXV, 1861-2, p. 69—who was led, by his experience as surgeon of the Panama Railroad Co., to regard dysentery as an essentially malarious disease that could be cut short by quinine; an experience which was confirmed during his subsequent residence at Fort Hamilton, N. Y. Harbor, and during the epidemic of 1859 in Genesee Co., New York; in the latter instance the disease was associated "with a severe form of remittent usually called typhoid fever, and which without the administration of quinine in many cases proved fatal."

See also O. C. GIBBS, late surgeon 21st New York volunteers—*Army correspondence*, The Med. and Surg. Reporter, Vol. IX, 1862-3, p. 82—who writes from near Sharpsburg, Md., of the condition of his regiment at the time

to the existence of a scorbutic taint, or of actual scurvy among our troops during the civil war, especially those who have expressed the belief that this condition was directly or indirectly an important cause of the alvine fluxes that prevailed: further evidence of the same character will be produced hereafter.

For myself, I cannot regard the scorbutic condition as a direct cause of the alvine fluxes, for it may undoubtedly exist to a marked degree without any looseness of the bowels; but there is probably no cachetic state that is more favorable to the action of the other causes of these disorders, or confers upon them a graver character when they are once established. Alimentary irritants of every kind, whether contained in the food itself or begotten by its fermentation in impaired digestive conditions, including the putrid products of the decomposition of the fæcal mass in cases of constipation, act with especial energy in scorbutic subjects. These local irritants acting upon subjects whose health is impaired by this constitutional condition are, I believe, to be ranked among the chief causes of the prevalence of fluxes in armies in time of war, and I fear often also in time of peace. I cannot fully assent to the view which has recently been ingeniously advocated by Brunner,* that

of the battle of Antietam: "Scurvy was breaking out, and in cases where this disease was not so manifest, prostration, or great fatigue on slight exertion, which symptoms were but the incipient stages of a scorbutic condition, was well marked. Diarrhœa was the prevailing disease." See also by the same—*Persulphate of iron in camp diarrhœa*, The Cincinnati Lancet and Observer, Vol. VI, 1863, p. 462: "I soon became convinced the disease had its origin in a lack of a suitable amount of vegetable food." He declares that "potatoes, onions, cabbages, &c., &c., were articles unknown in the army, for months in succession." H. H. GARDNER—*Chronic diarrhœa in the Army of the Cumberland*, American Med. Times, Vol. VIII, 1864, p. 102—declares that it owes its origin to two causes: "scurvy and miasmatic influences." I. A. COONS—*The cause of camp diarrhœa*, The Cincinnati Lancet and Observer, Vol. VII, 1864, p. 327: "The cause of camp diarrhœa seems to me to be the sameness of food, together with its deficiency in quality and quantity." And further on: "Camp diarrhœa is rather a symptom of scurvy than a disease of itself," p. 328. GEORGE D. WINCH—*Chronic diarrhœa*, Chicago Med. Jour., Vol. XXII, 1865, p. 346: "A want of vegetable diet is a common cause." Here, too, I may refer to the striking testimony of Brigade Surgeon C. H. RAWSON—*Health and hospitals in Mississippi*, The American Med. Times, Vol. V, 1862, p. 42—with regard to the prevalence of scurvy connected with diarrhœa in the army around Corinth in June, 1862. Surgeon RAWSON had been chief medical officer of the left wing of General POPE'S Army, and afterward Acting Medical Inspector. He testifies that the chief diseases among the troops at the time he wrote were "diarrhœa, remitting fever assuming a typhoid character, perhaps some typhoid fever, typhoid pneumonia, rheumatism, and scurvy." Of the latter, he says that it is "a species of land scurvy that is very insidious in its effects, and I think many men are suffering from it, who are being treated for many other diseases, * * *; the men complain they are daily becoming weaker, great muscular weakness, sometimes soreness with red spots, ecchymotic and swollen feet and legs, rheumatic pains, affecting bones, muscles, or any and every portion of the body. Some have pale, waxy, puffy, and anæmic swelling about the face; a few show ulcerated gums and mucous membrane, but they are comparatively few, appetite capricious and bowels irregular, but generally have diarrhœa." He emphasizes the occurrence of sudden death among this class of cases: "The man complains of lassitude and debility, is walking about, and finally dies very suddenly, or is found dead under a tree, where he has lain down to rest, or in using the chamber dies from the effort." In August, 1862, Surgeon RAWSON writes to the same Journal, same Vol., p. 125, from Corinth, Mississippi: "Diarrhœa, some dysentery, remittent and typhoid fevers, and scurvy, are the principal diseases at present. The latter prevails more extensively than it ought, but it is very difficult to get fresh vegetables in any quantity, nearly everything having to be brought from the north. The U. S. Sanitary Commission are furnishing some eggs, chickens, potatoes, etc., to general hospitals, but the supply is nothing to the demand and requirements." On noticing the first communication from Surgeon RAWSON, Dr. F. R. LYMAN, house-physician in Bellevue hospital, hastened to write to the same Journal—*Land scurvy*, same Vol., p. 125—that about 35 per cent. of all the patients received there from the Army of the Potomac from July 9th to August 20th, when he wrote, were affected with the same disease. Testimony as to the prevalence of the scorbutic taint or actual scurvy among the sick received in the general hospitals in Philadelphia from the Army of the Potomac, during 1862, has been given by STILLÉ—note §, p. 495, *supra*—and KEMPSTER, made similar observations elsewhere during the last two years of the war—same note. Here, too, I may refer to a paper by Assistant Surgeon W. E. WHITEHEAD, U. S. A.—*Camp diarrhœa*, Med. and Surg. Reporter, Vol. XV, 1866, p. 82—in which he advocates the view that the camp diarrhœa of soldiers is caused by a scorbutic condition of system, and this not merely from lack of antiscorbutics, but from improper cooking. His further suggestion, however, that the scorbutic condition of the blood may cause amyloid degeneration of the small arteries of the submucous coat of the intestine, and that this is the cause of the persistency of the disease, is a speculation unsupported by satisfactory evidence. D. A. MORSE, late Asst. Surgeon U. S. Vols.—*Camp diarrhœa*, same Vol., p. 296—has replied to the suggestions of WHITEHEAD: "I know of no reason why scurvy should be considered a cause of diarrhœa more than diarrhœa of scurvy." Yet if it were true generally, as he himself testifies of the prison at Camp Chase, that "nearly every one having scurvy had diarrhœa; but a large number having diarrhœa showed no signs of scurvy," it would be easy to see that the latter supposition is much more probable than the former. MORSE particularly emphasizes in this paper the fact that diarrhœa occurs in non-scorbutic subjects, which I suppose no one doubts.

* C. H. BRUNNER—*Zur Actiologie der Ruhr*, Berliner Klin. Wochenschrift, Jahrg. XIV, 1877, p. 353. His reasoning is briefly as follows: There can be little doubt that dysentery is an infectious disease; *i. e.*, that it is not produced by any known atmospherical or telluric factors, but by some specific unknown cause acting upon the body from without. The infectious diseases generally are characterized by their dependence upon locality and human intercourse, ("Verkehr.") The relation of the individual infectious diseases to these two circumstances is very different. Thus, cholera, yellow fever, plague, the acute exanthemata and whooping cough, at least in the matter of their pandemic distribution, are chiefly dependent upon intercourse, while the other infectious diseases, including ileotyphus and dysentery, are chiefly dependent upon locality. Dysentery, it is true, occurs epidemically, but as stationary or localized, not as progressive epidemics. Patients who leave dysenteric districts for healthy localities may convey the disease to other individuals, but epidemics do not thence arise. Thus, in spite of the transfer of the dysenteric patients of the besieging army of Metz and the prisoners there taken, to all parts of Germany, no epidemic was set up throughout that country. And the same was true of intestinal typhus, but alas not of small-pox! What now are the local influences that determine the spread of dysentery? We may think of the latrines, of local atmospheric infection, of the drinking water, or of the food. The latrines appear excluded by the slight transmissibility of the disease from individual to individual, and especially by its epidemic frequency among the crews of ships in Asiatic waters, for ships have, properly speaking, no latrines. These latter instances likewise exclude emanations from the soil; and the frequent sporadic occurrence of the disease as well as the comparative immunity which officers often enjoy on shipboard, though exposed to the same atmosphere as the men, are also opposed to this view. Against the opinion that the drinking water is to blame speaks the spread of the disease over wide territories, as in the case of invading armies, in spite of the diversity of the water used, and its occurrence on

spoiled bread is the usual vehicle of the dysenteric infection, if not the essential cause of the disease; but I do not doubt that insufficient and improper food is directly or indirectly responsible for a great part of the disability and mortality produced in armies by the alvine fluxes and allied diseases, or that the question of the ration is one of the most important of those that are to be considered in connection with the prevention of diseases of this class. With this question, which deals with a cause of disease quite under administrative control, I propose to deal when the subject of scurvy is discussed.

METEOROLOGICAL CONDITIONS.—The influences of certain meteorological conditions on the development of diarrhœa and dysentery are manifested on the one hand by the varying frequency with which these diseases occur at different seasons of the year, and on the other by their geographical distribution. Experience shows that they are more prevalent and fatal in hot weather and in hot climates, and this would seem to suggest that high temperature, of itself, may play an important part in their etiology.* Yet it must not be overlooked that these diseases make their appearance also at all other seasons of the year, though less frequently than during the hot months. Moreover, while, as we have already seen, August is the month of their greatest mortality among the civil population of the United States,† neither in their prevalence nor their mortality did they follow this rule with any strictness during the civil war, but fluctuated considerably in different years and regions, as has been shown with sufficient detail in a previous part of this Section.‡

Nor does the geographical distribution of the fluxes correspond at all rigidly either with the mean temperature of the year or the summer heat of individual districts. Abundant testimony to this effect has been collected with regard to dysentery by Hirsch and Dutroulau.§ According to Lubrez,‖ dysentery is endemic in certain provinces of the north of Russia, and is exceedingly frequent in St. Petersburg, while it is much rarer in southern Russia, and especially in the Crimea. I have already shown that the mortality from diarrhœa and dysentery among the civil population of the United States¶ is on the whole greater in the northern than in the southern portion of our territory, and that local as well as general epidemics of dysentery seem particularly to smite the northern districts, while the reverse was the case during the civil war and in our military garrisons in time of peace.** A consideration of these and similar facts would seem to show that elevated temperature is to be regarded rather as a predisposing than an exciting cause of the alvine fluxes; of itself it does not give rise to them, but it seems to produce a condition of the system favorable to the influence of other causes whenever they are brought into action. The effect of elevated temperature on the production of the fluxes among soldiers is perhaps most strikingly shown when they are marched for some time in the hot sun: diarrhœa is of common occurrence under such circumstances; yet even here it is usually so small a portion of the troops

ships that use only distilled water. These different influences being excluded, there remains only the food to be considered. In favor of this view is the fact of the primarily local character of dysentery, (*i. e.*, it is limited to the intestinal canal.) its frequent complication with scurvy, the well known influence of heat and moisture which favor decomposition of food, and especially the fact that dysentery is the constant scourge of armies, (of which he quotes several examples.) For precisely in war, as in naval expeditions to the tropical regions, vegetables are hard to get, and both they and the breadstuffs are very apt to be damaged, as is very often the case on ships doing business in the tropics, and as was too often the case also during the Franco-German war. To such facts it may be added that epidemics on board ships cease forthwith when on their return to Europe they get fresh provisions, and that the epidemic at Metz was gradually extinguished when more regular supplies were afforded. Hence the suspicion arises that the spoiled bread (verdorbenes Brod) may be the vehicle of the specific cause of the disease, if not the specific cause itself. No tenable reason can be urged against this view, which also explains the occurrence of isolated epidemics in garrisons.

* See, on the subject of heat as a cause of dysentery, the paper of Surgeon J. F. HAMMOND, U. S. A.—*Brief account of dysentery as it occurred at Fort Jefferson, Tortugas, Florida*, The Amer. Jour. of the Med. Sci., Vol. XLIII, 1862, p. 66.

exposed who suffer from disorder of the bowels, that the necessity of seeking for the coöperation of other causes is apparent.

With regard to the influence of variations in the hygrometric condition of the atmosphere upon the occurrence of the alvine fluxes, very little is known. Hirsch has pointed out the contradictory character of the testimony of observers as to this point in connection with tropical dysentery. Some of these have regarded a high degree of atmospheric moisture as favorable to the prevalence of the disease, while others with equal positiveness insist that it is most prevalent in extremely dry weather. Hirsch* examined the records of 119 epidemics of dysentery with reference to this point, and found that 62 began during or just after the occurrence of moist weather, while 57 arose and ran their course during persistent dry weather.† It seems probable, therefore, that variations in atmospheric moisture have little or no effect on the development of dysentery, or indeed of the alvine fluxes generally, though, probably, they exercise an occasional influence in connection with changes of temperature in producing the effect popularly described as taking cold.‡

Exposure to sudden changes of temperature is well known to act as the exciting cause of various internal inflammations, and these accidents appear more likely to occur when the atmosphere is damp, and especially during rainy weather. To these conditions troops in campaign, sleeping on the damp ground at night, their clothes wet through by the rain and no opportunity to change them afforded, are particularly exposed. Perfectly healthy and vigorous individuals often endure such exposures with impunity. Others are attacked, some with respiratory catarrhs, some with pleurisy or pneumonia, some with diarrhœa or dysentery.§ The diversity of effect is determined to a great extent by the individual peculiarities of those exposed; and of these peculiarities probably none are more influential than the previous existence of some actual morbid process. In popular language, it is the weak organ that suffers; that is, for the most part, the organ that is already more or less modified by disease.

The frequent occurrence under such circumstances of diarrhœa and dysentery among troops has long attracted the attention of military surgeons. Pringle‖ relates that the night following the battle of Dettingen the English troops lay on the field of battle without

* S. 235, *op. cit.*, last page.

† That heat and moisture favor the development of dysentery is an old belief. Thus HIPPOCRATES declared—*Aphoris. III*, 11, [Ed. Littré, IV, p. 491.]—that if the winter be dry and cold and the spring rainy and warm, acute fevers, ophthalmias and dysenteries will follow in the summer, especially among women, and men of moist constitution. On which GALEN comments—*Comm. in Aph. Hippoc., III*, 11, [Ed. Kühn, XVII, B, p. 578 *et seq.*]—that moisture and heat produce putrefaction of the humors: if the products remain in the body, fevers are generated, if expelled by the bowels, dysentery. "Manente igitur putridine in corpore fiunt febres; si vero ea per alvum vacuetur dysenteriæ"—p. 583.

‡ That alvine fluxes might originate in colds was known to GALEN, who declares—*Comm. III in Hippoc. de Humoribus Lib.*, § 11, [Ed. Kühn, XVI, p. 386,]—that from refrigeration or inequality and badness of the weather the stomach and intestines are vitiated, so that lientery, dysentery and diseases of the small intestine arise.

§ Surgeon C. A. HUNT, 126th Illinois volunteers—*Cold and wet a cause of camp disease, and its modus operandi*, Chicago Medical Examiner, Vol. IV, 1863, p. 226—has given an excellent illustration of this remark. Following a cold and protracted rain in the spring of 1863, twenty-five men of his regiment were taken sick in the camp near Jackson, Tennessee: "About ten had cold and cough, or catarrh; six took pneumonia biliosa; two pneumonia typhoides; two bronchitis with aphonia; one an intermittent, and about five with diarrhœa." One company of the regiment was stationed four miles south of Jackson; it had during the same time nine men taken sick: one with fever of a remittent type, and eight with "dysenteric flux."

‖ PRINGLE—*Obs. on the Diseases of the Army*, 7th Ed., London, 1774, p. 19. The battle of Dettingen was fought June 27, 1743. PRINGLE explains the circumstances mentioned in the text as follows: "For the summer had begun early, and the weather had been constantly warm; but the free and uninterrupted perspiration seemed to prevent any general sickness. Now, the pores were suddenly stopped, the body was chilled, and the humours tending to a resolution, from the preceding heats, were turned upon the bowels, and produced a dysentery, which continued a considerable part of the campaign." HEUBNER—S. 507, *op. cit., supra*, p. 529; also p. 525, Amer. Transl.—cites this incident as an example of the special influence of a particular camp site, and adds: "At a distance of half a mile from the rest of the army, though otherwise in like circumstances, (unter sonst ganz gleichen Verhältnissen,) a few companies had a camp close to the river, and remained perfectly well." This is a complete misrepresentation of PRINGLE'S narrative. These companies were not exposed to the rain, nor did they lie on the damp ground. PRINGLE says—*op. cit.*, p. 20: "Three companies of HOWARD'S which had not joined us, marched with the King's baggage from Ostend to Hanau, where arriving a night or two before the battle, and having orders to stop, they encamped for the first time about half a mile from the ground that was afterwards occupied by the army. These men had never been exposed to rain, nor had lain wet; by this separation from the line, they were also removed from the contagion of the privies; and having pitched close upon the river, they had the benefit of a constant stream of fresh air. By means of these favourable circumstances, it was remarkable, that while the main body thus suffered, this little camp almost entirely escaped."

tents, exposed to heavy rain. Next day they moved to Hanau and encamped on good ground in an open field, but it was wet, and for the first night or two the men wanted straw. During the eight days following the battle about five hundred men were seized with dysentery, and in a few weeks nearly half the army suffered from it. Not a few similar incidents occurred during our civil war. I have already referred to the siege of Fort Donelson* in February, 1862. The attack lasted three days, and about thirty thousand men were engaged. They were for the most part without tents or any other shelter, and could light no fires at night on account of the proximity of the enemy. The weather was at first excessively cold, then a light fall of snow, degenerating into sleet, occurred. I say nothing of the unavoidable suffering of the wounded; but Surgeon J. H. Brinton, U. S. V., the Medical Director of the Army of the Tennessee, to whom we owe this narrative, relates that "diarrhœa, dysentery, and pneumonia of a typhoid type became fearfully prevalent, and thousands of soldiers were broken down, and were then sent down the river to the general hospitals."

Similar was the experience of the troops belonging to the Army of the Potomac engaged in the operations against the Weldon railroad in December, 1864. Surgeon W. R. De Witt, Jr.,† U. S. V., Surgeon in Chief of the First Division, Fifth Corps, accompanied this expedition, and reports that the command to which he was attached moved on the 6th of December and returned on the 11th of the same month; "during this expedition there was considerable exposure, and, in consequence of the inclement weather, the men suffered greatly;" much sickness followed, chiefly "typhoid fever, chronic diarrhœa, typhoid pneumonia," etc. During the same month the Army of the Cumberland, under General Thomas, experienced similar misfortunes. Surgeon G. E. Cooper, U. S. A., Medical Director of that army, reports that during the pursuit of the retreating army of General Hood from Nashville to the Tennessee river the weather was of the most disagreeable character; rain fell for four successive days, and when this ceased it became severely cold. The results of this exposure were "severe affections of the pulmonary viscera, fevers, rheumatisms and diarrhœas, which served to fill the hospitals in this vicinity to their utmost capacity."‡

Incidents of this sort might readily be multiplied; but such extreme exposures as occurred in these instances are by no means necessary to produce similar results. Sleeping on the damp ground, or even standing on sentry duty during a summer night, will suffice, though to a less degree. Moreover, it appears to be rather the magnitude of the fluctuations than mere lowness of temperature that produces the morbific influence. The alternation of hot days with cool nights is therefore favorable to the development of colds. It is probable, indeed, that in a part of the cases in which direct exposure to heat, as on the march, appears to have given rise to alvine fluxes, subsequent chilling during the hours of rest or the succeeding night is really to blame. Such exposures were frequently accused in the reports of the medical officers of producing diarrhœa and dysentery during the civil war,§ and there can be no doubt that these accusations were often well founded.

See also, on the same subject, a letter from Surgeon J. W. LODGE, 31st Pennsylvania volunteers—*Camp diarrhœa*, Med. and Surg. Reporter, Vol. VI, 1861, p. 566—who explains the painless watery diarrhœas which were common in his regiment in September, 1861, as follows: "I believe that the principal cause is exposure to alternations of temperature while on sentinel duty at night. During a relief of two hours, the sentry is warmly housed in his tent; when his hour of duty arrives, he is aroused from sleep, and enters upon his duty and exposure. Occasionally, even during summer, these alternations are of an impressive character," &c. He explains the exemption of the officers by the fact that they do not perform sentry duty.

Influences of the class under discussion were elevated by Wilson, Akenside, Moseley, and especially by Stoll* and his school to the rank of the principal cause of dysentery, but this is altogether too exclusive a view. Taking cold can only be regarded as one of the exciting causes of diarrhœa and dysentery, and by no means as the chief. As to the mode in which this cause acts, there is no reason to regard it as essentially diverse from that by which similar exposures produce bronchial catarrhs and other inflammatory affections of the respiratory organs. The speculation of Treitz† that it acts primarily on the kidneys, is not warranted by actual observation. Nor is it probable that, as was formerly believed, it acts by the mere suppression of the cutaneous secretion and the consequent accumulation in the blood of noxious matters which the bronchial or intestinal mucous membrane attempts to excrete. The effects actually observed after complete suppression of the cutaneous secretion, brought about by varnishing the skin of animals, are of a very different nature.‡ The view that the impression produced on the peripheral nerves gives rise to disturbances of the nutrition and circulation of the internal organs through a reflex action propagated by the vaso-motor nerves seems the most reasonable, but must be regarded rather as an ingenious conjecture than as a positively established theory. Observation seems to render it probable that chilling the abdominal surface, as may occur from sleeping on the cold ground, is especially apt to give rise to alvine fluxes, while chilling the upper part of the body causes inflammations of the respiratory organs. The common belief that this is the case has given rise to the recommendation that a flannel bandage shall be worn over the abdomen by soldiers in campaign. But, besides the different effects of exposure that may be supposed to be determined in this way, and those resulting from the previous existence of pathological conditions in various parts of the body, to which I have already alluded, it seems probable that respiratory inflammations are especially prone to result from taking cold when the range of temperature is very low, the fluxes when the minimum temperature is more moderate; hence the former are more commonly produced during the winter months, the latter during the summer and autumn.

As for the consequences of other meteorological conditions, such as variations in the barometrical pressure, the condition of the atmospheric electricity and the quantity of ozone, nothing positive is known, and I will not, therefore, take space to discuss the opinions that have been advanced by some writers on these points. There is, however, one other probable occasional cause, which should be alluded to in this place: I refer to the contamination of the atmosphere with non-specific but putrid emanations from decomposing animal matter. Such emanations may arise from battle-fields when the dead lie unburied or are imperfectly covered in shallow trenches. Already Galen speaks of this circumstance as a cause of pestilence,§ but the number of observations which clearly connect it with the causation of the alvine fluxes is not very great. Fournier and Vaidy || relate a striking incident which occurred in August, 1796, and strongly supports this view. It is probable that during our

§ See note to p. 644, *infra*.

|| FOURNIER *et* VAIDY—p. 332, *op. cit.*, p. 362, *supra*. After a "warm affair" between Bamberg and Nuremberg, in August, 1796, the French army was victorious, pursued the enemy and left the dead unburied. On the fourth day one of the authors was sent to superintend their burial. He took four gendarmes with him and made some neighboring villagers bury the bodies. There were about 400 dead men and 200 dead horses. The odor was insupportable. Yet the surgeon sat on his horse, in spite of the nausea and colic he felt, and the restlessness of his animal, to encourage the villagers in their sad task. On returning to headquarters the surgeon and two of the gendarmes had a dysenteric flux, from which, however, they recovered in a few days. The horse died of colic the night of his return. What became of the villagers was not learned.

civil war this cause came occasionally into operation, but not very frequently, owing to the care with which the dead were usually buried; I find mention of it only in connection with the battle fields of Fair Oaks and Cold Harbor.* Under any other circumstances the effluvia of putrefying dead bodies appear to be capable of producing similar results. Desault† frequently said during his lectures on anatomy that the odor of putrid cadavers always gave him diarrhœa. Broussais‡ mentioned it as a well known fact that anatomical students often suffer from diarrhœa when they commence to frequent the amphitheatres. I myself have had this unpleasant experience more than once during my early anatomical studies, and suppose similar accidents to be far from uncommon. The effluvia which rise from fæcal accumulations may produce like effects; according to the testimony of Greenhow,§ this is a common cause of diarrhœal diseases in England, and the observations of Clouston‖ would seem to show that it may also give rise to dysentery. In this group of cases it is difficult to exclude the possibility of the presence of some specific contagion, a subject to which I shall refer further on; in all the others the effluvia appear to produce diarrhœa rather than dysentery; yet of course it must always be possible that the diarrhœa thus produced may, from the action of constitutional or other coöperating causes, ultimately pass into catarrhal or even into diphtheritic dysentery.

ENDEMIC AND EPIDEMIC INFLUENCES.—It must, however, be admitted that the conditions hitherto considered are insufficient to explain all the phenomena of the occurrence of the alvine fluxes. Especially are difficulties presented by the facts relating to the endemic and epidemic occurrence of dysentery. In addition to the considerations already discussed, the geological formation of the affected locality has been invoked. This suggestion gained strength at the commencement of the present century from the statement of Harris,¶ that the dysentery which prevailed in Mifflin county, Pennsylvania, during the summer and fall of 1797, 1798 and 1799, spared the inhabitants of those districts in which the soil rested on a limestone formation. Other observations have been reported that seemed to support this view. Thus Godineau** has affirmed that in the French Antilles the volcanic islands are ravaged by dysentery, while those of limestone formation escape. But experience has abundantly shown, as has been pointed out by Hirsch†† and others, that limestone districts enjoy no such fortunate immunity; and the general conclusion that must be drawn from the history of the epidemic and endemic prevalence of dysentery is that no definite relation exists between the geological formation and the occurrence of the disease.

---

* Assistant Surgeon H. E. BROWN, U. S. A.—p. 77, Appendix to Part I of this History, and p. 78, Section II, *supra*—reports that the effluvia from the battle-ground at Fair Oaks, and the impregnation of the surface water drunk, produced typhoid diarrhœa and dysentery among the troops there encamped. "Over 3000 dead had been buried there; the ground was covered with the remains of clothing and commissary stores. Dead horses, which had been but insufficiently buried or burnt, filled the air with a noxious effluvium, and the only water was that obtained from the surface, or by digging down a few feet, and this infiltrated with the decaying animal matter of the battle field." Surgeon MCKELWAY—p. 76, *supra*—draws a still more deplorable picture of the same battle field, describing the dead within the lines as "lying on the surface of the ground with but a sprinkling of earth thrown on them, while immediately without the dead bodies of men and horses were quite exposed or but slightly covered with brush; * * * diarrhœa and dysentery became more rife." Medical Director MCPARLIN reports—p. 161, Appendix to Part I—that in the early part of June, 1864, after the battle of Cold Harbor, "dead horses and offal of various kinds were scattered over the country everywhere, and between the lines were many dead bodies of both parties, unburied and decomposing in the burning sun." He reported to the Commanding General, June 5th, "sickness is increasing in the army, diarrhœa being especially prevalent."

** GODINEAU—*De l'hygiène des troupes aux Antilles Françaises*, Montpellier, 1844. I have not seen this work, and cite from BOUDIN—*Études, etc., sur l'état sanitaire et la mortalité des armées de terre et de mer*, Annales d'Hygiène, T. XXXVI, 1846, p. 98.

†† HIRSCH—Bd. II, S. 238, *op. cit.*, p. 551, *supra*. Compare BARRALLIER—p. 717, *op. cit.*, p. 603, *supra*; and SAVIGNAC—p. 12, *op. cit.*, p. 620, *supra*.

Nowhere is this better illustrated than in the case of the distribution of dysentery among the civil population of the United States, the most important facts with regard to which I have presented in a previous portion of this Section;* neither in its ordinary distribution nor in its epidemic prevalence has it borne any relation to geological formation in this country. There remains, therefore, it is confessed on every hand, a certain *quid ignotum* to which we must appeal in explaining the phenomena of the endemic and epidemic prevalence of dysentery. It would be as unreasonable to deny this as to place any confidence in the conjectures which have been advanced as to its nature. Two possibilities have here to be considered: The existence of some local or wide-spread influence operating simultaneously on many individuals, and the transfer of the disease from individual to individual by actual contagion.

The development in the atmosphere of various morbific miasmata, some especially hostile to plants or the lower animals, others to man, was assumed already by the Greek physicians† to explain the phenomena of pestilential diseases. Galen expounded this subject with his usual ingenuity.‡ According to him the miasmata were of a putrid nature, and might arise either from animal or vegetable decomposition, or from the action of heat and moisture on the ordinary constituents of the air; genuine *semina morborum* were thus produced, which were introduced into the economy chiefly by the respiratory act, and generated disease by exciting putrefaction in the humors of those exposed; this effect, however, does not result indifferently in all subjects, but only in those whose constitution, habits of life or previous morbid conditions favor the putrefaction of the humors. These fundamental notions as to the origin of epidemic and endemic diseases in general were long received by the physicians of modern Europe as a part of the humoral pathology. Accordingly it is by no means surprising to find them reappear from time to time with but little modification, in the various special treatises on dysentery, in explanation of the epidemic occurrence of that disease.

I may refer to the tracts of Fabricius Hildanus and Sennertus in illustration of the views which were dominant at the commencement of the seventeenth century. According to Hildanus,§ corruption of the air is the most dangerous of the external causes of dysentery. The epidemic of 1601–3 was preceded and accompanied by an excess of vapors and exhalations in the air, so that the sun, especially just after sunrise, was almost daily pallid and smoky. Then there were two earthquakes in the year 1600, one on the 8th of March, the other on the 7th of September, by which great quantities of corrupted vapors were emitted from the bowels of the earth. The air itself was infected by the putrefaction of

* Page 418 *et seq.*, *supra*.

† Thus, in the Hippocratic treatise *De Flatibus*, § 5–6, [Ed. Littré, VI, p. 96,] the air is said to be a source of disease when it is corrupted by morbific miasmata, (*νοσερὰ μιάσματα.*) and again, that when the air is infected by miasmata hostile to human nature men are smitten, but animals when the miasm is out of harmony with their nature.

‡ GALEN expounds the doctrine in the text most fully in his work *De Diff. Feb.*, Lib. I, Cap. 6, [Ed. Kühn, VII, p. 289.] Pestilential diseases are chiefly caused by breathing air infected with a putrid exhalation, (*σηπεδονώδης ἀναθυμίασις.*) As a source of such exhalations of animal origin he mentions the putrefaction of human bodies in time of war, but he was well acquainted with another important source, viz: city sewers, which he elsewhere—*Comm. III, in Hippoc. de Humor. Lib.*, § 3, [Ed. Kühn, XVI, p. 357,]—speaks of as corrupting the air and causing diseases. He also specifies the exhalations from marshes and stagnant water in summer. These exhalations constitute genuine *semina morborum*, (*λοιμοῦ σπέρματα,*) which, however, are limited in their action, as mentioned in the text. As an example of immoderate heat alone generating pestilence, he cites the account given by THUCYDIDES of the plague at Athens, whom he represents as saying that "it affected with corruption the bodies of men living in summer time in suffocating ill-ventilated huts;" to which GALEN adds that the pestilence began as a fever, because the humors of the body were prepared for putrefaction by bad food, and that perhaps also it happened because the air which blows from Ethiopia contained putrid miasmata (*σηπεδονώδη μιάσματα*) that caused fever in those predisposed; for he declares this should be especially remembered, that no cause can produce disease unless there is also a certain aptitude of body in those exposed to it. The account given by THUCYDIDES of this plague will be found in his *History*, Lib. II, Cap. 47–54; the passage cited by GALEN is in Cap. 52. THUCYDIDES declined to express an opinion as to the cause of the pestilence, saying that he would leave that question to others, whether physicians or unprofessional persons. An excellent though brief summary of the Galenical doctrine of epidemic and endemic diseases will be found in ÆTIUS—Tetrab. II, Serm. I, Cap. 94, Lyons Ed., 1549, p. 268.

§ FAB. HILDANUS—*De Dysenteria*, [1602,] in Opera, Frankfort, 1646, p. 669.

these exhalations and vapors, and this condition produced the epidemic. According to Sennertus,* atmospheric moisture is not necessary to the generation of the cause of dysentery, for the epidemic of 1624 broke out after an unusually hot and dry spring and early summer. Moreover, it is impossible to explain the constitution of the air which produces dysentery by merely considering heat, moisture, and other natural qualities. Something more must be invoked: Perhaps the occult qualities of the constellations and planets may generate the morbific influence. Be this as it may, the atmospheric impurities which result do not appear to infect the whole air, but rather to be scattered in certain tracts; and this circumstance, as well as the greater susceptibilities of some individuals, must be considered in interpreting the fact that all persons do not suffer from the disease during its epidemic prevalence. Such generalities as these paved the way for the conception of a special dysenteric miasma, which we find in the writings of Selle and Kreysig,† and in a modified form in the doctrine of a mephitis related to crowd-poisoning, developed in the monograph of Vogt.‡

More recently Niemeyer§ has taught that dysentery is an infectious disease in the sense that it depends upon a miasma, the germs of which are capable of growing and multiplying independently of the presence of the human organism. A high temperature and a certain degree of moisture are the most important conditions of the multiplication of these germs. Hence the disease is endemic throughout extensive districts in the tropics, while in Europe the necessary conditions are only occasionally present. Moreover, these germs are capable, under favorable circumstances, of multiplying in the bodies of the infected individuals, whose stools, hence, contain the germs of the disease either fully developed or in some preliminary stage. This view has been widely accepted in Europe and America. Heubner‖ has adopted a very similar opinion, dwelling, however, also upon the importance of a moist and swampy soil as a favorable condition, and upon a similarity between the dysenteric miasm and that which causes the malarial fevers.

But if we are to assume a special dysenteric miasm, we should at least endow it with characters that will account for all epidemics. Niemeyer himself felt some of the difficulties of his doctrine; for he acknowledges that dysentery does not always prevail when the requisite heat and moisture are present, and points out that this may be either because yet other conditions are indispensable, or because the dysenteric germs are not universally diffused, and their presence is indispensable as a starting point for their subsequent multiplication. But these are not the only difficulties surrounding the doctrine of a dysenteric miasm which requires heat and moisture as essential conditions. Such a view utterly fails to account for the epidemics that occur in winter,¶ or for the fact that the local outbreaks which occur during epidemic years in temperate climates bear no relation to the moisture

* D. SENNERTUS—*Tractatus de Dysenteria*, Wittemberg, 1626. p. 26; also *Pract. Med.*, Lib. III, Part. 2, Sect. 2, Cap. 7, Opera, Paris, 1641, T. III, p. 126. Elsewhere—*De Febribus*, (1619,) Lib. IV, Cap. 2, *op. cit.*, T. II, p. 685—he expresses in a more general way his belief that the stars are capable of generating various pestilential miasmata, and that the plagues thus produced are the severest and most widely diffused to which man is subject.

† C. G. SELLE—*Medicina Clinica*, Vienna, 1797, S. 139: "The cause of this disease is a special *miasma epidemicum* which causes in the intestines a sort of catarrh." F. L. KREYSIG—*De pecul. in dysenter. epidem. miasmat. præsentia et de iis, quæ id augere et propagare possunt*, Wittemberg, 1799: I have not seen this essay, and cite from NAUMANN—*Handb. der med. Klinik*, Bd. IV, 2, 1835, S. 41—who remarks: "It is difficult to give a definite idea of this miasma, concerning which, moreover, obscure and contradictory opinions are expressed."

‡ P. F. W. VOGT—*Monographie der Ruhr*, Giessen, 1856, p. 13 *et seq.*

§ F. v. NIEMEYER—*Lehrb. der Spec. Path. u. Ther.*, 7te Aufl., Berlin, 1868, Bd. II, S. 747: "Die Ruhr ist eine Infectionskrankheit; sie unterscheidet sich aber von dem Typhus und anderen Infectionskrankheiten dadurch, dass die Infection mit Ruhrgift nur im Darmkanal zu nachweisbaren pathologischen Veränderungen führt." He speaks here exclusively of diphtheritic dysentery, the only cause of which, according to him, is this infection: "Nichtsdestoweniger ist die Infection mit dem specifischen Gift die einzige Ursache der in Rede stehenden Krankheit." Catching cold, the use of unripe fruit, &c., only predispose the individual by making him more sensitive to the action of the poison, if he encounters it. He strongly inclines to the belief that the specific "Ruhrkeim" consists of specific lower organisms.

‖ S. 509, *op. cit.*, p. 529, *supra*. ¶ See p. 490, *supra*.

or swampy character of the soil, or to the distribution of the malarial fevers.* Heubner† has especially emphasized the circumstance that during the Franco-German war dysentery was epidemic chiefly in the camps around Paris and Metz, places already known to have been infested with endemic intermittent fever or dysentery. But these were the chief camps of the German army in that war; had their armies moved elsewhere in hostile array I suppose dysentery would have followed them wherever they went. Certainly in our own civil war, although, as has already been shown in detail, the malarial regions suffered most, no district in which troops were massed for war purposes was exempt from the scourge.‡

As to the intimate constitution of the dysenteric miasm, no satisfactory explanation has been offered. The various animal and vegetable germ theories have already been referred to in sufficient detail.§ It seems wiser to confess our ignorance of this unknown factor of disease than to embrace the undemonstrated hypotheses that have been brought forward. In this respect we might advantageously imitate the example of Sennertus,‖ who openly confessed, when he brought forward his speculation as to occult qualities, that it was the last asylum of human ignorance.

CONTAGION.—Is dysentery contagious?¶ Does the dysenteric subject generate in his intestinal mucous membrane, or elsewhere, a virus capable of causing the disease in others, if brought in contact with them by the air, the drinking water, or otherwise? These questions were answered in the affirmative for the malignant forms of dysentery by many of

* See the account given—*supra*, p. 48 *et seq.*—of the distribution of dysentery among the civil population of the United States; also the passages in the works of HIRSCH, DUTROULAU and others, cited on p. 401, *supra*.

† HEUBNER—*loc. cit.*—also brings forward, in support of his view that camp dysentery is always dependent on situation, PRINGLE'S story of the battle of Dettingen, concerning which I have already exposed his error—note ‖, p. 640, *supra*—and a statement which he attributes to MURSINNA, "that while the army of Prince Henry of Hesse was encamped at Nimes in Bohemia, in 1778, dysentery raged fearfully; but when the army moved to Leutmeritz, the disease immediately ceased, though the soldiers ate large quantities of fruit." Hence, HEUBNER affirms that camp dysentery "develops itself only in such places as are peculiarly predisposed to it, as is expressly emphasized by military authors, (Pringle and Mursinna.)" But it is not the military authors who have emphasized this view; it is HEUBNER himself, and he is no more fortunate in his citation from MURSINNA than in that from PRINGLE. I read in the work of MURSINNA—*Beob. über die Ruhr und die Faulfieber*, 2te Aufl., Berlin, 1787, Cap. 5, S. 86—that the army of Prince Henry reached Nimes, and encamped in its neighborhood, August 9, 1778. Here the weather was very hot and dry, (S. 98,) but for the first week the troops remained well, although some mild diarrhœas made their appearance. Afterwards persistent rainy weather set in, and it is to this circumstance, and not to the situation of the camp, that MURSINNA attributed the dysentery. He says: "Whoever has accompanied a campaign and lain in camp, especially if he is a practical physician, will know how much misery (Ungemach) such continuous bad weather causes; how many diseases are speedily produced by it among men and cattle, and how easily these become malignant. So it was now. There speedily arose a really putrid dysentery throughout the whole army." And he goes on to compare the weather on this occasion with that which accompanied the epidemic of 1779, at Herford, in Westphalia, described in a previous portion of his book, and expresses the opinion that the cause of the dysentery is to be found in the weather, on both occasions. September 12th, less than a month after the dysentery broke out, the army moved to Leutmeritz, after which very little dysentery occurred. Perhaps the cause of this was as much change of diet as change of camp. MURSINNA writes: "Fresh fruit was not to be had at Nimes, and all got sick. So soon as the army, on the 12th of September, encamped at Leutmeritz, we found the most splendid fruit, especially grapes in abundance, and all remained well, (S. 114.)" The fact brought forward by HEUBNER in the same connection—*op. cit.*, p. 567—that a marked improvement has frequently been noticed in the dysentery cases when a camp hospital has been moved from an unfavorable place, is often due chiefly to the circumstance that the sick are thus removed from the accumulated filth, contaminated privies, &c. I do not wish to be regarded as denying the influence of location on camp dysentery, but think that HEUBNER has exaggerated its connection with the etiology.

‡ See p. 9 *et seq.*, p. 230 *et seq.* and p. 414 *et seq.* § See p. 278 *et seq.* and p. 367 *et seq.*

‖ SENNERTUS—*Pract. Med.*, *loc. cit.*, last page: "Ideoque malo in hisce et aliis morbis eorumque causis ad necessarium illud in hac humanæ mentis caligine ignorantiæ asylum, occultas qualitates, confugere, et causas veras saltem nominare, si eas non satis explicare possum, quam falsas ac fictas afferre, quod nonnulli hodie faciunt, qui ut Antiquitatis egregii Patroni et defensores videantur, vanissimo et irrito conatu omnia ad qualitates prima deducere, et incerta per æque incerta probare conantur." In the like spirit, about the close of the seventeenth century, BAGLIVI wrote—*Prax. Med.*, Lyons, 1699, Lib. II, Cap. 9, p. 231: "In morbis enim, sive acutis, sive chronicis producendis, viget occultum quid, per humanas speculationes fere incomprehensibile." These expressions may well be commended to the consideration of modern medical speculators, who too often fall into the error, censured by SENNERTUS, of endeavoring to explain uncertain things by others equally uncertain.

¶ I use the word contagion in the same sense in which it was employed by SENNERTUS, who defined it as follows—*De Febribus*, Lib. IV, Cap. 3, Opera, Paris, 1641, T. II, p. 688: "Unde definimus contagium esse *μίασμι* seu seminium vitiosum, e corpore ægro emissum, quod in analogo corpore receptum, similem in eo morbum gignere et producere aptum natum est." According to SENNERTUS, the substance thus emitted by the sick body, and producing disease in another, may either be of a gaseous or fluid nature: "Semen hoc corpus quoddam est, sed nunc spirituale, nunc etiam humoris natura præditum;" and he declares it to act like a ferment: "Habetque *μίασμα* hoc se instar fermenti, quod alteri massæ non fermentatæ mistum facit, ut et ipsa effervescat." This latter notion is the basis of the modern doctrine of zymotic diseases. I take from SENNERTUS neither this notion, which is now pretty thoroughly exploded, nor his belief that the contagious body may be a gas, for the facts with regard to contagion seem to be intelligible only on the supposition that it is particulate. But neither of these notions are essential to the definition given above. In this sense the word contagion is used by most of the best modern authors. Some unsuccessful attempts have been made on the one hand to limit it to diseases in which the contagion is not diffused through the air, *e. g.*, syphilis; on the other hand to extend it to embrace the atmospheric influences producing epidemic or endemic diseases, *e. g.*, the malarial fevers, which are not transferable from individual to individual. These latter affections are very often spoken of as infections, and their cause designated infection; terms which are used by different writers in very different senses. Thus, according to G. B. WOOD—*Treatise on the Practice*

the physicians of the sixteenth and seventeenth centuries. Helidæus of Padua* declared that he had often seen dysentery communicated by the use of clyster pipes previously used in the treatment of those suffering from that disease and not properly cleaned. Horstius and Fabricius Hildanus† taught that the contagion is not produced by the whole body of those laboring under dysentery, but is a specific and malignant corruption of the humors generated by the ulcerated intestine; the use of latrines contaminated by dysenteric excreta is therefore particularly dangerous. Sennertus‡ held similar views, but not so exclusively; according to him it often happens in dysentery that the whole mass of the blood becomes contaminated, and hence he insists that those using the beds or eating utensils of such patients, or breathing the same air, may be infected, even though they do not use the same privies. Frid. Hoffmann,§ on the other hand, adhered quite closely to the doctrine of Horstius, and Van Swieten‖ took nearly the same view, declaring that those who wash bed-linen soiled by the dysenteric discharges are attacked by the disease, and that physicians may contract it while examining the dysenteric stools, which give off malignant exhalations.

---

of Medicine, 6th Ed., Philadelphia, 1866, Vol. I, p. 183—they are usually applied to those contagious diseases which are transmitted from individual to individual through the air, while "Chomel confines it to the action of the morbific exhalation which arises from the person, when numbers, either in health or sickness, are crowded together," and remarks: "In this confusion of meaning, it is best to abandon the terms infection and infectious altogether, especially as we can express all that is essential without them." The definition of contagion given by DUNGLISON—*Dict. of Med. Sci.*, new Ed., revised by his son, Philadelphia, 1874, p. 250—agrees with that of SENNERTUS and WOOD, but he adds: "Contagion and infection are generally esteemed synonymous." In like manner AITKEN—*Science and Practice of Medicine*, 3d Am. Ed., Philadelphia, 1872, Vol. I, p. 751—remarks: "Considerable confusion has always pertained to the use of these terms, contagion and infection; but when observations like those of Drs. Chauveau and Burdon Sanderson can demonstrate that the essential poison-carrying substance is a germ or granule of minute microscopic size, capable of indefinite growth and multiplication, when it comes in contact with suitable soil, the contagiousness of infecting miasms becomes quite intelligible, and the one word becomes synonymous with the other." LITTRÉ et ROBIN—*Dict. de Méd.*, Paris, 1865, p. 346—define contagion as "Transmission de la maladie d'un individu à un autre par l effet d'un contact médiat ou immédiat." GALLARD—Art. *Contagion*, Nouv. Dict. de Méd. et de Chir. Pratiques, T. IX, Paris, 1869, p. 210 *et seq.*—gives essentially the same definition, and explains that mediate contact can operate, A, through persons, B, through things, C, through the atmospheric air; (an excellent bibliography will be found at the close of this article.) LITTRÉ et ROBIN—*op. cit.*, p. 782—define infection to be the action exercised on the economy by morbific miasms. It differs from contagion in that the latter can reproduce itself indefinitely; while infection, due to the action of putrefying animal and vegetable substances on the surrounding air, only acts in the neighborhood whence the morbific miasms arise. Infection can, it is true, propagate itself from individual to individual like contagion, but this is not by contact; it is by altering the surrounding air, in relation to which the diseased individual plays the role of a focus of infection. Still another broader use of the term infection has lately come into use in Germany, by which it is employed as a generic term to embrace both contagion and the unknown cause of the non-transmissible endemic and epidemic diseases. An interesting exposition of this view has been given by LIEBERMEISTER—*Einleitung zu den Infectionskrankheiten*, Ziemssen's Handb., Bd. II, Th. 1, S. 3 *et seq.*; also Amer. Transl., Vol. I, p. 1 *et seq.*—to whose work I refer the reader. He divides infectious diseases into: 1. Those that are purely contagious; 2, those that are purely miasmatic; and 3, miasmatic contagious diseases. Under the first head he embraces measles, scarlet fever, &c.; under the second, the malarial diseases; under the third, "cholera, typhoid fever, dysentery, and probably, also, yellow fever and the plague." These diseases he believes are not transmitted from individual to individual, and are the result of a miasm generated outside of the body, which, however, is only generated if an individual suffering from the diseases furnishes the necessary germ.

* HELIDÆUS of PADUA; see note ‡, p. 538, *supra*, with regard to the time when this physician flourished. I borrow this statement from ETTMÜLLER—*De Morb. Human. Corporis in Genere*, Cap. 9, p. 125, in Opera, Lyons, 1690, T. I: "Sed etiam notatu dignum est quod observat Helidæus Paduanus in *observat.* p. 104. per clysteres etiam communes oriri dysenteriam: dicit enim hinc videmus sæpius dysenteria corripi eos, quibus clyster infunditur instrumento non bene abluto, quo antea dysentericus fuit usus."

† GREGORIUS HORSTIUS—*De Morbis eorumque Causis, Lib.*, Giessen, 1612, Exercit. 5, Quæstio 13; I have not seen this work, and give the reference from HILDANUS—*loc. cit., infra*. The passage is reprinted in the Opera Medica of HORSTIUS, Nuremberg, 1660, T. I, p. 274: "In dysenteria malignitatem adesse, non respectu totius, quia morbus hic universalis non est, sed ratione specificæ et malignæ corruptionis illorum humorum, qui intestinorum exulcerationem fœtidam generarunt. Quatenus autem hæc corruptio specifica singulari quidam parti, nimirum intestinis, et non simpliciter toti contraria est et inimica, eatenus facillime recipitur et vim suam exerit tum temporis, ubi quis aliquo modo dispositus ad cloacas ægrotantium accedens per inferiorem gutturem (ut Plautus loquitur) venenatas expirationes excretorum recipit." HILDANUS—p. 671, *op. cit.*, p. 644, *supra*—cites this passage to express his own views, remarking: "Familiaritas quoque et conversatio ægrotis, et præcipue latrinarum usus eum iis communis, periculosus est, et facillime inficit."

‡ SENNERTUS—T. III, p. 127, *op. cit.*, p. 645, *supra*—expresses essentially the same views as HORSTIUS and HILDANUS, but insists on other modes of contagion besides the excreta, remarking: "Quia tamen in dysenteria non solum alvus afficitur, ut in ophthalmia et phthisi pars una reliquis salvis afficitur, sed sæpe tota massa sanguinea inquinata est (unde etiam febres dysenteriæ sæpe conjunguntur) nec conversationem cum dysentericis satis tutam puto, et dysenteriam ex lecto dysenterico communi vel communibus poculis aut patinis aut ære inspirato attrahi posse existimo; cum experientia doceat, non paucos ex conversatione cum dysentericis in dysenteriam incidisse, qui nunquam in locum communem alvum exonerarunt." According to OZANAM—T. III, p. 281, *op. cit.*, p. 609, *supra*—the Lyons epidemic of 1624-5 was described by JEAN DE LAMONIÈRE—*Obs. Fluxus Dysenterici*, &c., Lyons, 1626; a work I have been unable to see—as decidedly contagious; the physicians, apothecaries and others who visited the sick were attacked by the disease.

§ FRID. HOFFMANN—*Med. Rat. Syst.*, T. II, Pars 2, Cap. 3, De venenis corporis humani, § 20, Scholion, Opera, T. I, Geneva, 1740, p. 265: "Purulentus dysentericorum fluxus effluvia spargit, quæ ano excepta, præsertim si quis eædem sellæ insideat, intestinorum tunicas petunt, et fœtidissimum hunc morbum pariunt. Ex veteri pulmonum ulcere ere suscepti halitus corruptivæ labi pulmonibus inferendæ aptissimi sunt." In the same scholion he declares that the materia from scabies reproduces disease of the skin, and that from gonorrhœa or lues venerea is especially injurious to the genital organs. We well know at the present time the error of such generalizations.

‖ G. VAN SWIETEN—*Comm. in H. Boerhaave Aphorismos*, T. II, Leyden, 1745, § 722 ad fin., p. 396. He mentions that a distinguished physician of his acquaintance contracted the disease from examining the stools of a patient. The same author—in his *Kurze Beschreibung und Heilungsart der Krankheiten welche am öftesten in dem Feldloger beobachtet werden*, Vienna, 1758 p. 108—declares that in camps the healthy soldiers are speedily infected, by the foul exhalations which rise from the fæcal matters, if they use the same sinks as the sick.

Not a few subsequent observers maintained the contagious character of dysentery in the same broad manner in which it was taught by Sennertus. Degner* not merely declared that the disease spread from street to street through Nimeguen, but that the physicians who attended the sick contracted it from them. Pringle† affirmed that in camps the contagion passes from one who is ill to his companions in the same tent, and thence to those in the next. Tissot‡ asserted that if there be a truly contagious disease it is dysentery, and related a striking incident in support of his opinion. Cullen§ lent to this view the support of his great authority. The dreadful epidemic of dysentery which decimated the army of the allies after the battle of Valmy, September 20, 1792, and has been described in detail by Chamseru and Montgarny,‖ seemed to afford ghastly evidence in its favor; this dysentery was highly contagious, and speedily spread to the victorious French army and the miserable population of the towns and villages through which the beaten army passed in its retreat; long after, it was known in France as the Courrée prussienne. According to Gilbert,¶ the epidemic dysentery of the great French Army during the campaign of 1807, in Prussia and Poland, was also highly contagious: it spread from bed to bed; the straw on which the sick lay became infectious; the physicians who merely examined the discharges for a moment were smitten with the disease.

It would be easy to multiply authorities in favor of the contagion of dysentery, and to cite additional instances of particular outbreaks which appear to support this view.** The first authoritative voice which was raised against it was that of Stoll,†† whose views of the pathology of the disease led him to deny contagion in toto, and who declared that in the Vienna hospital it was never communicated to the physicians or hospital attendants. This opinion was shared by almost all of those who accepted the catarrhal origin of dysentery.‡‡ Others, more conservative, held with Zimmermann§§ that dysentery is contagious or non-contagious according to circumstances; after the excrements acquire a cadaverous smell, in fatal cases, they become contagious; and so also where many persons are sick at

* DEGNER—p. 3 *et seq.* and p. 94 *et seq.*, *op. cit.*, p. 625, *supra*. He went so far as to express the opinion that the whole epidemic originated from a single case, and regarded it as a general possibility, "ut ab uno ægroto integra civitas imo regio possit infici."

† PRINGLE—Part III, Chap. 6, p. 254, *op. cit.*, p. 640, *supra*. He adds: "The foul straw becomes infectious. But the greatest sources of infection are the privies, after they have received the dysenteric excrements of those who first sicken. The hospitals likewise spread it; since those who are admitted with the flux, not only give it to the rest of the patients, but to the nurses and other attendants of the sick." Further on he remarks: "The infection is carried from one to another by the effluvia, or clothes, or bedding, &c., of the tainted person, as in the case of the plague, small-pox and measles. Yet the dysenteric miasma is of a less catching nature than any of those; so that in the milder epidemics it may pass unnoticed."

‡ TISSOT—*Avis au Peuple sur sa Santé*, (1761,) Chap. 24, T. III. p. 28, Ed. cited p. 625, *supra:* "S'il y a une maladie véritablement contagieuse, c'est celle ci." A family of six persons lived in a healthy country house, in the vicinity of which no dysentery prevailed. One of their sons returned from Holland, where he had been a soldier, in bad health, and shortly after his arrival was attacked by dysentery. One after the other of the whole family contracted the disease, and two of them died. In the same chapter (p. 16) TISSOT declares, "les excrémens sont très-contagieux."

§ CULLEN—*First Lines*, § 1075, Thomson's Ed. of Works, Vol. II, Edinburgh, 1827, p. 321: "The dysentery does often manifestly arise from the application of cold, but the disease is always contagious; and, by the propagation of such contagion, independent of cold, or other exciting causes, it becomes epidemic in camps and other places."

‖ CHAMSERU—*Exposé des maladies qui ont régné dans les hôpitaux ambulans à la suite de l'armée de réserve pendant l'été et l'automne de* 1792, Jour. de Méd. Chir. et Pharm., T. 95, 1793, p. 27 *et seq.* and 173 *et seq.* The essay of HARMAND DE MONTGARNY—*Hist. médico-pratique du flux dyssentérique, appelée Courrée prussienne*, Verdun, 1793—I have not been able to see. There is a pretty good abstract of it in the work of F. MARÉCHAL—*Tableau, etc. des Maladies Endémiques, Épidémiques et Contagieuses, qui ont régné à Metz et dans le Pays-Messin*, Metz, 1850, p. 283 *et seq.* See also OZANAM—T. III. p. 302 *et seq.*, *op. cit.*, p. 647, *supra*. This dysentery and the contagious typhus with which it was associated may be said to have destroyed the allied army, which, according to OZANAM—p. 303—lost one-half of its men and horses during the twenty-two days of the retreat.

¶ N. P. GILBERT—*Tableau Hist. des Maladies, etc., qui ont affligé la Grande Armée dans la campagne de Prusse et de Pologne*, Berlin, 1808; I have not been able to see a copy of the original, but quote from the German translation of Bock, Erfurt, 1808, S. 52. GILBERT declares that contagion was the most important cause of the disease.

** A number of interesting facts of this kind have been collected by FOURNIER et VAIDY—p. 334 *et seq.*, *op. cit.*, p. 362, *supra*.

†† MAX STOLL—p. 327, *op. cit.*, note †, p. 342, *supra*—"Contagium dysentericum pauci in dubium vocarunt, idque effluvium ex uno homine expirans communicari adstantibus posse, plerique credunt. Miror Hercle, qui nos immunes per omnes hos annos a dysenteria manserimus, medici, medicorum adjutores, et ægrorum custodes. Atqui quotidie mane singulorum fæces lustramus ea nocte exceptas, et vel inviti haurimus putidissima effluvia totis naribus." He admitted that the dejecta of dysentery corrupted the air, and might cause putrid diseases, especially hospital diseases, but not dysentery.

‡‡ For example, MOSELEY—*Treatise on Tropical Diseases*, 3d Ed., London, 1792, p. 267—writes: "As to contagion from infection in the dysentery, I must confess I never saw an instance of it: neither do I believe there is any such thing. But this is a field for speculation, that has long amused the pedantry of the schools, and should never be entered by practical writers."

§§ ZIMMERMANN—*Von der Ruhr unter dem Volke*, Zurich, 1767, S. 342.

the same time, and their putrid excrements accumulate without proper precautions being taken, contagion arises. Zimmermann admitted that the bedding and clothes of dysenteric subjects might communicate the disease, but according to Van Geuns* this was not the case in the Harlingen epidemic of 1783; and Mursinna,† who believed the camp dysentery at Nimes to be contagious, declared that during the epidemic at Herford, in 1779, neither clothing nor individuals transmitted the disease, and that the physicians, clergymen and nurses who attended the sick were not infected. Pinel,‡ who held, like Zimmermann, that dysentery is not constantly contagious, suggested its complication with some contagious adynamic fever as one of the circumstances that might render it so. Harty,§ likewise, declared that it is only when combined with typhus that dysentery is contagious, and a similar view was maintained by Broussais|| in explanation of at least those cases in which the contagion appears to be at all energetic.

On the other hand, Fournier and Vaidy¶ revived the old opinion of Horstius, that dysentery is contagious only through the dejecta, and that the virus must actually find its way to the mucous membrane of the alimentary canal before it can generate the disease. This opinion has been maintained by many subsequent authors, among the latest of whom I may particularly mention Heubner.** Even of those who are uncertain as to this point there are not a few who are inclined to agree with Bamberger,†† that it is practically safest to act as though the stools were contagious, and take every precaution against exposing the well to their effluvia. So, too, the opinion of Zimmermann, that dysentery, though not primarily contagious, may become so when great numbers of patients are crowded together, has found followers in modern times,‡‡ some of whom, however, insist that even in this case the poison is generated exclusively by the dysenteric stools. Only Savignac,§§ among prominent modern writers on dysentery, boldly ranges himself among the strict contagionists, and maintains that, independently of the dejecta, aerial effluvia from the sick may propagate the disease. Finally, in recent times some of those who adopt the view of Niemeyer, that dysentery is an infectious disease in the sense that it is generated by a miasm that can multiply without the body, are, like Barrallier,|||| inclined to make light of

* M. VAN GEUNS—*Die epidem. Ruhr*, German Transl., Dusseldorf, 1790, S. 91. † MURSINNA—S. 14 u. 99, *op. cit.*, p. 646, *supra*.

‡ PINEL—T. II, p. 328, *op. cit.*, p. 605, *supra*.

§ HARTY—*Obs. on the Simple Dysentery and its Combinations*, London, 1805, Chap. 4, Sect. 2, p. 119.

|| BROUSSAIS—Vol. III, p. 23, *op. cit.*, p. 643, *supra*—pointed out that when the air is rendered impure by vegetable ferments, such as proceed from marshes, intermittent fever is produced; when charged with decomposing animal corpuscles, continued fevers of malignant type, (mauvais caractère.) Perhaps the exhalations of filth, of privies and all kinds of excrements especially enjoy this property. But he held that the contagion even of the dysenteric excrements is slight, and that it is impossible for dysentery to show itself strongly contagious unless it is mingled with a malignant fever.

¶ FOURNIER et VAIDY—p. 347, *op. cit.*, p. 362, *supra*. They admit that the breath of dysenteric subjects is sometimes contagious, but affirm that this occurs only when the disease is complicated with typhus.

** HEUBNER—S. 510, *op. cit.*, p. 529, *supra*. Even NIEMEYER—Bd. II, S. 748, *op. cit.*, p. 645, *supra*—admits this mode of contagion. So, too, AITKEN—Vol. II, p. 657, *op. cit.*, p. 647, *supra*—remarks: "There is, therefore, good reason to believe that the exuviæ of dysenteric patients, as passed by stool, may, like those of typhoid fever, propagate the disease."

†† BAMBERGER—S. 389, *op. cit.*, p. 578, *supra*.

‡‡ Even ANNESLEY—Vol. II, p. 248, *op. cit.*, p. 631, *supra*—while he declares that he knew of no instance in which dysentery proved contagious in India, admits that it might possibly be so "under circumstances of crowding together of the sick, want of ventilation, and inattention to cleanliness and the removal of the evacuations." Prominent among those who adopted the view of ZIMMERMANN I may mention NAUMANN—Bd. IV, Abth. 2, S. 44, *op. cit.*, p. 645, *supra*—who held that the exhalations (Ausdünstungen) of the sick, though to a less degree than the dejecta, might act contagiously under favorable circumstances; and HAUFF—S. 342 *et seq.*, *op. cit.*, p. 534, *supra*—who has elaborated this view with great ingenuity. HEUBNER—*loc. cit.*, *supra*—takes very similar grounds, but refers the contagion wholly to the dejecta: "It would seem, then, that there is a limited contagion by means of the excreta of dysentery, which, however, only becomes active when a large mass of excreta is collected together." So, too, JACCOUD—*Traité de Path. Interne*, Paris, 1872, T. II, p. 330: "Si l'on entend par contagion, selon le sens rigoureusement étymologique, la transmission d'une maladie par contact direct, non, la dysentérie n'est pas contagieuse; mais si l'on veut avec moi, entendre par contagion, la transmission d'une maladie de l'homme malade à l'homme sain par un produit émané du malade, oui, certes, la dysentérie est contagieuse; et le contage, c'est-à-dire l'agent de la transmission, constitué vraisemblablement par des organismes inférieurs, est contenu surtout, sinon exclusivement, dans les matières alvines."

§§ SAVIGNAC—p. 51, *op. cit.*, p. 620, *supra*—mentions that a young lady, who visited a ward in a hospital under his direction in which there were several dysenteries, contracted the disease. He adds that if dysentery is contagious when it is endemic, it ought to be still more so when epidemic.

|||| BARRALLIER—p. 728, *op. cit.*, p. 603, *supra*. He simply remarks: "We ought not to pass in silence the deleterious action exercised by the emanations disengaged by the dysenteric dejections, especially on individuals obliged to stay in places where numerous cases of dysentery are collected," and adds that adequate ventilation will generally modify the injurious influence of this "local miasm."

the question of the contagion of the dejecta, or, even like Lubrez,* go so far as to deny that there is any evidence to prove that the dysenteric stools are more dangerous than healthy human fæces or any animal matters in a state of decomposition.

The very fact of the great diversity of opinion on this subject of contagion, which after so much controversy still exists, indicates that the evidence relied upon in support of the several views is far from being of a conclusive character. And in like manner the fact that the majority of the great observers, no matter what their opinion in other respects, agree in regarding the dejecta as contagious, would seem to indicate that the evidence as to this point is of a more satisfactory character than as to any other. For myself, I strongly incline to adopt the view of the contagion of the stools for at least a certain class of dysenteric cases, yet I frankly admit the recorded evidence on this head is by no means so conclusive as that which we possess with regard to typhoid fever. I sometimes think that the greater harmony of opinion as to this point among physicians before the time of Stoll grew out of the fact that typhoid fever cases were not sharply discriminated from those of dysentery;† and I do not doubt in the least that in such camp epidemics as those described by Chamseru and Gilbert, the association of dysentery with typhus explains the apparent intensity of the dysenteric contagion.

I have already discussed the slender evidence by which the opinion that drinking water contaminated by the dysenteric dejecta can propagate the disease is supported.‡ The opinion that it may be propagated by aerial effluvia from the dejecta has, likewise, a few apparently well observed facts in its favor. I admit that I cannot bring forward out of the experience of our civil war a single fact that can be regarded as positive in support of this view. The dreadful mortality from dysentery at certain points, as, for example, among the prisoners at Andersonville, seems to have been produced by the concurring influences of many factors, from among which it is impossible to isolate the share due to the dejecta. Belief in the contagion of dysentery, notwithstanding the extent to which the reasonable views of the accomplished Professor Alfred Stillé had been made public early in the war,§ was by no means common among our medical officers, and if any systematic effort was made to collect facts for or against any doctrine of contagion, it was not brought to my knowledge. In our great general hospitals dysenteric patients were treated for the most part side by side with the wounded and those suffering with other diseases, and it was a matter of common opinion among the medical officers with whom I have conversed, that the occurrence of dysenteric attacks among the physicians and hospital attendants was less and less frequent in proportion as the hospitals were more and more distant from the theatre of war; so that even these hospital cases were not usually attributed

---

* J. M. LUBREZ—p. 44, *op. cit.*, p. 618, *supra*: "Il reste maintenant à déterminer si les émanations des matières fécales dysentériques sont plus dangereuses que les matières fécales provenant d'hommes sains, que les matières animales en décomposition. Cette question est très-délicate; cependant rien ne semble le prouver." So, too, SEITZ—*loc. cit.*, note †, p. 631, *infra*—regards the supposition that the "germ of the infections" is to be found in the dysenteric stools as questionable.

† See p. 463 *et seq.*, *supra*. ‡ See p. 612 *et seq.*, *supra*.

§ ALFRED STILLÉ—*Dysentery*, Military Medical and Surgical Essays prepared for the U. S. Sanitary Commission, Philadelphia, 1864, p. 359: "The truth appears to be that its milder varieties are not contagious, but that its typhoid forms are highly so, and that its intermediate grades sometimes, however rarely, display this property. There is abundant evidence that the disease has been communicated by the dejections of the patients, by the privies or close-stools they have used, and by the clothes they have worn or soiled. Numerous instances prove that the introduction of a single case of dysentery into a hospital has been followed by a diffusion of the disease among the patients; that the arrival of such a patient in a healthy neighborhood has been followed by the attack of persons in direct communication with him; that persons employed in the wards of these sick with dysentery have, without being themselves affected, carried the disease to their families; and, finally, that the attendants upon dysenteric patients, even when they did not contract the disease, exhibited its malignant influence in numerous subcutaneous abscesses and an eruption of sero-purulent blebs, (rupia.)" If by "abundant evidence" Professor STILLÉ intended to indicate modern evidence, relating to dysentery from which actual complication with typhoid or typhus fever is carefully excluded, the hope may be expressed that at some time he will find it convenient to bring it forward, for certainly but little evidence of this kind has as yet been published.

to contagion. Nowhere have I heard of any local outbreak of dysentery among the civil population which was distinctly traceable to the arrival of any of the tens of thousands of dysenteric subjects who went home to recover or to die.

During the Franco-German war of 1870 the experience on this point was for the most part of a very similar character. According to Heubner,* in the reserve hospital No. 1, Leipsic, where out of six or seven hundred patients, two hundred or more had dysentery, no single case of undoubted contagion occurred. Seitz† reports that in the hospital at Munich there was not a single case among the attendants or patients in the hospital with the exception of those who had returned from the army in France, where they might be supposed to have contracted the disease. On the other hand, it is said that both physicians and nurses were attacked in the Metz hospitals,‡ and, according to Bayer,§ the same occurred in the hospitals at Bazeilles and Remilly, near Sedan. Heubner states, further, that several trustworthy army physicians informed him that in the field in France, when patients were crowded together, infection very often occurred by means of the privies, until stringent measures were taken to avoid it, after which it did not occur again. It will be observed that the stools appeared to be contagious only in places where the disease was prevailing; and we are assured by both Heubner and Brunner|| that the dysenteric patients sent home to Germany during the war nowhere spread dysentery among the civil population, as would have happened in the case of a contagious disorder.

In the year 1875 an outbreak of dysentery occurred in a French regiment at the camp near Chalons, in which, according to Czernicki,¶ the disease was unmistakably spread by the latrines; he even goes so far as to assert positively that the minimum period of incubation was seven days. This observation recalls the account given by Clouston,** ten years before, of an outbreak of dysentery in the Cumberland and Westmoreland Asylum, which appeared to be caused by the offensive exhalations of a field irrigated with sewage, and ceased when arrangements were made to convey the sewage elsewhere: the period of incubation is said to have been from three to six days; but the facts in this case would seem to indicate that the exhalations of ordinary sewage, without any contamination with dysenteric excreta, are capable of generating dysentery, so that the narrative is, on the whole, unfavorable to the doctrine of a specific contagion.

* HEUBNER—*loc. cit.*, p. 553, *supra*.

† F. SEITZ—*Aerztliche Beob. aus dem deutsch-französischen Kriege im Jahre* 1870–71 *besonders über die herrschende Ruhr*, Bayerisches Aerztliches Intelligenz-Blatt, No. 6, 1872, S. 73.

‡ HEUBNER—*loc. cit.* § J. BAYER: I cite from SEITZ—*loc. cit.* || BRUNNER—*op. cit.*, p. 638, *supra*.

¶ CZERNICKI—*Relation d'une épidémie de dysentérie qui a sévi sur le* 8e *régiment de dragons, durant les manœuvres du camp de Chalons (Sept.* 1875), Rec. de Mém. de Méd. de Chir. et de Pharm. Militaires, T. XXXII, 1876, p. 125. The first cases occurred seven days after the regiment camped at two farms, (Vadenay and Piémont,) where they used latrines (fosses d'aisances) previously used by a regiment in which a number of cases of dysentery had occurred; the squadron lodged in the building nearest the latrines had most cases. The part of the regiment camped at Piémont arrived two days later than that which went to Vadenay, and the disease broke out among them two days later than in the other part. The regiment left the farms Sept. 9th and 10th, and the epidemic speedily ceased. The author concludes that direct contagion (in the sense of the transmission of the disease from the sick to the well without the intervention of any focus of infection) is not demonstrated, but that epidemic dysentery is certainly and energetically transmitted by latrines which have been used by individuals suffering under that disease; that the minimum period of incubation is seven days, and that the evacuation of the infected places arrested the epidemic.

** CLOUSTON—*op. cit.*, note † to p. 438, *supra*, at the end of the note. This outbreak began early in April, 1864, and ceased in August quite suddenly, on the change in the disposition of the sewage being made. The disease, therefore, ceased at the very time when dysentery is usually most prevalent. The irrigated field was about 300 yards from the female ward, where the greatest number of cases occurred, and 350 yards from the corresponding male ward. The several outbreaks which occurred during the season always followed, by a few days, periods when the wind blew from the field to the asylum: "From the first of the season, up till July, when the direction of the effluvia would be determined chiefly by the wind, males and females were attacked at different times, according as the wind blew towards the male or female side of the Asylum; in July and August, when, through the sultry calm nights, with a high barometrical pressure, the effluvia would spread in all directions along the ground, males and females were attacked promiscuously," p. 569. In March, 1865, there were five additional cases of dysentery, four of whom died; these cases occurred a few days after the sewage had for a single night been allowed to flow upon the same field when the wind was blowing towards the house. Moreover, "an obstructed drain was found near the ward in which the cases occurred, which had formed a little cesspool under the soil immediately below the windows of the ward." Now in this last outbreak it would appear that sewage not yet contaminated with dysenteric excreta produced the disease; and so with the earliest cases of the preceding year.

Additional special studies of local outbreaks of dysentery, undertaken with a view to the investigation of this question, are greatly to be desired. Especially should the nature of each particular endemic be considered in such investigations; for surely if the analogy of the throat holds good in matters of etiology, as it certainly does in pathological anatomy, it is only in the case of the diphtheritic form of dysentery that a contagion is to be anticipated. Yet this distinction, which must be regarded as essential to any fruitful investigation of the subject, seems to have been practically ignored in all the observations hitherto made.* No wonder that they have been unsatisfactory and conflicting in their tendency. No wonder that, although such suspicion attaches to the dejecta of the diphtheritic cases that prudence dictates the practice of all possible precautions with regard to their disposal, it cannot yet be said that their specific power of transmitting the disease is positively established as a fact.

In view of this uncertainty as to the very existence of a contagion, whether in the stools or otherwise, it would be wise to pause till further evidence is obtained, before indulging in speculations as to the ultimate nature of the contagion, if it should be proven that any exists. I have already sufficiently discussed the various hypotheses by which it is assumed that the contagion consists of low animal or vegetable organisms, and the speculation of Lionel Beale, who seeks it in minute particles of bioplasm.† A modification of this latter view has recently been advocated by Richardson,‡ under the title of the glandular origin of contagious diseases. According to him all contagia are modified secretions from glands: that of glanders, for instance, is generated by those of the nasal mucous membrane, that of hydrophobia by the salivary glands, that of typhoid fever by the glands of the intestinal mucous membrane. This view, if applied to the case of dysentery, would closely approximate that suggested by Horstius, which I confess appears to me quite as reasonable as any subsequent conjecture on the subject. Into any detailed discussion of such questions it would be unprofitable to enter in this place.

Nor is it possible in the present state of our knowledge to offer in all cases a satisfactory explanation as to why any one of the causes heretofore considered, or any combination of them, should in a given case produce dysentery rather than diarrhœa, or the reverse. On the one hand, it has been held by Virchow§ that external causes of all kinds, including even epidemic and endemic influences and contagion, give rise only to catarrhal inflammation of the intestinal mucous membrane, and that for this to pass into the diphtheritic process requires the coöperation of local influences, especially of fæcal accumulations. On the other hand, Niemeyer,‖ while agreeing with the first part of this proposition, insisted that the diphtheritic process requires for its development the action of a specific germ of infection which must be introduced into the organism from without.

---

* Certain modern writers, as, for example, NIEMEYER—*loc. cit.*, p. 645, *supra*—after having carefully discriminated between catarrhal and diphtheritic dysentery, and assumed infection, with or without contagion, through the stools, for diphtheritic dysentery only, proceed to bring forward in support of this view the old observations, made not only without any recognition of the difference between these forms of dysentery, but without distinct recognition of the difference between dysentery and typhoid fever with bloody stools. Conclusions arrived at in this way are of little value.

† See p. 278 *et seq.* and p. 367 *et seq.*, *supra*.

‡ BENJ. W. RICHARDSON—*A theory as to the natural or glandular origin of the contagious diseases*, (being the address by the President to the Sanitary Congress, Leamington, Oct. 3, 1877,) Nature, Oct. 4, 1877, p. 489.

§ VIRCHOW—S. 356, *op. cit.*, p. 631, *supra*: "Im Allgemeinen würden wir also annehmen, dass der einfache Darmkatarrh sich bei Anwesenheit des entsprechenden Zersetzungsmaterials und an den Stellen, wo es sich findet, zur Diphtheritis steigert, und dass diess Zersetzungsmaterial am häufigsten durch retinirte Fäkalstoffe, die zuweilen vegetabilischer Art sind, geliefert werde. Der Katarrh kann bald aus epidemischen, bald aus endemischen, bald aus humoralen (dyskrasischen), bald aus localen Einwirkungen hervorgehen; die Retention der Fäkalstoffe kann durch Erschlaffung der Muskelhäute, durch anomale Lagerung der Därme, durch Fixation einzelner Stellen derselben etc. bedingt sein;" and again: "Mag man auch immerhin eine grössere Häufigkeit von Erkältungen, öfterm Genuss schwerer verdaulicher Substanzen oder Aehnliches, späterhin Contagion als Ursache der katarrhalischen Darmaffektion ansehen, so ist es doch wahrscheinlich, dass ohne das andere Moment die diphtheritische Steigerung nicht eingetreten sein würde," p. 357.

‖ NIEMEYER—*loc. cit.*, p. 645, *supra*.

I confess that I am not prepared to adopt either of these exclusive views. I have already attempted to show that Virchow's assumption of the invariable participation of fæcal accumulations in the development of diphtheritic dysentery is in many instances contradicted by observation; and surely, if we imagine the existence of a dysenteric infection or contagion similar to that which appears to exist in the case of throat diphtheria, analogy would favor the opinion that the dysenteric germs would be themselves capable of developing even the most malignant diphtheritic process without the coöperation of any other local irritant. The view of Niemeyer seems, therefore, much more logical; but is it in accordance with the facts? Is it not true that single sporadic cases of dysentery occasionally assume all the clinical characters of the diphtheritic form, terminate fatally, exhibit on dissection all the typical features of the diphtheritic process, and yet do not act as a focus of infection from which other cases are developed?

I willingly agree with Virchow that local influences, such as he has described, may induce a catarrhal inflammation of the intestinal mucous membrane to assume the diphtheritic form; but I incline to believe also that a sufficient degree of intensity or duration in the action of any of the other local irritants of the intestinal mucous membrane which have been discussed may do the same, especially if favoring constitutional conditions coexist. I also willingly agree with Niemeyer that epidemic or endemic influences, possibly also a contagion contained in the dejecta, are capable of producing diphtheritic dysentery in those predisposed by constitutional or local causes; but I am not prepared to admit that the action of such influences is a condition indispensable to the development of this form of dysentery, or that their presence must be assumed in every sporadic case that presents its symptoms during life, or even its anatomical characters after death.

Still less can I admit that in the case of armies in times of war the prevalence of diarrhœa and dysentery in the camps is of itself any necessary indication of the existence of a genuine epidemic or endemic influence over which human agencies could be hoped to exercise little or no control. Not recent investigations only, but the general tenor of all military medical history is thoroughly opposed to any such deplorable doctrine. On the contrary, a careful survey of the evidence seems fully to justify the belief that these diseases generally result from the simultaneous action upon large numbers of men of several of the predisposing and exciting causes which have been discussed; some of the most dangerous of which—contaminated drinking water, insufficient or faulty alimentation, camp filth of every kind, especially human excreta, and all the reckless exposures and fatigues which are not required by the actual necessities of the campaign—it is quite possible, even in the present state of our knowledge, for an intelligent Medical Staff to point out and a wise Army Administration to avoid.

These preventable causes determine, I fully believe, of themselves alone, a great proportion of the diarrhœas and dysenteries of camps; when other less understood, and therefore less avoidable, causes come into play the preventable causes still vastly increase the number of cases and the resulting mortality. The subject of the etiology of the fluxes still presents many obscure questions for future investigation, but the requirements of national economy and the natural desire for success in war, as well as the instincts of humanity, alike demand that the soldier in the field should enjoy to the fullest extent the benefit of the knowledge we already possess.

6. Treatment of Diarrhœa and Dysentery.

A systematic and complete analysis of the various methods proposed for the treatment of the several forms of diarrhœa and dysentery is quite out of the question here, both on account of the time required to prepare it and the space it would occupy; I have therefore determined only to attempt a sketch of those which have been most generally esteemed useful. In this I shall not try to present under separate headings an account of the plan of treatment adapted to each variety of flux, which would involve needless repetitions, but will endeavor, in connection with each of the several measures discussed, to indicate the limits of its usefulness.

Prophylaxis.—In the first place a few words must be said with regard to means of prevention, especially in the case of armies in times of war. These are to be sought in those wise administrative precautions which are also best adapted to preserve the troops from other destructive diseases. Officers skilled in medical topography should be consulted before selecting camp sites; the camps should not be overcrowded, and should be kept as cleanly as possible; strict rules should be adopted with regard to the position and management of the sinks and the disposition of offal; the best available water supply should be selected for drinking purposes, and the utmost vigilance exercised in preventing its contamination with fæcal matters or other filth; the supply of food should be liberal and judiciously selected; reasonably good arrangements should be made to secure proper cooking; suitable clothing should be supplied, and shelter provided whenever military necessity does not absolutely forbid. I suppose there is no military surgeon of experience now living who does not believe that an intelligent application of these simple rules, to an extent quite within the limits of possibility, would vastly diminish both the number of cases and the mortality of the fluxes and fevers of armies in times of war.

No doubt sins of omission in any of the directions indicated have a share in determining the prevalence and fatality of both groups of disease, but those connected with the food supply have unquestionably a preponderating influence in connection with the occurrence of the fluxes. So soon as from insufficient quantity, quality or variety of the food that general constitutional condition is developed which may be conveniently designated a *scorbutic taint*, the number and fatality of the cases of these disorders begin to assume colossal proportions. When the subject of scurvy comes to be discussed, the question of a proper ration for the soldier, and especially how far it is essential and possible for fresh vegetables to be supplied to troops in time of war, will be considered. At present it must suffice merely to indicate this as one of the most important questions connected with the prevention of the fluxes.

A knowledge of the precautionary rules just mentioned will serve to indicate the measures that should be taken when, after the neglect of these precautions, fluxes begin to prevail. The neglect does not always proceed from ignorance; it is often, to some extent at least, the inevitable result of the sad necessities of war; but in either case the methods which should be adopted are quite the same, and if in the emergency it is impossible to resort to them, no amelioration of the pestilence that may have arisen can reasonably be expected. It must, of course, be admitted that even the most conscientious adoption of hygienic regulations cannot in the present state of our knowledge be hoped to afford com-

plete protection against the occurrence of the fluxes. It has been shown that the facts of the distribution of these diseases, especially in civil populations, clearly indicate the existence at certain times and places of an unknown etiological factor; and against an unknown cause no trustworthy defensive measures can be contrived. But even in civil populations it is clear that the neglect of known hygienic precautions has much to do with the endemic and epidemic prevalence of the fluxes, and certainly, both in civil populations and armies, such negligence has a great share in determining both the number of cases and the mortality on any particular occasion.

The strictest application of the hygienic rules indicated is, therefore, demanded so soon as diarrhœa or dysentery appears in epidemic form, whether in armies or among the people. A systematic application of disinfectants, not only to the apartments occupied by the sick, to their dejecta and clothing, but to the dwellings and surroundings of the well, is also indicated. In the case of camps, after the enforcement of rigid police, the tents or huts, the latrines used by the well, and all gutters or drains should be thoroughly disinfected. In villages and towns the same process should be applied to the privies, alleys, sewers and the squalid abodes of the poor. A belief in the contagious character of the disease long ago suggested the precaution of separating the sick from the well,* and whatever opinion may be adopted in connection with the question of contagion, there can be no doubt that in the case of military hospitals it is advisable to treat patients laboring under diarrhœa and dysentery in separate wards rather than to mix them indiscriminately with those suffering from other diseases or, still worse, with the wounded, whose condition cannot fail to be imperilled by such a course.

Whether, in addition to these hygienic precautions, it is practicable for individuals to secure immunity during the epidemic or endemic prevalence of these diseases by any special regimen or mode of life is by no means established with certainty. The use of aromatic fumigations in the homes of the well, supposed to destroy the *semina morborum* in the air, has long since lost credit and been replaced by the more intelligent modern use of disinfectants.† So, too, the employment by the well of various aromatic and mild astringent medicaments, under the idea that they strengthen the bowels and render them less liable to the inroads of disease, has deservedly passed out of use.‡ Great stress was formerly laid on the use of a suitable diet as a means of prevention; only the most digestible articles should be employed; unripe fruits should be especially avoided; excesses at the table, and especially excess in the use of wine and ardent spirits, should be shunned.§ There is a certain amount of truth in the representations which have been made on this subject, but it is exceedingly doubtful whether any precautions of this kind, beyond those which should be taken at all times by whoever desires to enjoy good health, are of the slightest importance; and whatever may be said of the use of unripe fruit, the ripe fruits of the season should not be interdicted.

Some of the older writers attached much importance to keeping the bowels open during the epidemic prevalence of dysentery by the occasional administration of laxatives and

* Compare, for example, the remarks of DEGNER—Cap. IV, § 15, S. 253, *op. cit.*, p. 625, *supra*.

† FAB. HILDANUS—Cap. 21, p. 697, *op. cit.*, p. 644, *supra*—has given a detailed account of the formulæ of this kind which were relied upon at the commencement of the seventeenth century.

‡ See, particularly, the discussion of this subject by FAB. HILDANUS—p. 698, *op. cit.*, last note—who enumerates among the substances which may be used Bezoar stone, burnt hartshorn, terra sigillata, juniper berries, absinthium, tormentil, bistort and other vegetable astringents; nutmeg, mace, cloves and other aromatics; and gives several elaborate formulæ composed of these and similar ingredients, to which he attributes special power as corroborants of the stomach and intestines, which thus assisted are better able to resist the influence of the morbid cause.

§ Compare, on this subject, also p. 697, *op. cit.*, last note.

clysters; and more recent observations by Virchow are favorable to this view.* Certainly it is more than ever desirable under such circumstances to relieve constipation by suitable medicines. So, too, prompt medical treatment should be at once resorted to for any cases of slight diarrhœa that may occur; and it is more than usually important that evacuating measures should be relied on for this purpose, rather than the diarrhœa mixtures consisting of opiates, astringents, stimulants and aromatics, which are so often recklessly employed under these circumstances.

General management of the sick.—In all cases of acute diarrhœa, and still more so in acute dysentery, it is desirable, particularly in the case of soldiers, that the patient be at once put to bed.† In the more severe cases this is imperatively required, no matter what the occupation of the sufferer; but in the case of soldiers it is important, from the military point of view, to shorten as much as possible the time each man is excused from duty, and absolute rest greatly favors this result. Exercise aggravates the intestinal disorder in proportion to its activity, while quiet and repose are favorable to the restorative operations of nature. In the more aggravated diphtheritic cases the patient should not even be allowed to rise to evacuate his bowels or to urinate, but should be furnished with a bedpan. During convalescence from the acute fluxes, however, and during the slow progress of chronic cases, a certain amount of passive exercise or even of walking in the open air becomes sooner or later desirable.‡

---

* Thus Fab. Hildanus—*loc. cit.*, note ‡, last page—remarks: "Toto contagionis tempore alvus lubrica esse debet." He prescribes the use of clysters, suppositories and laxatives for this purpose, and adds: "Per intervalla quoque corpus purgandum est," for which purpose he specially recommends rhubarb. Now, Virchow—S. 357, *op. cit.*, p. 631, *supra*—has recorded that during the prevalence on several occasions of epidemic contagious dysentery in the Charité hospital at Berlin, the disease always chiefly spared the syphilitic wards in which at that time the patients were treated, without mercury, by a plan in which laxative medication was prominent. This observation would seem to show that the old practice was not without merit, and, indeed, of all medical prophylactic plans it appears the most reasonable.

† No one has more intelligently presented the importance of these measures than Fab. Hildanus—Cap. VII, p. 675, *op. cit.*, p. 644, *supra*—who has also given a rude wood-cut representing a form of bedpan suitable for such cases which is still in general use. Long before, Celsus—Lib. IV, Cap. 15, Lee's Ed., Vol. I, London, 1831, p. 296—had said, in connection with the management of dysentery: "In the first place rest must be enjoined, for every species of agitation ulcerates;" and still earlier Hippocrates directed motion to promote and rest to moderate the evacuant action of hellebore, showing that he fully appreciated the influence of these conditions upon the functions of the alimentary canal; see *Aph.* IV, 15, [Ed. Littré, IV, p. 507;] also the commentary of Galen on this passage, [Ed. Kühn, XVII, B, 675.]

‡ Whether the exercise of a special function is also beneficial to dysenterics is a question concerning which there is a curious literature. In the Hippocratic treatise *De Morbis Vulgaribus*, Lib. VII, § 122, [Ed. Littré, V, p. 468,] the following passage occurs: Ἡορνείη ἄχρωμος δυσεντερίης ἄκος, which Foes—Frankfort Ed., 1595, Sect. VII, p. 339—translates: "Impudens scortatio difficultati intestinorum medetur," and Littré—*loc. cit.*—"Le coït, remède de la dysenterie." A number of critics have protested that this could not have been the meaning of Hippocrates. Thus Calvus, who made the first Latin translation of Hippocrates, (published 1526,) from a manuscript in the Vatican, substituted Ἡορνή, *i. e.*, meretrix, for the first word, and supposed ἄχρωμος to be the name of a woman who had a remedy for dysentery. I have not been able to see this version, which, according to Le Clerc—*Hist. de la Méd.*, La Haye, 1729, p. 241; I cite from Goulin, p. 10, *op. cit.*, *infra*—reads, "Meretrix Achromos dysenteriæ medela." Goulin—*loc. cit.*—has, however, pointed out that neither this version nor the Greek, as rendered above, bears the meaning attributed to it by Le Clerc, but would properly signify "La courtisanne nommée Achromos est le remede, ou un remede contre la dysenterie." He points out, however, that Le Clerc has misquoted Calvus, who rearranged this sentence with the two preceding ones, making from them but a single one, which terminates thus: "Quam potionem meretricula, Achromos nomine, dysentericis remedium dedit." But the belief represented by the subsequent Latin versions was one well grounded in ancient medicine. Thus Ætius, citing from Rufus the Ephesian—Tetrab. I, Serm. III, Cap. 8, Lyons Ed., 1549, p. 142—explains hat the exercise of this function should be shunned during acute fluxes, but that "inveterata aliquando per venerem resiccantur," and Paulus Ægineta—Lib. I, Cap. 35, Vol. I, p. 45, Ed. cited p. 624, *supra*—expressed the same opinion. Accordingly Foes—*op. cit.*, Sect. VII, p. 341—exclaims: "Adeo ridiculum est quod de Achromo meretrice hic somniat Calvus." Another attempt to escape the significance of this passage was made by Dacier—*Les Œuvres d' Hippocrate traduites en François*, Paris, 1697, T. II, p. 571; I cite from Goulin, p. 7, *op. cit.*, *infra*—who, by modifying the text, makes the passage read, "La fornication est un méchant et un détestable remede à la dysenterie," but this reading has found few adherents. Somewhat better received has been the ingenious transposition of Triller—*De vitandis sordidis ac lascivis remediis antidysentericis præsertim vero de fœda scortatione*, &c., Opusc. Med., T. III, Frankfort, 1772, p. 40 *et seq.*—who, after a most elaborate and curious commentary, to which I refer the learned reader as very entertaining, proposes a rearrangement of the words of the passage in question and those of the preceding sentence, so as to wring out of them the following interpretation: "Qui ex spinali medulla tabescebat, a nimia scortandi libidine, decolor et enervatus, septima die mortuus est: prodeuntibus prius excrementis, liquidis, crudis et indigestis. Salsa cum melle, sunt dysenteriæ medela," p. 83. Nevertheless the majority of commentators favor a more literal reading. Amatus Lusitanus—*Cur. Med.*, Venice, 1557, Cent. II, Cur. 47, p. 289—declared that he himself had known cases of epidemic dysentery to be cured by this hygienic measure, and relates one in illustration. In the scholia to this observation he seems to think the meaning of Hippocrates even more gross than the ordinary interpretation makes it, remarking: "Est autem scortatio, sive ut ille ait, turpis scortatio, ea qua Diogenes Cynicus, quum meretricem expectaret usus fuit. Cui quum ad illum expectantem, sed tarde pervenisset, turpiter, et contra Dei præcepta objecit, manus Hymenæum celebrando te prævenit. Ejecerat autem in terram semen pudendis manu admota." A more temperate, and, as I think, a sounder commentary than any of these, has been offered by Ackermann, (1777,)—p. 150, *op. cit.*, p. 620, *supra*—who points out that, according to the common opinion of the ancients, the secretion in question is formed from the most subtle portions of the four humors believed to compose the body, and especially from the phlegm; in support of which he cites the Hippocratic treatise, *De Genitura*, [Ed. Littré, VII, pp. 471–475.] Hence the ancients thought the exercise of this function, by diminishing any superabundance of phlegm in the system, produced a favorable effect in those diseases which, like certain forms of dysentery, were, in their opinion,

In arranging accommodations for patients laboring under the fluxes great care should be taken to avoid overcrowding, and all the influences that are embraced under the generic term hospitalism. Special precautions are desirable in cases of dysentery and the chronic fluxes. It is an old experience that the sick do better in tents* than in buildings, and in suitably constructed barrack-hospitals than in hospitals improvised in churches, public buildings or private dwellings. Nevertheless all the unfavorable conditions of hospitalism may be developed in overcrowded ill-ventilated tents placed too closely together, allowed to remain too long on the same spot or to become filthy. The utmost cleanliness, good ventilation† and the avoidance of overcrowding are therefore indispensable conditions in all cases. Cleanliness should extend not merely to the condition of the wards or tents, but especially to the bedding, clothing and persons of the sick. When bedpans are used in the ward some disinfectant fluid, as, for example, solution of sulphate of iron mixed with impure carbolic acid, should be introduced into the vessel before it is used, and afterwards it should be immediately removed from the apartment, and the sinks or water closets into which the discharges are thrown should be frequently disinfected. After each motion the anal region should be carefully washed with warm water and soap, and, if found necessary, the skin should be protected by anointing it with a suitable ointment. In case of involuntary evacuations, soiled clothing or bedding should be promptly removed from the ward, and saturated with some disinfectant before attempting to wash it. The washing of such articles should be conducted separately. In view of the frequency of pneumonia as a complication in both acute and chronic cases, it is important that the patients should not be exposed to unnecessary draughts; and in winter the apartment should be kept duly warmed, (65° to 70°, Fah.)

In case of tardy convalescence from dysentery and in the chronic fluxes, a change of climate often becomes desirable, and is not unfrequently the only means by which life can be saved. The English and French colonial experience has amply demonstrated the beneficial effects of the return of such invalids to their native soil;‡ and in the fluxes of armies, it has long been well known that escape from the alimentation and atmosphere of the camps and military hospitals and return to the diet and surroundings of home are often

caused by a flux of phlegm. He points out that this doctrine is clearly taught by HIPPOCRATES—*De Morb. Vulg.*, Lib. VI, Sec. 5, [Ed. Littré, V, p. 321,]—in a passage which FOES translates, "Veneris usus morbis a pituita confert," *op. cit., supra*, Sect. VII, p. 279, and LITTRÉ, *loc. cit.*, "Le coït est avantageux dans les maladies provenant du phlegme." The commentary of GALEN—Ed. Kühn, T. XVII, B, p. 284—on this passage fully sustains these interpretations, though he explains that the measure in question is only useful to such patients as are not already too much debilitated. A view similar to that of ACKERMANN was taken by GOULIN—*Explication d'un passage des Épidémies d'Hippocrate*, Paris, 1783—who, besides the quotation from Epidem. VI, recalls one of the *Problems* of ARISTOTLE, Sect. I, § 59, Opera Gr. Lat., T. IV, Didot's Ed., Paris, 1857, p. 117: "Cur morbis qui contrahuntur a pituita, res venerea prodest? An quod semen genitale excrementi cujusdam detractio est, naturamque præ se fert pituitæ, ita ut, quoniam multum pituitosæ detrahit materiei, juvet concubitus?" which shows that the great naturalist entertained a similar opinion. GOULIN, however, substituted the words δὲ χρονίου for ἄχρωμος, and translates the passage "Coitus diuturnæ dysenteriæ medela." LITTRÉ—*loc cit.*—as seen by his version, adopts the general opinion. ACKERMANN—*loc. cit.*—has, however, prudently remarked that, even if the remedy be a good one, it is not always possible to employ it in serious cases: "Sæpius enim evenit, ut in tanta nervorum totius corporis debilitate animus quoque languescat, suavissimasque concubitus illecebras vix persentiat; nervusque * * * quamvis tota palpetur nocte, quiescat inersque jaceat, immo torpeat, nullaque eunnum petendi neque cupiditate, flagret, neque vi polleat," *op. cit.*, p. 153.

* MURSINNA—Cap. 5, p. 99, *op. cit.*, p. 646, *supra*—emphasized this circumstance on the occasion of dysentery of the camp near Nimes. He found the cases treated in camp, in spite of the persistent rain, were manifestly more manageable and got well sooner than those treated in the neighboring village, only a few thousand paces distant, where two houses had been fitted up for hospital purposes.

† These points were already dwelt on at length by FAB. HILDANUS—*loc. cit.*, note †, p. 655, *supra*.

‡ The general practice of the English physicians in India may be summed up in the language of Prof. W. C. MACLEAN—Art. *Dysentery*, Reynolds' Syst. of Med., Vol. I, London, 1866, p. 123: "*Chronic Dysentery.*—Whenever the disease falls into this stage and resists treatment, the patient should as soon as possible be sent to a better climate. If the locality be malarious, this should be done at once. Often moving him to the sea-coast suffices. More frequently a voyage to Europe is essential to recovery; many lives are lost by delaying this measure until it is too late." According to MOREHEAD—*Clinical Researches on Disease in India*, 2d Ed., London, 1860, p. 312 *et seq.*—the overland journey from India is exceedingly trying, unless the patient is in a state of advanced convalescence, and the sea-passage should be preferred. The English soldier who has contracted a chronic flux in India, or other tropical colonies, is sent home to be treated at Netley; the French from Cochin-China, &c., to the naval hospitals at Brest, Toulon and Cherbourg. The French troops in Algeria equally experience the necessity of evacuating their chronic fluxes upon France. HASPEL—T. II, p. 147, *op. cit.*, p. 621, *supra*—strongly insists upon this point, and also upon the necessity of not postponing the transfer until the patients are too exhausted to support the fatigues of the journey.

followed by prompt restoration to health.* This result was strikingly illustrated by the experience of our civil war, as must always be the case when an invading army campaigns in a more southern region than its native land. It was constantly observed that the transfer of those sick with fluxes to the more northern hospitals proved beneficial to great numbers of them. Still more beneficial appeared to be the result of a long furlough, or discharge from service on surgeon's certificate of disability. Undoubtedly under such circumstances the change of climate counts for much, especially when the transfer is made from a warmer to a cooler, from a malarial to a non-malarial, from a low to an elevated region; but even the most favorable change of this kind cannot be expected to produce its full benefit unless the patient in his new locality is surrounded with favorable hygienic conditions and supplied with proper food. It will be understood without argument that it is only when the destruction of the mucous membrane by ulceration or sloughing is not too extensive that such a change can effect a cure; but it would be unsafe to assume from the abundance of pus, or from any other characters of the stools, or from almost any degree of debility or exhaustion of the vital powers, that this condition exists in any particular case, and experience shows that apparently desperate cases occasionally recover.

The prompt removal of convalescents from dysentery and patients laboring under chronic fluxes from the camps of an invading army, and from the neighboring base hospitals, is therefore a measure of the utmost importance. It is demanded not merely by humanity to the sick, but by economy and the best interests of the fighting force. Liberally supplied hospitals should be established at convenient healthy points for the treatment of such cases; soldiers who have comfortable homes should be freely furloughed, and none should be ordered back to duty until their health is fully reëstablished; the wholesale discharge from service of such cases on surgeon's certificate of disability, which was so commonly practiced during our civil war, would thus be rendered unnecessary. Such a policy as has been sketched will produce better results, in the maintenance of a serviceable army in the field, than can flow from vain attempts to keep the sick with or near the army, where they must embarrass its movements and increase its mortality.

DIET.—Suitable alimentation for patients laboring under the fluxes is of equal, perhaps even of greater, importance than wise medication. This subject was treated by the ancients with a minuteness which has not been excelled in modern times, and their conclusions, based upon observation, are in many particulars supported by the experience of the best instructed recent investigators.

THE DRINK.—In the first place the greatest care should be taken to secure good *drinking water*, and where the ordinary supply is of doubtful character, especially if there is reason to suspect sewage contamination, special arrangements should be made for the sick. Rain water, if collected with reasonable precautions, may be advantageously employed, as was long ago recommended for patients suffering under dysentery by Ætius, Alexander of Tralles and Paulus Ægineta.† Probably distilled water would be still safer, but it is not

* No one has more pertinently insisted upon this point than DONALD MONRO—*Obs. on the Means of preserving the Health of Soldiers, &c.*, Part II, Sect. 10, 2d Ed., London, 1780, Vol. I, p. 129 *et seq.*

† ÆTIUS—Tetrab. III, Serm. 1, Cap. 45, Lyons Ed., 1549, p. 605—recommends the use of rain water in dysentery from the beginning of the case, but cautions against employing that collected from roofs covered with lead, which he says will give dysentery even to well men. If rain water cannot be obtained, that of springs will do, but well water should always be avoided, especially if it is subsaline, as it perturbs the bowels. Rain water is also recommended by ALEXANDER OF TRALLES—Lib. VIII, Cap. 8, p. 432, Ed. cited p. 624, *supra*—in rheumatic dysentery; and by PAULUS ÆGINETA—Lib. III, Cap. 42, Vol. I, p. 527, *op. cit.*, p. 624, *supra*. CELSUS—Vol. I, p. 297, *op. cit.*, p. 656, *supra*—had long before recommended the use of pure water in dysentery, to be taken warm if there was fever, while later in the case he advised very cold water, which he regarded as an astringent. On the other hand, PAULUS—*loc. cit.*—recommends cold water, especially if "the intemperament is very hot."
